Once lanes and bands have been detected, it is also possible to quantify the amount or at least relative amount of nucleic acid or protein present in each band. The amount in a band is related to the sum total of the intensity values of each pixel subtracted by the background value for each pixel in a band. For absorptively detected bands, intensity values are converted to OD values. The total value that is calculated is equivalent to the volume of the band and can be directly compared to other bands that are within the linear range for the visualization method. If standards of known amounts are loaded onto the same gel, they can be used to generate a standard curve that converts band volume into standard units such as micrograms. For greatest accuracy, it is important to be able to generate multiple standard curves when using visualization methods, such as Coomassie blue staining, that are affected by band or spot composition.

Quantitation becomes more complicated when bands are not fully resolved. In this case, material from one band is contributing to the volume measurement of an adjacent band and vice versa. The simplest method for handling this is to partition into each band only the volume within its edges. Alternatively, a Gaussian curve can be fitted to each band and the volume contained within the curve used to estimate the amount of the band. Since most electrophoresis bands have a pronounced skew towards the leading edge of the band, modified Gaussian curves have also been used (Smith and Thomas, 1990). In either case, the curve-fitting process is calculation intensive and can significantly increase analysis times for images with many bands.

Software for Two-Dimensional Analysis

In two-dimensional analysis, the first-dimension separation is performed in a single column or lane followed by a second separation performed perpendicular to the first. The result after visualization is a rectangular image of up to 10,000 spots. The most common two-dimensional gel type is one in which protein is separated first by apparent pI and second by molecular weight, although two-dimensional separation of nucleic acids is also possible. While many of the concepts and analysis techniques used with one-dimensional gels are applicable to two-dimensional gels, the complex nature of most two-dimensional gels requires somewhat different methodology. For example, spots are more difficult to detect since they are not conveniently arranged in lanes and can vary more in shape and overlap than bands. In addition, two-dimensional experiments usually require some method of comparing between two images whereas one-dimensional images usually contain all of the information from an experiment.

See Table 10.5.4 for sources of two-dimensional electrophoresis imaging software.

Spot detection

Probably the most difficult aspect of two-dimensional analysis is efficient and accurate spot detection. If it is incorrectly done, it can lead to hours of manual editing. Due to the complexity and computational intensity of some algorithms, the detection process itself can last hours on relatively fast desktop computers. One theoretically effective but computationally intense method is to treat the image as essentially a three-dimensional

image with spots treated as hills and background as valleys. A large number of Gaussian curves are then combined to describe the topology of the image. Many other methods make use of a digital-imaging technique known as filtering. In essence, filtering is a way to weight the value of a pixel and its neighbors in order to generate a new value for a pixel. By passing a filter across an image pixel by pixel, a secondary image is generated. Filters can be designed for many tasks, including sharpening an image or removing high-frequency noise. Filters can also be generated to help detect spots by making images that are first and second derivatives of the original image. The derivative images indicate inflection points in the intensity pattern and can be used to detect spot centers and edges. In a different method, called thresholding, filters can be used to detect the edges of objects. Instead of looking for inflection points, threshold filters identify intensities above a set level or at ratios between central and edge pixels above a set value. Since the edges on two-dimensional spots tend to be diffuse, sharpening filters are sometimes used prior to the thresholding filter. In some cases, multiple techniques are used to detect spots (Glasbey and Horgan, 1994).

Unlike one-dimensional detection, detection on images of two-dimensional experiments usually requires secondary processing to get acceptable performance. One example of a secondary process is to discard spots with sizes below a set minimum or above a set maximum. Another is to analyze spots that are oval for possible splitting into two spots. Even after secondary processing, it is likely that a small amount of manual editing will be necessary. When manually editing an image, care must be taken to use as objective criteria as possible, especially if two or more images are to be matched and spot volumes compared.

Characterization

In a two-dimensional system, determination of protein or nucleic acid mobility is complicated by the fact that there are two mobilities to account for and that the second-dimension separation tends to make estimation of the separation which occurred in the first dimension more difficult. One method for dealing with this is to have a series of markers in the sample that, after both separations are completed, are evenly distributed within the gel and image. It is also possible to estimate separation characteristics from calibration points located at the periphery of the gel. For example, distance measurements can be used to pass calibration data from the first dimension separation, and standards can be separated at the ends of the gel to calibrate for mobility in the second dimension. Regardless of the method used, in many instances, a series of related images will be examined and similar spots in each image will be matched. When this occurs, it is possible to calibrate one image and then pass the calibration information via the matches to the related images.

Quantity determination is similar in many regards to that which occurs in one-dimensional analysis, but there are some differences. If spot edges are detected, a simple method of determining spot volume is to take the sum of the intensity value of each pixel in the spot reduced by a background intensity value. Multiple Gaussian curves can also be fitted to the spot to approximate the volume (Garrels, 1989). More difficult is attempting to compensate for a skewed distribution in a size-separating dimension while trying to use a regular Gaussian fit for a pI separation, such as is encountered with the most common form of two-dimensional protein separations. The distribution of background makes quantitation more difficult in two-dimensional gels. There is no lane-dependent component, so it is necessary to use other methods such as image stripes, finding local minima values or using values derived from the spot edges to determine background values.

Matching

Matching is the process in which proteins or nucleic acids with similar separation properties are linked or clustered together. Matching can occur within one image or between multiple images as long as a frame of reference is established. Matching allows for comparisons between samples. It also makes annotation and data entry easier, since if one spot or band is matched to others and is characterized or annotated, this information is easily passed to all the other matches. An underlying assumption of matching is that objects with similar separation properties are actually similar. Care must be taken to confirm the identity of matched spots or bands by other methods on critical experiments.

A simple form of matching is to link bands or spots at similar positions on the gel images. This works well when separation and imaging conditions are uniform. This is very seldom the case, since slight differences in the electrophoresis, visualization, and imaging conditions across a gel and between gels generates incorrect matching with this method. Since bands on one-dimensional gels are relatively easy to calibrate for mobility, matching can occur along contours of equal mobility. This dramatically decreases but does not eliminate the variability in detecting similar bands. Much of the remaining variability can be attributed to calibration errors. This error can often be compensated for by allowing a small tolerance in mobility values in determining whether a band is matched or not. Because of the difficulties in calibrating mobility in two-dimensional gels, it is often more practical to use matched spots for calibrating mobility than vice versa. Spot matching between two two-dimensional images starts by finding a small number of landmark spots that are used as seeds for subsequent matches (Appel et al., 1991; Monardo et al., 1994). There are many methods for finding the landmarks in both images, including finding the highest intensity spots, spots in unique clusters, and manual positioning. The most common procedure from this point is to derive a vector that describes the direction and extent of the path from one matched spot to the other when the two images are superimposed. The vector is used as the basis for finding more matches near the landmark matches. To allow for error, the area within a small radius is searched extending from the end of the vector. Once another match is found, its vector is computed and used as the starting point for finding neighboring matches. From this progression, the entire gel is matched. If all vectors are displayed graphically when matching is complete, questionable matches can often be identified as vectors that are significantly different from neighboring vectors.

One specialized use of matching is as an estimator of the similarity and potential genetic relatedness of organisms. For example, on a one-dimensional gel image, a ratio of the matched to unmatched bands for each pairwise combination of lanes can be calculated. This ratio can be used as an indicator of similarity, with values near 1 indicating a pair of highly similar lanes, and values near zero indicating very dissimilar lanes. Assuming that the contents of the lanes are valid samples of the originating organism's genetic makeup, the information on lane similarity can be converted to estimates of genetic similarity. A convenient way to display this similarity data graphically is to generate a dendrogram with similar objects close to each other and less similar objects more distantly placed. An example of such a dendrogram is presented in Figure 10.5.5, where samples from *Listeria* isolates are arranged based on banding pattern.

Databases

In many cases, image analysis is not the last step in the process. The image and analysis data need to be archived in a searchable format. There may be a need to analyze the data from multiple experiments conducted at different sites or in laboratories around the world. Bioinformatic links to diverse data sources might be desired to help develop a unified understanding of the biology behind particular phenomena. When these situations arise, database programs can be utilized to store, link, and search image analysis results.

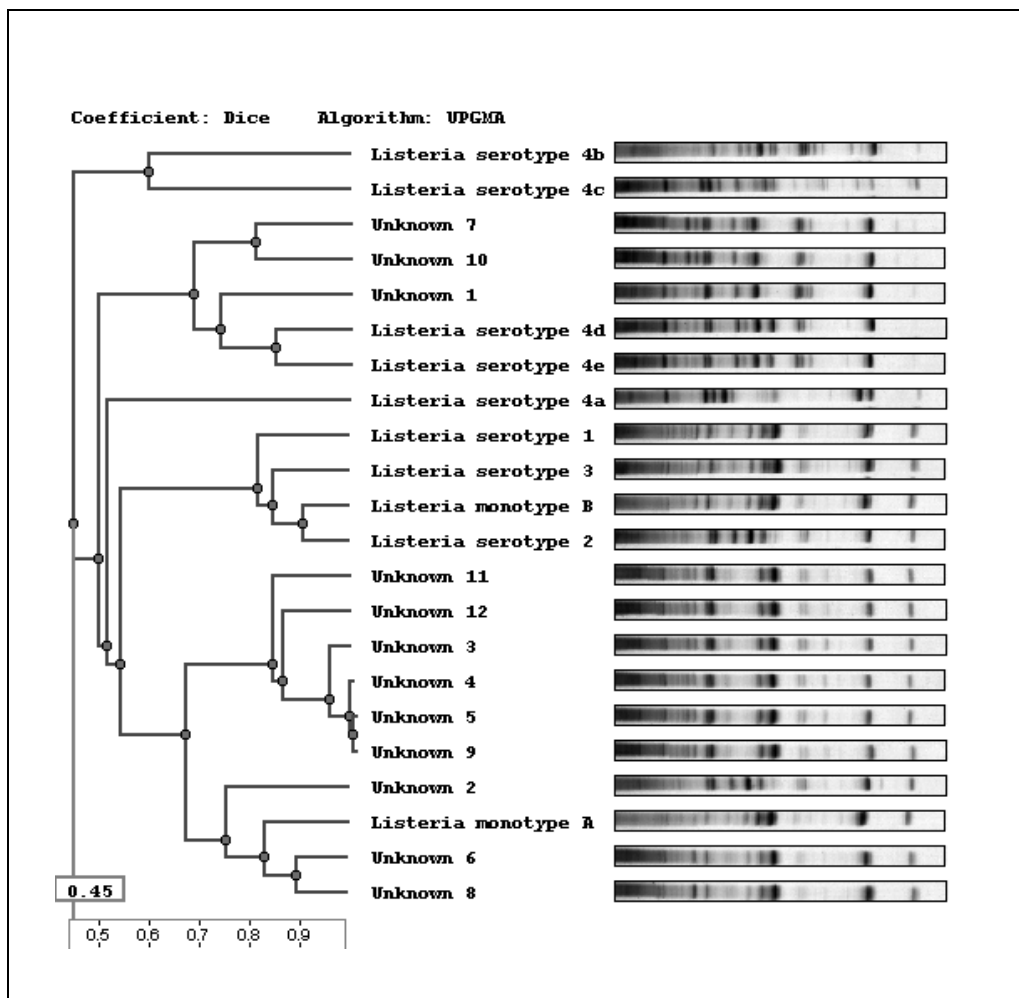

Figure 10.5.5 Example of a dendrogram generated from similarity data on band matching between lanes. DNA samples from 22 isolates of *Listeria* were subjected to Random Amplification of Polymorphic DNA (RAPD) analysis and the resulting electrophoresis image was analyzed with ImageMaster software (Amersham Pharmacia Biotech). Clustering was performed using the Dice coefficient with a tree structure based on the Unweighted Pair-Group Method using Arithmetic Averages (UPGMA). Similarity values between isolates can be determined by locating the node that connects the isolates and reading the value from the scale on the lower left edge of the dendrogram.

As the number of images that are captured and analyzed grows, it becomes increasingly more difficult to find particular information from the large number of files that are stored. Relatively simple databases can be used if the major requirement is to find previously analyzed images and associated data. Such databases often display a miniaturized version of each image to aid in visual scanning for the file as well as simple searching for image-specific information such as date of analysis, file name, or other information that was entered at the time of image capture. More powerful database products are also available that can perform complex searches on data generated during the analysis. For an example, a search on a two-dimensional database might include finding proteins exhibiting a specific expression profile and having a molecular weight >20 kDa with a pI between 3 and 5 or 8 and 10 with an amount <50 ng in a series of experiments conducted <1 year ago. Such searches can quickly target potentially interesting molecules for further analysis.

With the increasing ease of transferring data through the Internet as well as local- and wide-area networks, it has become practical to quickly find and examine data from distant

locations. Of course, great care must be taken to ensure that similar experimental conditions are employed, otherwise the results will be difficult to compare. In this manner it is sometimes possible to dramatically increase the sample size and statistical accuracy as well as the probability of detecting rare events. In addition, if one data set is more completely characterized, this extra information can be extracted and applied to the other data set. For example if there is a band in common in two databases and there is sequence information for it in one database, that sequence information can be added to the other database. Currently most public electrophoresis database sites are two-dimensional protein databases. A list with links to many of these Internet database sites can be found at <http://www-lmmb.ncifcrf.gov/EP/table2Ddatabases.html>.

With biological questions becoming more complicated and the answers to the questions often requiring information from a variety of sources, it is becoming increasingly important to be able to move easily between information sources. A relational type of database can help achieve this. Unlike a conventional database with a fixed arrangement of data, relational databases have links between related files that allow for easy movement from one file to another. Another approach to interconnecting electrophoresis data with data from other sources is to generate a series of hypertext links between data sets, similar to what occurs on the Internet. Selecting a specific link moves the search to the related network site and the related information. Regardless of the method, the end goal is similar. An example of what is possible: a researcher selects a protein spot on a two-dimensional gel image which triggers accessing of related information on this protein. The protein sequence is accessed from mass spectroscopy analysis of the spot on a separate gel. The sequence of the gene and the cDNA that generated the protein is retrieved. The expression pattern of the gene in various tissues and conditions as well as information on similar genes in other organisms is incorporated. Citations and annotations to this are retrieved as well. All of this information is compiled automatically into an interactive report about the protein. From this report, the researcher can formulate a more refined hypothesis and plan the most appropriate experiments to test it.

DETECTION OF PROTEINS

The protocols in this section require that detectable proteins be previously separated using either one-dimensional (UNIT 10.2) or two-dimensional (UNITS 10.3 & 10.4) electrophoresis. In UNIT 10.6, detection by Coomassie blue and silver staining of protein-containing bands or spots in a gel is described. Alternatively, proteins in a gel may be electrophoretically transferred to a blot transfer membrane and detected by staining with India ink or colloidal gold (UNIT 10.7) or by immunoblotting (UNIT 10.8). Another method is via biosynthetic labeling of the protein of interest using [³⁵S]methionine (UNIT 10.18), followed by autoradiography (APPENDIX 3).

Staining Proteins in Gels

UNIT 10.6

The location of a protein in a gel can be determined by either Coomassie blue staining (see Basic Protocol 1) or silver staining (see Basic Protocol 2). The former is easier and more rapid; however, silver staining methods are considerably more sensitive and thus can be used to detect smaller amounts of protein. Rapid staining procedures are provided for each method in Alternate Protocols 1, 2, and 3. Support Protocol 1 describes how to photograph stained gels.

Fluorescent staining has become a popular alternative to traditional staining procedures, mainly because it is more sensitive than Coomassie staining, and often as sensitive as silver staining. The unit therefore includes a protocol describing SYPRO Orange or SYPRO Red staining of proteins in SDS-polyacrylamide gels (see Basic Protocol 3); variations on that procedure for proteins in nondenaturing gels are included as well (see Alternate Protocol 4). SYPRO Ruby staining of two-dimensional gels is also described (see Basic Protocol 4). Support Protocol 2 describes the photography of the fluorescently stained proteins.

Additional fluorescent techniques have been developed to monitor phosphorylated and glycosylated proteins. Alternate Protocol 5 describes the staining of phosphoproteins in minigels and larger, two-dimensional gels with Pro-Q Diamond phosphoprotein gel stain, while Support Protocol 3 tells how to image and document the findings from the phosphoprotein staining. Support Protocol 4 details a method for selectively detecting phosphotyrosine residues.

Alternate Protocol 6 details the differential fluorescent staining of glycosylated and nonglycosylated proteins, and Support Protocol 5 describes how to photograph these gels.

COOMASSIE BLUE STAINING

Detection of protein bands in a gel by Coomassie blue staining depends on nonspecific binding of a dye, Coomassie brilliant blue R, to proteins. The detection limit is 0.3 to 1 μg/protein band. In this procedure, proteins separated in a polyacrylamide gel are precipitated using a fixing solution containing methanol/acetic acid. The location of the precipitated proteins is then detected using Coomassie blue (which turns the entire gel blue). After destaining, the blue protein bands appear against a clear background. The gel can then be stored in acetic acid or water, photographed, or dried to maintain a permanent record.

BASIC PROTOCOL 1

Analysis of Proteins

10.6.1

Materials

Polyacrylamide gel (UNIT 10.2A)
Fixing solution for Coomassie blue and silver staining (see recipe)
Coomassie blue staining solution (see recipe)
Methanol/acetic acid destaining solution (see recipe)
7% (v/v) aqueous acetic acid
Whatman 3MM filter paper (optional)
Gel dryer (optional)

1. Place the polyacrylamide gel in a plastic container and cover with 3 to 5 gel volumes of fixing solution. Agitate slowly 2 hr at room temperature on an orbital shaker or rocking platform.

If agitation is too rapid, the gel may break apart. Use fixing solution only once.

2. Pour out fixing solution. Cover the gel with Coomassie blue staining solution for 4 hr and agitate slowly.

Use staining solution only once.

3. Pour out staining solution. Rinse the gel briefly with ~50 ml fixing solution.
4. Pour out fixing solution. Cover the gel with methanol/acetic acid destaining solution for 2 hr and agitate slowly.
5. Pour out destaining solution. Add fresh methanol/acetic acid destaining solution and continue destaining until blue bands and a clear background are obtained. Store the gel in 7% aqueous acetic acid or water.

Do not store gels in fixing solution because protein bands will eventually disappear. Gels can be stored up to 1 year at 4°C in a sealable plastic bag.

6. If desired, photograph the gel (see Support Protocol 1).
7. If desired, dry the gel to maintain a permanent gel record. Place the gel on two sheets of Whatman 3MM filter paper and cover top with plastic wrap. Dry in a conventional gel dryer 1 to 2 hr at ~80°C.

Alternatively, place gel on filter paper and dry according to instructions supplied with gel dryer.

ALTERNATE PROTOCOL 1

RAPID COOMASSIE BLUE STAINING

Protein bands stained using this protocol can be detected within 5 to 10 min after adding rapid Coomassie staining solution. Because the Coomassie blue concentration is lower than that used in Basic Protocol 1, the gel background never stains very darkly and the bands can be seen even while the gel remains in the staining solution. Another difference is that isopropanol is substituted for methanol in the fixing solution. This method is slightly less sensitive than the standard procedure (see Basic Protocol 1).

Additional Materials (also see Basic Protocol 1)

Isopropanol fixing solution (see recipe)
Rapid Coomassie blue staining solution (see recipe)
10% (v/v) acetic acid

1. Place a polyacrylamide gel in a plastic or glass container. Cover the gel with 3 to 5 gel volumes isopropanol fixing solution and shake gently at room temperature. For a 0.7-mm-thick gel, shake 10 to 15 min; for a 1.5-mm-thick gel, shake 30 to 60 min.

2. Pour out fixing solution. Cover the gel with rapid Coomassie blue staining solution and shake gently until desired intensity is reached, 2 hr to overnight at room temperature.

Bands will become visible even in the staining solution within 5 to 30 min, depending on gel thickness. The gel background will never stain very darkly.

3. Pour out staining solution. Cover the gel with 10% acetic acid to destain, shaking gently ≥ 2 hr at room temperature until a clear background is obtained.
4. If necessary, pour out 10% acetic acid and add more. Continue destaining until clear background is obtained. Store gel in 7% acetic acid or water, or in plastic wrap at 4°C.

It is usually unnecessary to add additional destaining solution.

5. If desired, photograph (see Support Protocol 1) or dry (see Basic Protocol 1, step 7) the gel.

SILVER STAINING

Detection of protein bands in a gel by silver staining depends on binding of silver to various chemical groups (e.g., sulfhydryl and carboxyl moieties) in proteins. The detection limit is 2 to 5 ng/protein band. In this procedure, proteins separated in a polyacrylamide gel are successively fixed in methanol/acetic acid and glutaraldehyde. After exposure to silver nitrate, the gel is treated with developer to control the level of staining. When the desired staining intensity is reached, the gel is fixed, photographed, and dried.

Materials

Polyacrylamide gel (UNIT 10.2)
Fixing solution for Coomassie blue and silver staining (see recipe)
Methanol/acetic acid destaining solution (see recipe)
10% (v/v) glutaraldehyde (freshly prepared from 50% stock; Kodak)
Silver nitrate solution (see recipe)
Developing solution (see recipe)
Kodak Rapid Fix Solution A
Whatman 3MM filter paper (optional)
Gel dryer (optional)

NOTE: Wear gloves at all times to avoid fingerprint contamination.

1. Place a polyacrylamide gel in a plastic container and add 5 gel volumes of fixing solution. Agitate slowly ≥ 30 min at room temperature on an orbital shaker.
2. Pour out fixing solution. Fix the gel with 5 gel volumes of methanol/acetic acid destaining solution for ≥ 60 min, agitating slowly.

No actual destaining takes place in this step; fixation continues using the same solution used for destaining in Basic Protocol 1.

3. Pour out destaining solution. Add 5 gel volumes of 10% glutaraldehyde and agitate slowly 30 min in a fume hood.

CAUTION: *Wear gloves and work only in a fume hood.*

4. Pour out the glutaraldehyde. Wash the gel at least four times with water, ≥ 30 min for each wash and preferably overnight for the last wash. Agitate slowly with each wash.

BASIC PROTOCOL 2

Analysis of Proteins

10.6.3

5. Pour out the last wash. Stain the gel with ~5 gel volumes silver nitrate solution (to cover the gel) for 15 min with vigorous shaking.

CAUTION: Dispose of ammoniacal silver solution immediately by flushing with copious amounts of water, as it becomes explosive upon drying.

6. Transfer the gel to another plastic box and wash five times with deionized water, exactly 1 min for each wash. Agitate slowly with each wash.
7. Dilute 25 ml developing solution with 500 ml water. Transfer gel to another plastic box, add enough diluted developer to cover the gel during agitation, and shake vigorously until the bands are as intense as desired. If the developer turns brown, change to fresh developer.

Development should be stopped immediately when gel background starts to appear.

8. Transfer to Kodak Rapid Fix Solution A for 5 min.

If necessary, swab gel surface with soaked cotton to remove residual silver deposits.

9. Pour off Rapid Fix Solution and wash the gel exhaustively in water (four to five times).
10. Photograph the gel (see Support Protocol 1).

Gels should be photographed as soon as possible because there may be slight changes in color intensity and increases in nonspecific background. The silver-stained proteins remain clearly visible for at least 18 hr.

11. Dry the gel to maintain a permanent record (see Basic Protocol 1, step 7) or store in sealable plastic bag (will last 6 to 12 months).

ALTERNATE PROTOCOL 2

NONAMMONIACAL SILVER STAINING

This nonammoniacal silver staining procedure uses more stable solutions and detects certain proteins not stained using the preceding protocol (Morrissey, 1981).

Additional Materials (also see Basic Protocol 2)

- 5 µg/ml dithiothreitol (DTT; APPENDIX 2)
- 0.1% (w/v) silver nitrate solution (store in brown bottle at room temperature up to ~1 month)
- Carbonate developing solution (see recipe)
- 2.3 M citric acid
- 0.03% (w/v) sodium carbonate (optional)

1. Place a polyacrylamide gel in a glass or polyethylene container and add 100 ml fixing solution. Agitate slowly 30 min at room temperature on an orbital shaker.

Times are appropriate for all gel sizes.

2. Pour out fixing solution. Immerse gel in methanol/acetic acid destaining solution and agitate slowly 30 min.
3. Pour out destaining solution. Cover gel with 50 ml 10% glutaraldehyde and agitate slowly 10 min in a fume hood.

CAUTION: Wear gloves and work only in a fume hood.

Fixing in glutaraldehyde ensures that the gel will not bleach (and will probably last longer) and is important for retention and detection of very small proteins.

4. Pour out glutaraldehyde. Wash the gel *thoroughly* in several changes of water (or in running water) for 2 hr to ensure low background levels.

5. Pour out water. Soak the gel in 100 ml 5 $\mu\text{g}/\text{ml}$ DTT for 30 min.

Treating proteins with DTT results in more reproducible silver staining.

6. Pour out DTT. Without rinsing, add 100 ml 0.1% silver nitrate solution and agitate slowly 30 min.
7. Pour out silver nitrate. Wash the gel once quickly with a small amount of water, then twice rapidly with a small amount of carbonate developing solution.
8. Soak the gel in 100 ml carbonate developing solution and agitate slowly until desired level of staining is achieved.
9. Stop staining by adding 5 ml 2.3 M citric acid per 100 ml carbonate developing solution for 10 min and agitate slowly.

Pay attention to the volumes of carbonate and citric acid solutions (steps 8 and 9). These must be balanced carefully to bring the pH to neutrality. If the pH is high, the reaction will not stop; if the pH is too low, the gel will bleach.

10. Pour off the solution. Wash the gel several times in water, agitating slowly 30 min.
11. Photograph the gel (see Support Protocol 1) and/or store by soaking 10 min in 0.03% sodium carbonate and wrapping in plastic wrap or sealing in a heat-sealable bag.

RAPID SILVER STAINING

This protocol (Bloom et al., 1987) is based upon the preceding nonammoniacal silver staining method. It is rapid and gives low background but may not be quite as sensitive in detecting very small proteins because there is no glutaraldehyde fixation.

Additional Materials (also see Alternate Protocol 2)

Formaldehyde fixing solution (see recipe)
0.2 g/liter sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$)
Thiosulfate developing solution (see recipe)
Drying solution (see recipe)
Dialysis membrane soaked in 50% methanol
Glass plates

1. Place a polyacrylamide gel in a plastic container and add 50 ml formaldehyde fixing solution. Agitate slowly 10 min at room temperature on an orbital shaker.
Times indicated are flexible and are appropriate for a 0.75-mm \times 5.5-cm \times 8-cm, 12.5% acrylamide slab gel. Each gel is placed in an 8 \times 14-cm plastic container.
2. Pour out fixing solution. Wash the gel twice with water, 5 min for each wash. Agitate slowly for each wash.
3. Pour out water. Soak gel 1 min in 50 ml 0.2 g/liter $\text{Na}_2\text{S}_2\text{O}_3$, agitating slowly.
4. Pour out $\text{Na}_2\text{S}_2\text{O}_3$. Wash the gel twice with water, 20 sec for each wash.
5. Pour out water. Soak gel 10 min in 50 ml 0.1% silver nitrate solution, agitating slowly.
6. Pour out the silver nitrate. Wash the gel with water and then with a small volume of thiosulfate developing solution.
7. Soak the gel in 50 ml fresh thiosulfate developing solution and agitate slowly until band intensities are adequate (~1 min).

Development continues a little after stopping (next step), so do not overdevelop here.

**ALTERNATE
PROTOCOL 3**

**Analysis of
Proteins**

10.6.5

8. Add 5 ml of 2.3 M citric acid per 100 ml thiosulfate developing solution and agitate slowly 10 min.

Pay attention to the volumes of thiosulfate developing and citric acid solutions (see Alternate Protocol 2, step 9).

9. Pour off the solution. Wash the gel in water, agitating slowly 10 min.
10. Pour off the water. Soak the gel 10 min in 50 ml drying solution.
11. Sandwich gel between two pieces of wet dialysis membrane on a glass plate. Clamp edges of the plate with notebook clamps and dry overnight at room temperature.

SUPPORT PROTOCOL 1

GEL PHOTOGRAPHY OF COOMASSIE- OR SILVER-STAINED GELS

Many research facilities have photographic services that are well versed in gel photography and can provide excellent documentation of experiments. The following guidelines and equipment should be used to achieve optimal results. Any good single-lens reflex (SLR) camera attached to a copy stand will work. If larger-format cameras are available, sheet film will give spectacular resolution. The light box must produce relatively even lighting.

Kodak T-Max 400 film is a fine-grained panchromatic half-tone film that provides extremely high resolution and that works well for 35-mm gel photography. For contrast enhancement of Coomassie blue-stained gels, photographing the gels through a deep-yellow to yellow-orange filter (Wratten #8 or 9 or a yellow-orange Cokin filter) is recommended. Silver-stained gels are photographed with a blue-green filter (Wratten #58 or a blue Cokin filter). Develop according to manufacturer's instructions. Medium-contrast resin-coated paper is recommended for printing.

The instant films from Polaroid are ideal for fast, high-quality photographs of gels for laboratory notebooks and publications. Typically, type 57 (4 × 5-in., MP4 camera) or type 667 (3¼ × 4¼-in., DS 34 camera) black and white film is used for documentation at a shutter speed of 1/60 to 1/30 sec with an aperture of *f*16. Type 55 and 665 positive/negative films provide not only a high-quality print, but also a fine-grain, medium-format negative that can be used to produce multiple photographs of the gel in any size; for these films, use a shutter speed of 1/4 to 1/2 sec and an aperture of *f*16. Aperture settings of *f*11 or higher should be used for sharp photographs. If the picture is too light, increase the shutter speed or go to a higher *f* number. If the picture is too dark, decrease shutter speed or go to a lower *f* number (adapted from *Polaroid Guide to Instant Imaging*).

A simple test for the effectiveness of a filter is to place the gel on a light box and observe the gel through the filter. Increased contrast of the bands should be obvious. Silver staining can produce bands of various colors, which can present a problem in filter selection. Kodak X-Omat Duplicating Film is a useful alternative because it yields black banding in spite of the coloration caused by the silver staining (Anderson, 1988).

BASIC PROTOCOL 3

FLUORESCENT STAINING USING SYPRO ORANGE OR RED

Fluorescent dyes have a number of advantages over traditional protein stains. SYPRO Orange and Red protein gel stains, outlined in the procedure below, can detect 1 to 2 ng protein/band. This is more sensitive than Coomassie brilliant blue staining and as sensitive as many silver staining techniques. Staining is straightforward, with less hands-on time than typical silver staining protocols, and is complete in <1 hr. Stained proteins can be visualized using a standard 300-nm UV transilluminator or a laser scanner. Although the protocol below is limited to one-dimensional SDS-PAGE, alternative kits for native,

isoelectric focusing (IEF), and two-dimensional SDS-PAGE applications are available from the supplier (Molecular Probes). Coomassie Fluor Orange protein gel stain, a premixed fluorescent stain, is also available from Molecular Probes.

The staining properties of the two SYPRO dyes are similar, and both are equally suitable for use in most procedures. The SYPRO Orange gel stain is slightly brighter, whereas the SYPRO Red gel stain has somewhat lower background fluorescence. For those using a laser-excited gel scanner, the authors recommend the SYPRO Orange stain for argon-laser-based instruments and the SYPRO Red stain for instruments that employ green He-Ne or Nd/YAG (neodymium:yttrium-aluminum-garnet) lasers. Both dyes are efficiently excited by UV or broad-band illumination and, with the proper filters, work nicely with CCD camera archiving systems.

Materials

SYPRO Orange or Red fluorescent staining solution (see recipe)

7.5% (v/v) acetic acid

0.1% (v/v) Tween-20

Additional reagents and equipment for one-dimensional SDS-PAGE (UNIT 10.2A)

1. Prepare and separate proteins using SDS-PAGE (UNIT 10.2A), but use 0.05% SDS in the running buffer instead of the usual 0.1% SDS.

Gels run in 0.1% SDS show the same sensitivity for staining as those run with lower SDS concentrations, but require either more time in staining solution or a 10-min rinse in water before staining to reduce the background fluorescence that is produced by dye interaction with SDS. Gels run in 0.05% SDS show no change in the migration of proteins and can be photographed sooner because they require less time in the staining solution to clear the SDS from the gel. Gels run in SDS concentrations <0.05% or in old running buffer exhibit poor resolution of bands and other problems, so it is essential that the SDS stock solution used to prepare the running buffer be fresh and be at the proper SDS concentration.

Do not fix the proteins in the gel with methanol-containing solutions. Methanol removes the SDS coat from proteins, strongly reducing the signal from SYPRO Orange or Red stains.

2. Pour SYPRO Orange or Red fluorescent staining solution into a small plastic dish. For one or two standard-size minigels, use ~50 ml staining solution. For larger gels, use between 500 and 750 ml staining solution.

Staining dishes should be cleaned and rinsed well before use, as detergent will interfere with staining.

Alternatively, use Coomassie Fluor Orange protein gel stain which is available as a premixed staining solution.

3. Place gel into the staining solution. Cover the container with aluminum foil to protect the dye from bright light.

The staining solution may be reused up to four times. However, due to reduced sensitivity, the use of fresh staining solution is recommended.

Several alternate methods of staining can be used. (1) Gels may be stained in sealable plastic bags. However, it is still important to use the proper amount of staining solution. (2) For low-percentage gels and for very small proteins, increasing the staining solution from 7.5% to 10% acetic acid will result in better retention of the protein in the gel without compromising sensitivity. (3) Protein gel stains can be dissolved 5000-fold into the cathode (top) running buffer to stain proteins as the gel runs. The dye moves through the gel with the SDS front, so that all sizes of protein are stained. Staining does not influence relative migration of proteins through the gel. This method results in poorer protein staining than the standard poststaining method, and requires the same amount of time because the gel must be destained for 15 to 40 min in 7.5% acetic acid to reduce background fluorescence.

4. Gently agitate at room temperature for 10 to 60 min.

The staining time depends on the thickness and percentage of the gel. For 1-mm-thick 15% polyacrylamide gels, the signal is typically optimal after 40 to 60 min staining. Once the optimal signal is achieved, additional staining time (several hours to overnight) does not enhance or degrade the signal. Gels can be left in stain for up to a week with only a small loss in sensitivity; the detection limits under these conditions are ~2 to 4 ng/band.

5. Rinse briefly (<1 min) with 7.5% acetic acid.

This brief rinse removes excess stain from the gel surface to reduce background fluorescence on the surface of the transilluminator or gel scanner (see Support Protocol 2).

6. Store gel in staining solution, protected from light.

The signal decreases somewhat after several days, but, depending on the amount of protein in the bands, gels may retain a usable signal for many weeks. Gels may be left in staining solution overnight without losing sensitivity. However, fixation in acetic acid is relatively mild, so, for low-percentage gels or very small proteins, photographs should be taken as soon as possible after staining, before the proteins begin to diffuse.

Gels may be dried between cellophane membrane backing sheets (Bio-Rad), although there is sometimes a slight decrease in sensitivity. If the gels are dried onto paper, the light will scatter and the sensitivity will decrease. Other types of plastic sheets are not typically transparent to UV light. Store dried gels in the dark to prevent photobleaching.

7. Destain gel by incubating overnight in 0.1% Tween-20.

Alternatively, incubating in several changes of 7.5% acetic acid will eventually remove all of the stain. Incubating in methanol will strip off dye and SDS, but will also precipitate proteins.

8. Photograph gel (see Support Protocol 2).

ALTERNATE PROTOCOL 4

FLUORESCENT STAINING ON NONDENATURING GELS USING SYPRO ORANGE OR RED

Proteins can be stained after native gel electrophoresis (UNIT 10.2B) by dissolving SYPRO dyes in water and then following Basic Protocol 3. Staining proteins in nondenaturing gels is highly protein selective and will generally be less sensitive than staining proteins in SDS gels; however, because there is essentially no background fluorescence, photographic exposures can be very long. If it is not necessary to maintain the protein in a native state after electrophoresis, the best sensitivity can be achieved if the gel is soaked in 0.05% SDS for ~30 min and then stained with a solution of SYPRO dye diluted in 7.5% acetic acid.

BASIC PROTOCOL 4

FLUORESCENT PROTEIN STAIN USING SYPRO RUBY FOR 2-D GEL ANALYSIS

Fluorescent gel stains are gaining popularity due to the combination of simplicity and sensitivity that they offer. SYPRO Ruby protein gel stain is an ultrasensitive, fluorescent stain for the specific detection of proteins separated by polyacrylamide gel electrophoresis (PAGE). This stain, designed especially for use in 2-D PAGE (Fig. 10.6.1; UNIT 10.4), has proven to be the most sensitive protein gel stain for standard 1-D SDS-PAGE (UNIT 10.2A) and an excellent stain for isoelectric focusing (IEF) gels (UNIT 10.3) as well. SYPRO Ruby protein gel stain achieves comparable sensitivity to that of the silver-staining techniques (see Basic Protocol 2 and Alternate Protocols 2 and 3) and offers substantial processing advantages including the absence of overstaining, a linear quantitation range of over three orders of magnitude, and less protein-to-protein variability. In addition, the SYPRO Ruby

Figure 10.6.1 Typical two-dimensional gel stained with SYPRO Ruby gel stain.

staining protocol below stains glycoproteins, lipoproteins, calcium-binding proteins, fibrillar proteins, and other difficult-to-stain proteins, and does not interfere with subsequent analysis of proteins by Edman-based sequencing or mass spectrometry. The stain can be used with many types of gels, including 2-D gels (*UNITS 10.3 & 10.4*), Tris-glycine SDS gels (*UNIT 10.2A*), and Tris-tricine precast SDS gels and nondenaturing gels (*UNIT 10.2B*). SYPRO Ruby stain is also compatible with gels adhering to plastic backings.

Materials

1-D or 2-D polyacrylamide *or* IEF gels (*UNITS 10.2-10.4*)

Fixing solution for SYPRO Ruby staining of 2-D polyacrylamide gels (see recipe)

Fixing solution for IEF gels: 40% (v/v) methanol/10% (w/v) trichloroacetic acid in H₂O

SYPRO Ruby protein gel stain (Molecular Probes; see recipe)

10% (v/v) methanol (or ethanol)/7% (v/v) acetic acid

2% (v/v) glycerol

Plastic staining dishes of appropriate size for gels: polypropylene (e.g., Rubbermaid Servin' Savers) or PVC photographic staining trays (e.g., Photoquip Cesco-Lite 8-in. × 10-in., for large-format 2-D gels)

Orbital shaker

Additional reagents and equipment for photography of fluorescently stained gels (see Support Protocol 2)

Fix, stain, and wash the gel

- 1a. *For 1-D polyacrylamide gels:* Proceed directly to step 2 (no fixation required).
- 1b. *For 2-D polyacrylamide gels:* Fix for 30 min in an appropriate fixing solution for SYPRO Ruby staining of polyacrylamide gels.

It is also possible to use serial combinations of these fixatives. Note that the combination of ethanol and acetic acid can result in the formation of ethyl acetate, which is not only toxic but may interfere with identification of proteins by mass spectrometry.

- 1c. *For IEF gels:* Fix for 3 hr in 40% methanol/10% trichloroacetic acid, and then perform three washes, each for 10 min in distilled water, before proceeding to the staining step.
2. Transfer the gel to a clean polypropylene or PVC dish of appropriate size. Incubate the gel in the appropriate amount of undiluted SYPRO Ruby protein gel stain with continuous gentle agitation, e.g., on an orbital shaker at 50 rpm. For maximum sensitivity in 1-D or 2-D gels, incubate the gel for at least 3 hr. For IEF gels, incubate the gel overnight.

The authors have found that polypropylene dishes, such as Rubbermaid Servin' Savers, are the optimal containers for staining because the high-density plastic adsorbs only a minimal amount of the dye. For small gels, circular staining dishes provide the best fluid dynamics on orbital shakers, resulting in less dye aggregation and better staining. For large-format 2-D gels, polyvinyl chloride (PVC) photographic staining trays, such as Photoquip Cesco-Lite 8 inch × 10 inch photographic trays also work well. Glass dishes are not recommended. The minimal staining volumes for typical gel sizes are: 50 ml, for 8 cm × 10 cm × 0.75-mm gels; 330 ml, for 16 cm × 20 cm × 1-mm gels; 500 ml, for 20 cm × 20 cm × 1-mm gels, or ~10× the volume of the gel for other gel sizes.

Using too little stain will lower the sensitivity. For convenience, gels may be left in the dye solution overnight or longer without overstaining. Do not dilute the stain, as diluted stain will result in decreased sensitivity. Do not reuse the staining solution, as this will result in a significant loss of sensitivity.

3. To reduce background fluorescence and increase sensitivity, transfer the gel to a clean staining dish and wash it in 10% methanol (or ethanol)/7% acetic acid for 30 min. For polyacrylamide gels, perform this wash once; for IEF gels, perform the wash three times.

This transfer step helps to minimize the deposition of stain speckles on the gel. To reduce organic waste, stained gels may alternatively be washed in distilled water, although this method does not reduce background fluorescence to the same extent. The gel may be monitored periodically using UV epi-illumination to determine the level of background fluorescence.

4. *Optional (for permanent storage):* Incubate the gel in a solution of 2% (v/v) glycerol at room temperature for 30 min. Dry the stained gel using a gel dryer.

Note that proteins present at very low levels may no longer be detectable after gel drying.

5. View and photograph the gel (see Support Protocol 2).

SYPRO Orange or Red Stains

Photographing and archiving the gel is essential to obtain high sensitivity. The camera's integrating effect can make bands visible that are not visible to the eye. Place the fluorescently labeled gel directly on a standard 300-nm UV transilluminator or a blue-light transilluminator (e.g., Clare Chemical Dark Reader). Plastic wraps, such as Saran Wrap, should not be used, as they fluoresce naturally and will fluoresce even more when exposed to SYPRO Orange or Red stain. This results in a large background signal, making it impossible to achieve good sensitivity. Pharmacia PhastGels have a polyester backing material (Gelbond) that is not only highly autofluorescent, but also binds the SYPRO Orange and Red protein gel stains, producing additional background fluorescence. Consequently, the plastic backing should be removed before trying to visualize bands. Pharmacia markets a gel backing remover for use with their Phast Transfer system. The surface of the transilluminator should be cleaned with water and a soft cloth after use, to minimize the buildup of fluorescent dyes.

When using a Polaroid camera, use Polaroid 667 black-and-white print film and a SYPRO protein gel stain photographic filter (Molecular Probes) to obtain the highest sensitivity. Do not use standard ethidium bromide filters, as they will block much of the light and lead to lower sensitivity. Supplemental UV blocking filters are not usually required. Polaroid 667 film is a fast film with an ISO rating of ASA 3000. The use of different film types may require longer exposure times or different filters. Exposure time will vary with the intensity of the illumination source; with an *f*-stop of 4.5, 2 to 5 sec is typical for SYPRO Orange, and 3 to 8 sec is typical for SYPRO Red. Noticeable photobleaching can occur after several minutes of exposure to ultraviolet light. If a gel becomes photobleached, it can be restained by simply returning it to the staining solution.

Charge-coupled device (CCD) cameras provide good sensitivity. Contact the camera manufacturer for the optimal filter sets to use. For those using a laser-excited gel scanner, the SYPRO Orange stain is recommended for argon laser-based instruments, and the SYPRO Red stain is recommended for instruments that employ green He-Ne or Nd/YAG lasers.

SYPRO Ruby Stain

The SYPRO Ruby protein gel stain has two excitation maxima, one at ~280 nm and one at ~450 nm, and has an emission maximum near 610 nm. Proteins stained with the dye can be visualized using a 300-nm UV transilluminator, a blue-light transilluminator, or a laser scanner. The stain has exceptional photostability, allowing long exposure times for maximum sensitivity.

UV or blue-light transilluminator

Proteins stained with SYPRO Ruby protein gel stain are readily visualized using a UV or blue-light source. The use of a photographic camera or CCD camera and the appropriate filters is essential to obtain the greatest sensitivity. The instrument's integrating capability can make bands visible that cannot be detected by eye. It is important to clean the surface of the transilluminator after each use with deionized water and a soft cloth (like cheese-cloth); otherwise fluorescent dyes such as SYPRO stains, SYBR stains, and ethidium bromide will accumulate on the glass surface and cause a high background fluorescence. The authors use a 300-nm transilluminator with six 15-W bulbs. Excitation with different light sources may not give the same sensitivity. Using a Polaroid camera and Polaroid 667 black-and-white print film, the highest sensitivity is achieved with a 490-nm long-pass filter, such as the SYPRO protein gel stain photographic filter (S-6656), available

from Molecular Probes. The authors typically photograph minigels using an *f*-stop of 4.5 for 1 sec. Using a CCD camera, images are best obtained by digitizing at $\sim 1024 \times 1024$ pixels resolution with 12- or 16-bit grayscale levels per pixel. The camera manufacturer should be consulted for recommendations on filter sets to use. A CCD camera-based image analysis system can gather quantitative information that will allow comparison of fluorescence intensities between different bands or spots. Using such a system, the authors have found that the SYPRO Ruby gel stain has a linear dynamic range over three orders of magnitude. The polyester backing on some premade gels is highly fluorescent. For maximum sensitivity using a UV transilluminator, the gel should be placed polyacrylamide-side-down and an emission filter, such as the SYPRO protein gel stain photographic filter, should be used to screen out the blue fluorescence of the plastic. The use of a blue-light transilluminator (UVP Visi-Blue Transilluminators) or laser scanner will reduce the amount of fluorescence from the plastic backing so that the gel may be placed polyester-side down.

Laser-scanning instruments

Gels stained with the SYPRO Ruby protein gel stain can be visualized using imaging systems equipped with lasers that emit at 450, 473, 488, or 532 nm. For the analysis of stained proteins, note that SYPRO Ruby dye sometimes generates small speckles of precipitated dye on the gel. The speckles have diameters $\sim 20\%$ the size of the smallest stained protein spot, making them very easy to distinguish. Analysis software for 2-D gels will ignore small speckles if the minimum spot size of the program is set appropriately (determined by trial and error).

For the identification of individual protein spots, it should be noted that SYPRO Ruby protein gel stain does not bind covalently to proteins. Edman-based sequencing or mass spectrometry data can be obtained after staining, with no interference from the stain. Accurate mass spectrometry has been performed on a spot containing as little as 75 fmol of stained protein.

ALTERNATE PROTOCOL 5

FLUORESCENT PHOSPHOPROTEIN GEL STAINING FOR SELECTIVELY STAINING PHOSPHOPROTEINS IN POLYACRYLAMIDE GELS

Fluorescent phosphoprotein gel staining provides a method for selectively staining phosphoproteins in polyacrylamide gels. It is ideal for identification of kinase targets in signal transduction pathways (see Chapter 18) and for phosphoproteomic studies. This fluorescent stain allows direct, in-gel detection of phosphate groups attached to tyrosine, serine, or threonine residues. The stain can be used with standard SDS-polyacrylamide gels or with 2-D gels. Blotting is not required, and there is no need for phosphoprotein-specific antibodies or immunoblot detection reagents. The protocol delivers results in 4 to 5 hr. The stain is also compatible with mass spectrometry, allowing analysis of the phosphorylation state of entire proteomes with detection of as little as 1 to 16 ng of phosphoprotein per band. For individual phosphoproteins, the strength of the signal correlates with the number of phosphate groups and is linear over three orders of magnitude. The fluorescent stain with its $\sim 555/580$ nm excitation/emission maxima can be detected by use of a visible-light scanning instrument, a visible-light transilluminator, or a 300-nm transilluminator.

Materials

- Protein-containing sample of interest
- Methanol, spectroscopy grade
- Chloroform, spectroscopy grade
- Appropriate $1\times$ sample buffer for electrophoresis (*UNITS 10.2-10.4*)

Table 10.6.1 Examples of Commercially Available Phosphorylated and Nonphosphorylated Proteins for Use as Controls

Protein	Mol. wt. (Da)	Number of phosphate residues	Lower limit of detection
Riboflavin-binding protein	29,200	8	1-3 ng
α -Casein	23,600	8	1-2 ng
β -Casein	24,500	5	1-2 ng
Ovalbumin	45,000	2	4-8 ng
Pepsin	35,500	1	8-16 ng
Carbonic anhydrase	30,000	0	Not applicable
Bovine serum albumin (BSA)	66,000	0	Not applicable

Phosphoprotein standards (PeppermintStick Phosphoprotein Molecular Weight Standards, Molecular Probes; also see Table 10.6.1)

Fixing solution for phosphoprotein gels (see recipe)

Pro-Q Diamond phosphoprotein gel stain (Molecular Probes; see recipe)

Phosphoprotein gel destain solution (see recipe, or purchase from Molecular probes)

Polystyrene staining dish (e.g., a weighing dish)

Orbital shaker

Additional reagents and equipment for polyacrylamide gel electrophoresis (*UNITS 10.2-10.4*), SYPRO Ruby protein gel staining (see Alternate Protocol 5), Coomassie blue stain (see Basic Protocol 1), silver staining (see Basic Protocol 2), and imaging and documenting phosphoprotein-stained gels

Prepare samples by desalting and delipidating

1. Place a 150- μ l sample containing ~150 to 300 μ g of protein in a 1.5-ml microcentrifuge tube. Add 600 μ l of methanol and mix well by vortexing, then add 150 μ l of chloroform and mix well by vortexing. Finally, add 450 μ l of distilled water and mix well by vortexing.

A delipidated and desalted sample is essential for adequate separation of the proteins by electrophoresis and subsequent staining by Pro-Q Diamond phosphoprotein gel stain.

2. Microcentrifuge 5 min at ~12,000 rpm, room temperature. Discard the upper phase, keeping the white precipitation disc that forms between the upper and lower phases. Add 450 μ l of methanol and mix well by vortexing.
3. Microcentrifuge 5 min at ~12,000 rpm, room temperature. Discard the supernatant and dry the pellet in a Speedvac evaporator for 10 min. Resuspend the pellet in standard 1 \times sample buffer for electrophoresis.

Separate by electrophoresis

4. Separate the proteins using standard polyacrylamide electrophoresis techniques (*UNITS 10.2-10.4*) along with phosphoprotein standards. To ensure detection of less abundant phosphoproteins, use approximately the same mass of protein that would be used for a typical Coomassie blue dye-stained gel (see Basic Protocol 1).

Use known phosphorylated and nonphosphorylated proteins as controls to help verify the phosphorylation status of the unknown protein. Table 10.6.1 lists several commonly available proteins that can serve as positive and negative controls

Fix the gel

- 5a. *For minigels:* Transfer gel to a staining dish (plastic container or large plastic weighing dish). Immerse the gel in ~100 ml of fixing solution for phosphoprotein minigels (containing acetic acid) and incubate at room temperature with gentle agitation, e.g., on an orbital shaker at 50 rpm, for at least 30 min. If needed, repeat the fixation step once more to ensure that all of the SDS is washed out of the gel. If desired, leave gels in the fixing solution overnight.

If reusing a plastic container, clean thoroughly and rinse it with 70% ethanol.

Adhere strictly to the volumes and times specified in this protocol for fixation, washing, staining, and destaining. Replicating the protocol is essential for consistent gel-to-gel and day-to-day comparisons.

- 5b. *For larger 2-D gels:* Transfer gel to a staining dish (plastic container or large plastic weighing dish). Immerse the gel in ~500 ml fix solution for phosphoprotein 2-D gels (containing trichloroacetic acid) and incubate at room temperature overnight with gentle agitation, e.g., on an orbital shaker at 50 rpm. Perform a second fixation, for 1 hr, to ensure that all of the SDS is washed out of the gel.

In both of the above fixation steps, the second fixation is especially important if non-electrophoresis-grade SDS has been used.

Wash the gel

- 6a. *For minigels:* Incubate the gel in ~100 ml water with gentle agitation for 10 min. Repeat this step for a total of two washes.
- 6b. *For larger 2-D gels:* Incubate the gel in ~500 ml water with gentle agitation for 15 min. Repeat this step three times for a total of four washes.

In both of the above washing steps, it is important that the gel be completely immersed in the water in order to remove all of the methanol and acetic acid from the gel. Residual methanol or acetic acid will interfere with Pro-Q Diamond phosphoprotein staining.

Stain the gel

- 7a. *For minigels:* Incubate the gel in the dark in 50 ml of Pro-Q Diamond phosphoprotein gel stain with gentle agitation for 75 to 120 min.
- 7b. *For larger 2-D gels:* Incubate the gel in the dark in 500 ml of Pro-Q Diamond phosphoprotein gel stain with gentle agitation for 3 to 4 hr.

In both of the above staining steps, if directly comparing multiple gels, it is important that the incubation time be the same for each gel. Under no circumstances should the gel be stained overnight, as this will result in higher background staining.

For selective detection of phosphotyrosine residues, see Support Protocol 5.

Destain the gel

- 8a. *For minigels:* Incubate the gel in the dark in 80 ml of phosphoprotein gel destain solution at room temperature for a total of ~3 hr with two changes of destain solution (e.g., three incubations of 60 min each).

The first destaining step may be as short as 45 min; the last destaining step may be as long as overnight.

- 8b. *For larger 2-D gels:* Incubate the gel in the dark in 500 ml of phosphoprotein gel destain solution at room temperature for a total of ~4 hr with three changes of destain solution (e.g., four incubations of 60 min each).

If desired, the last destaining step may be overnight.

Image and document the gel

9. Image and document the phosphoprotein-stained gel using the appropriate instrumentation (see Support Protocol 3).

The phosphoprotein staining pattern must be viewed and documented before proceeding with total-protein staining (steps 10 a or b), because the stain will be washed away during the staining procedure for total protein.

Stain the gel for total protein

- 10a. *For minigels:* After obtaining results with the Pro-Q Diamond phosphoprotein gel stain, stain the gel with a quantitative total-protein stain, such as SYPRO Ruby protein gel stain (see Alternate Protocol 5), to ascertain the relative phosphorylation state of proteins.

In this way, an abundant nonphosphorylated protein that exhibits low nonspecific staining with Pro-Q Diamond stain can be distinguished from a less abundant highly phosphorylated protein. Note that nonquantitative total-protein stains, such as silver stains, are much less useful in this application.

- 10b. *For larger 2-D gels:* After staining with Pro-Q Diamond stain, treat the gel with a total-protein stain, such as SYPRO Ruby protein gel stain (see Alternate Protocol 5), Coomassie blue stain (see Basic Protocol 1), or a silver stain (see Basic Protocol 2).

A quantitative stain such as Coomassie blue or SYPRO Ruby protein gel stain will be the most useful, because it will aid in determining the relative phosphorylation state of a given protein. Furthermore, for 2-D gels, total protein staining makes it easier to localize a protein to a particular spot within a complex protein pattern.

IMAGING AND DOCUMENTING THE PHOSPHOPROTEIN-STAINED GEL

The phosphoprotein stain used in Alternate Protocol 5 has an excitation maximum at ~555 nm and an emission maximum at ~580 nm. Imaging instruments with light sources and filters that match the excitation and emission maxima will result in the highest sensitivity.

Visible Light–Based Scanners

Stained gels are best visualized using excitation at 532 to 560 nm, such as that provided with a visible light laser–based or xenon arc lamp–based gel-scanning instrument. For most instruments, a ~580 nm long-pass or a ~600 nm band-pass emission filter is recommended.

Transillumination

Stained gels can be visualized on a blue-light transilluminator, such as the Visi-Blue series of transilluminators (UVP), Dark Reader transilluminator (Clare Chemical Research), or on a 300-nm UV transilluminator; however, the sensitivity will be lower than with a scanning instrument. Images can be documented using either conventional or digital photography. With a Polaroid camera and Polaroid 667 black-and-white film, use an appropriate long-pass filter, such as the SYPRO photographic filter (S-6656), and exposure times of ~15 to 30 sec. The red-orange filters typically used to photograph gels stained with ethidium bromide will not work well. For digital cameras, use a filter that corresponds closely to the emission characteristics of the stain, such as a 600 nm band-pass filter.

SUPPORT PROTOCOL 3

Analysis of Proteins

10.6.15

SELECTIVE DETECTION OF PHOSPHOTYROSINE RESIDUES

Phosphotyrosine residues can be selectively detected by removing phosphoserine and phosphothreonine residues through a β -elimination reaction. To detect only phosphotyrosine residues, one must perform the β -elimination reaction before carrying out Pro-Q Diamond staining as in Alternate Protocol 5. To obtain data on all phosphorylation sites, stain with Pro-Q Diamond as in Alternate Protocol 5, then document the gel image. Next, perform the β -elimination reaction and stain the gel with Pro-Q Diamond stain again. All spots or bands appearing in the first staining but not appearing in the second staining will be due to phosphoserine or phosphothreonine residues.

Additional Materials (also see *Alternate Protocol 5*)

Gel for phosphoprotein fluorescent staining (either before fixation/staining or after fixation/staining/destaining; see *Alternate Protocol 5*)

Barium hydroxide octahydrate

Argon source

Glacial acetic acid

50°C shaking water bath

1. If the gel has not already been fixed and stained, perform fix and wash steps (see *Alternate Protocol 5*, steps 5a or b and 6a or b). If the gel has already been fixed, stained, and destained, then perform only the wash procedure (see *Alternate Protocol 5*, step 6a or b).
2. Prepare a saturated solution of barium hydroxide by dissolving 12.6 g barium hydroxide octahydrate in 40 ml of degassed distilled water. Mix for 15 to 20 min and centrifuge 10 min at $10,000 \times g$, room temperature, to pellet any insoluble barium hydroxide. Store under argon gas.
3. Incubate 40 ml of the saturated barium hydroxide solution in a 50°C water bath for 30 min. At the same time, warm 40 ml of degassed distilled water to 50°C in the water bath.
All solutions should be treated with argon gas to remove atmospheric carbon dioxide and prevent the formation of insoluble barium carbonate.
4. Mix 40 ml of the warmed barium hydroxide solution with 40 ml of the warmed degassed water; and incubate the gel in the diluted solution at 50°C for 30 min with gentle agitation.
5. Stop the reaction by lowering the pH to 4.0 with addition of ~6 ml glacial acetic acid.
6. Wash and stain the gel (see *Alternate Protocol 6*, steps 6a or b and 7 a or b).
7. Document the results (see *Support Protocol 3*).

FLUORESCENT STAINING FOR DIFFERENTIALLY STAINING GLYCOSYLATED AND NONGLYCOSYLATED PROTEINS IN THE SAME GEL

Fluorescent staining provides a powerful method for differentially staining glycosylated and nonglycosylated proteins in the same gel. The technique combines a highly sensitive glycoprotein stain with ultrasensitive SYPRO Ruby protein gel stain. Both stains provide simple, sensitive, and robust detection. The Pro-Q Emerald 300 glycoprotein stain reacts with periodate-oxidized carbohydrate groups, creating a bright green fluorescent signal on glycoproteins. Using this stain, it is possible to detect as little as 0.5 ng of glycoprotein per band, depending upon the nature and the degree of glycosylation, making it about 50-fold more sensitive than the standard periodic acid–Schiff base method using acidic fuchsin dye. The green fluorescent signal can be visualized with 300-nm UV illumination. The second staining uses SYPRO Ruby protein gel stain (see *Basic Protocol 4*) to detect

total protein. This easy-to-use fluorescent stain provides the same sensitivity as silver staining, but has the advantage that it does not require glutaraldehyde, which can produce false positive responses when glycoproteins are stained. The use of SYPRO Ruby stain makes it possible to detect contaminating proteins and to easily compare the sample with molecular weight standards. For 2-D gels, total-protein staining makes it easier to localize a protein to a particular spot in the complex protein pattern. Proteins show orange-fluorescent staining when illuminated with a 300-nm UV transilluminator or a laser scanner with a 473-nm, 488-nm, or 532-nm light source. Glycosylated molecular weight standards are also highlighted containing a mixture of glycosylated and nonglycosylated proteins, which, when separated by electrophoresis, provide alternating positive and negative controls.

Materials

Protein-containing sample of interest

8-cm × 10-cm SDS- polyacrylamide minigel (*UNIT 10.2A*)

Sample buffer (*UNIT 10.2A*)

Pro-Q Emerald glycoprotein gel staining kit (Molecular Probes) including:

Pro-Q Emerald 300 staining reagent (component A), 50× concentrate in DMF (store at −20°C up to 6 months, protected from light)

Pro-Q Emerald 300 staining buffer (component B; store at room temperature up to 6 months)

Oxidizing reagent (component C): 2.5 g of periodic acid (add 250 ml of 3% v/v acetic acid and store at room temperature up to 6 months)

CandyCane glycoprotein molecular weight standards (store at −20°C up to 6 months)

Fixing solution: 50% (v/v) methanol in H₂O

Wash solution: 3% (v/v) glacial acetic acid in H₂O

Polystyrene staining dish (e.g., large weighing dish)

Orbital shaker

Additional reagents and equipment for SDS-PAGE (*UNIT 10.2A*), viewing and documenting glycoprotein-stained gels (see Support Protocol 5), and SYPRO Ruby staining (see Basic Protocol 4)

NOTE: The following procedure is optimized for staining 0.5- to 0.75-mm thick, 8-cm × 10-cm minigels. Large 2-D gels (20 cm × 20 cm) require much larger volumes and longer fixation and staining times, as indicated in the annotations to the respective steps.

1. Dilute protein sample to ~10 to 100 μg/ml with sample buffer and load 5 to 10 μl of the diluted sample per lane of an 8-cm × 10-cm polyacrylamide gel. Also dilute 0.5 μl of the CandyCane standard mixture (from the Pro-Q Emerald glycoprotein gel staining kit) with 7.5 μl of sample buffer, vortex, and load in a lane of the gel. Perform standard SDS-PAGE as described in *UNIT 10.2A*.

In the standard lane there will be ~250 ng of each standard protein included in the CandyCane standard mix; for larger gels increase the amount of standard and buffer used. Larger gels typically require twice as much material for sample and standards.

2. Transfer gel to a polystyrene staining dish and immerse the gel in 100 ml of fixing solution (50% methanol) and incubate at room temperature with gentle agitation (e.g., on an orbital shaker at 50 rpm) for 45 min. Repeat this wash step to ensure that all of the SDS is washed out of the gel.

For large (20 × 20-cm) 2-D gels, use 700 ml of fixing solution and incubate at room temperature overnight.

3. Wash the gel by incubating in 50 ml of wash solution (3% acetic acid) with gentle agitation for 10 min. Repeat this step once.

Use 700 ml of wash solution for large 2-D gels.

4. Oxidize the carbohydrates by incubating the gel in 25 ml of oxidizing solution (component C in the Pro-Q Emerald 300 kit; 2.5 g periodic acid in 250 ml of 3% acetic acid) with gentle agitation for 30 min.

Large 2-D gels require 500 ml of oxidizing solution and should be incubated for 1 hr. The 250-ml volume of oxidizing solution can be diluted with 250 ml of 3% acetic acid in order to have an adequate volume for large 2-D gels.

The Pro-Q Emerald glycoprotein gel staining kit provides sufficient materials to stain ten 8-cm × 10-cm, 0.5 to 0.75-mm thick gels.

5. Wash the gel by incubating in 50 ml (700 ml for large 2-D gels) of wash solution (3% acetic acid) with gentle agitation for 5 to 10 min. Repeat this step two more times for a total of three washes.

For large 2-D gels, 700 ml wash solution should be used for each wash and three additional washes (for a total of four washes) should be performed.

6. Just before use, dilute the 50× concentrate of Pro-Q Emerald 300 staining reagent (component A in the kit) 50-fold into Pro-Q Emerald 300 staining buffer (component B in the kit); e.g., dilute 500 µl of component A into 25 ml component B. Stain the gel by placing it in the dark in 25 ml of the mixed staining solution while gently agitating for 90 to 120 min.

The signal can be seen after about 20 min and maximum sensitivity is reached at about 120 min. The authors do not recommend staining overnight. A 200-ml volume of staining solution and staining period of 2.5 hr are required for large 2-D gels.

7. Wash the gel in 50 ml wash solution (3% acetic acid) at room temperature for 15 min. Repeat this wash once for a total of two washes. Do not leave the gel in wash solution >2 hr, as the staining will start to decrease.

Use 700 ml of wash solution for large 2-D gels.

8. View and photograph the gel to document the staining pattern (see Support Protocol 5).

For best results, the Pro-Q Emerald 300 stain should be used first and the glycoprotein staining pattern documented before proceeding with SYPRO Ruby staining. After SYPRO Ruby staining, the fluorescent signal from the Pro-Q Emerald 300 glycoprotein stain can still be seen, but the sensitivity will be somewhat decreased.

9. Stain the gel with SYPRO Ruby (see Basic Protocol 4).

10. View and photograph the gel (see Support Protocol 5).

SUPPORT PROTOCOL 5

VIEWING AND PHOTOGRAPHING THE GLYCOPROTEIN-STAINED GEL

The green-fluorescent Pro-Q Emerald 300 staining should be viewed and documented before staining total proteins with SYPRO Ruby protein gel stain. The Pro-Q Emerald 300 stain has an excitation maximum at ~280 nm and an emission maximum near 530 nm. Stained glycoproteins can be visualized using a 300-nm UV transilluminator (UVP). The use of a photographic camera or CCD camera and the appropriate filters is essential to obtain the greatest sensitivity. The instrument's integrating capability can make bands visible that cannot be detected by eye. It is important to clean the surface of the transilluminator after each use with deionized water and a soft cloth (e.g., cheesecloth); otherwise fluorescent dyes can accumulate on the glass surface and cause a high back-

ground fluorescence. Some fluorescent speckling may occur, especially near the edges of the gel. This speckling is an intrinsic property of the stain and does not affect sensitivity. When analyzing amounts of glycoprotein near the limit of detection, the authors advise that samples be run in the middle lanes of the gel. The authors use a 300-nm transilluminator with six 15-W bulbs. Excitation with different light sources may not give the same sensitivity. Using a Polaroid camera and Polaroid 667 black-and-white print film, the highest sensitivity is achieved with a 490-nm long-pass filter, such as the SYPRO protein gel stain photographic filter, available from Molecular Probes. The authors typically photograph minigels using an *f*-stop of 4.5 for 2 to 4 sec, using multiple 1-sec exposures. Using a CCD camera, images are best obtained by digitizing at $\sim 1024 \times 1024$ pixels resolution with 12-, 14-, or 16-bit grayscale levels per pixel. The camera manufacturer should be consulted for recommendations on filters to use. A CCD camera-based image-analysis system can gather quantitative information that will allow comparison of fluorescence intensities between different bands or spots. The polyester backing on some precast gels is highly fluorescent. For maximum sensitivity using a UV transilluminator, the gel should be placed polyacrylamide-side-down and an emission filter should be used to screen out the blue fluorescence of the plastic.

SYPRO Ruby staining for total protein is described in Basic Protocol 4. Viewing and photographing SYPRO Ruby-stained protein gels is described in Support Protocol 2. One should keep in mind that SYPRO Ruby protein gel stain has two excitation peaks and can be viewed using either UV illumination or blue-light illumination with a laser scanner. With UV illumination, both stains can be visualized simultaneously, although the signal from the green fluorescent glycoprotein stain may be somewhat reduced, compared to what it was before SYPRO Ruby staining. For documentation, the orange-red fluorescent SYPRO Ruby staining can be separated from the green-fluorescent Pro-Q Emerald 300 staining in one of two ways. If using UV illumination, use either a long-pass filter with a cutoff between 620 and 650 nm, or a band-pass filter with a center wavelength at about 645 nm, to document the SYPRO Ruby stain alone. Filters with cutoffs at wavelengths shorter than 620 nm may show some bleed-through of the Pro-Q Emerald 300 signal. Alternatively, the gel can be imaged using visible-light excitation, such as used in a laser scanner. Visible light will excite the SYPRO Ruby stain, but not the Pro-Q Emerald 300 stain. The fluorescent signal from the SYPRO Ruby stain can then be documented as described.

REAGENTS AND SOLUTIONS

Use high-quality deionized, distilled water (≥ 18 M Ω) in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Carbonate developing solution

- 0.5 ml 37% formaldehyde per liter solution
- 3% (w/v) sodium carbonate
- Prepare fresh before use

Coomassie blue staining solution

- 50% (v/v) methanol
- 0.05% (w/v) Coomassie brilliant blue R-250 (Bio-Rad or Pierce)
- 10% (v/v) acetic acid
- 40% H₂O

Dissolve Coomassie brilliant blue R in methanol before adding acetic acid and water. Store for up to 6 months at room temperature. If precipitate is observed following prolonged storage, filter to obtain a homogeneous solution.

Developing solution

0.5 g sodium citrate
0.5 ml 37% formaldehyde solution (Kodak)
H₂O to 100 ml
Store up to ~1 month at room temperature

Drying solution

10% (v/v) ethanol
4% (v/v) glycerol
86% H₂O
Store up to ~1 month at room temperature

Fixing solution for Coomassie blue and silver staining

50% (v/v) methanol
10% (v/v) acetic acid
40% H₂O
Store up to ~1 month at room temperature

Fixing solution for phosphoprotein gels

For minigels:

50% (v/v) methanol
10% (v/v) acetic acid

For 2-D gels:

50% (v/v) methanol
10% (w/v) trichloroacetic acid

One 6-cm × 9-cm × 0.75-mm minigel will require ~200 ml of fix solution; one 20-cm × 20-cm × 1-mm 2-D gel will require ~1 liter of fix solution. In order to improve the specificity of phosphoprotein staining in 2-D gels, the authors recommend fixing them in 10% trichloroacetic acid/50% methanol instead of 10% acetic acid/50% methanol.

Store fixing solutions up to 1 month at room temperature

Fixing solution for SYPRO Ruby staining of 2-D polyacrylamide gels

Fix with any of the following solutions (all prepared in H₂O):

10% (v/v) methanol
7% (v/v) acetic acid/25% (v/v) ethanol
12.5% (w/v) trichloroacetic acid/10% (v/v) ethanol
7% (v/v) acetic acid/50% (v/v) ethanol
3% (v/v) acetic acid/40% (v/v) ethanol
10% (v/v) acetic acid

Store up to 1 month at room temperature

These fixative solutions are used in 5- to 10-fold excess of the gel volume. Thin (<0.75-mm) gels will equilibrate with fixative much more quickly than thick gels. Larger-format gels require more fixative to effectively exchange the gel buffers for the fixative.

Formaldehyde fixing solution

40% (v/v) methanol
0.5 ml 37% formaldehyde per liter solution
60% H₂O
Store up to ~1 month at room temperature

Isopropanol fixing solution

25% (v/v) isopropanol
10% (v/v) acetic acid
65% H₂O
Store indefinitely at room temperature

Methanol/acetic acid destaining solution

5% (v/v) methanol

7% (v/v) acetic acid

88% H₂O

Store up to ~1 month at room temperature

Phosphoprotein gel destain solution

15% (v/v) 1,2-propanediol (propylene glycol)

50 mM sodium acetate, pH 4.0

For each liter of destain solution to be prepared, add 50 ml of 1 M sodium acetate, pH 4.0, to 800 ml of distilled water. Add 150 ml of 1,2-propanediol (or 40 ml of acetonitrile; see below). Bring the volume to 1 liter with distilled water and mix thoroughly. Alternatively, this destain Solution is available from Molecular Probes as a separate product. Store up to 1 month at room temperature.

If 1,2-propanediol (propylene glycol) is not available, 4% acetonitrile may be substituted. However, note that acetonitrile is a hazardous compound and its use will involve waste disposal restrictions.

The destaining step is very important for maximizing detection sensitivity for phosphoproteins while minimizing nonspecific staining of nonphosphorylated proteins. One 6-cm × 9-cm × 0.75-mm minigel will require ~250 ml of destain solution; one 20-cm × 20-cm × 1-mm 2-D gel will require ~2 liters of destain solution.

Pro-Q Diamond phosphoprotein gel stain

Purchase Pro-Q Diamond phosphoprotein gel stain from Molecular Probes (available in 200-ml, 1-liter, and 5-liter quantities). 200 ml provides sufficient material to stain ~4 minigels; 1 liter provides sufficient material to stain ~20 minigels or two large-format 2-D gels; 5 liters provide sufficient material to stain ~100 minigels or 10 large-format gels. Upon receipt, store the stain at room temperature, protected from light. For long-term storage, store the stain at 2° to 6°C, protected from light. When stored properly, the stain should be stable for at least 6 months.

Rapid Coomassie blue staining solution

10% (v/v) acetic acid

0.006% (w/v) Coomassie brilliant blue G-250 (Bio-Rad)

90% H₂O

Store indefinitely at room temperature

Silver nitrate solution (ammoniacal)

Add 3.5 ml concentrated NH₄OH (~30%) to 42 ml 0.36% NaOH and bring the volume to 200 ml with H₂O. Mix with a magnetic stirrer and slowly add 8 ml of 19.4% (1.6 g/8 ml) silver nitrate. Use within 20 min.

If the solution is cloudy, carefully add NH₄OH until it clears. Alternatively, use NH₄OH that is <3 months old.

CAUTION: *This solution is potentially explosive when dry and therefore should be precipitated by the addition of an equal volume of 1 M HCl. The resultant silver chloride can be washed down a drain with a large volume of cold water.*

SYPRO Orange or Red fluorescent staining solution

Allow stock vial of SYPRO Orange or Red protein gel stain (Molecular Probes) to warm to room temperature and then briefly microcentrifuge to deposit the dimethyl sulfoxide (DMSO) solution at the bottom of the vial. If particles of dye are present, dissolve by briefly sonicating the tube or vortexing it vigorously after warming. Dilute stock 1:5000 (v/v) in 7.5% (v/v) acetic acid and mix vigorously. Store in very

continued

clean, detergent-free glass or plastic bottles, protected from light, at 4°C (stable ≥3 months).

SYPRO Orange: 300 and 470 nm excitation, 570 nm emission; SYPRO Red: 300 and 550 nm excitation, 630 nm emission.

The stock solutions should be stored protected from light at room temperature, 4°C, or 20°C. When stored properly, they are stable for 6 months to 1 year.

SYPRO Ruby protein gel stain

Purchase SYPRO Ruby protein gel stain from Molecular Probes (available in 200-ml, 1-liter, and 5-liter quantities; 200 ml provides sufficient material to stain ~4 minigels). Store at room temperature protected from light (stable for at least 9 months). For convenient storage and dispensing, the 5-liter unit size is packaged in a cubical box with a spigot. Once opened, the box can be stored on its side with the top flap closed to protect the stain from light.

Thiosulfate developing solution

3% (w/v) sodium carbonate

0.0004% (w/v) sodium thiosulfate

0.5 ml 37% formaldehyde per liter solution (add immediately before use)

Store indefinitely without formaldehyde at room temperature

COMMENTARY

Background Information

Coomassie brilliant blue (Basic Protocol 1) binds nonspecifically to proteins (Wilson, 1983). Because the dye does not bind to the polyacrylamide gel, proteins will be detected as blue bands surrounded by clear gel zones.

Silver staining relies on differential reduction of silver ions, which is the basis for photographic processes. A highly sensitive photochemical silver staining technique (Switzer et al., 1979; Merrill et al., 1984) permits the detection of polypeptides in gels at more than 100× lower concentrations than Coomassie brilliant blue (i.e., femtomole levels of protein). The basic silver staining protocol described here (Basic Protocol 2) is derived from a modified technique developed by Oakley et al. (1980), which is simpler and less expensive than the original procedures. The first alternate silver staining protocol presents a very popular method described by Morrissey (1981). The second alternate silver staining protocol is a very rapid method described by Bloom et al. (1987).

Fluorescent protein gel stains provide a number of advantages over conventional colorimetric stains. The SYPRO Orange and Red protein gel stains described here can detect 1 to 2 ng protein per minigel band, more sensitive than Coomassie brilliant blue staining and as sensitive as many silver staining techniques. In addition, staining is complete in <1 hr. After electrophoresis, the gel is simply stained,

rinsed, and photographed; no separate fixation or destaining step is required and there is no fear of overstaining the gel (Steinberg et al., 1996a,b, 1997). In addition, stained proteins can be visualized using a standard 300-nm UV transilluminator or a laser scanner (Fig. 10.6.2). Because the dyes interact with the SDS coat around proteins in the gel, they give more consistent staining between different types of proteins compared to Coomassie or silver staining and do not exhibit negative staining. Furthermore, the dyes detect a variety of proteins down to ~6500 Da without staining nucleic acid or lipopolysaccharide contaminants that are sometimes found in protein preparations derived from cell or tissue extracts.

Critical Parameters

The high sensitivity of the silver staining technique renders it susceptible to impurities and staining artifacts. It is mandatory that the polyacrylamide gels and all staining solutions be prepared from high-quality reagents in order to avoid staining artifacts. Especially important is the use of high-quality water (glass-distilled or deionized, carbon-filtered). The glassware used for gel polymerization and plastic containers should be cleaned thoroughly, and gels should be handled with vinyl, powder-free gloves. To avoid uneven staining of the gel surface, the polyacrylamide gel should be covered with a sheet of Parafilm in order to uniformly wet the gel surface during staining, and

Figure 10.6.2 Identical polyacrylamide minigels stained with (A) SYPRO Orange gel stain, (B) SYPRO Red gel stain, (C) silver stain, and (D) Coomassie brilliant blue stain according to standard protocols. The SYPRO-stained gels were photographed using 300-nm transillumination, a SYPRO Orange/Red protein gel stain photographic filter, and Polaroid 667 black-and-white print film. The Coomassie- and silver-stained gels were photographed using transmitted white light and Polaroid 667 black-and-white print film; no optical filter was used.

should be touched only very gently with gloved hands. If silver staining is performed infrequently, commercial silver staining kits should be used; those distributed by Bio-Rad and Pierce have been tested and found to be reliable and sensitive.

For immunoblotting and other blotting techniques, fluorescent stains can be diluted in standard transfer buffer. However, staining the gel in transfer buffer will result in lower sensitivity. Therefore, for blotting techniques, staining the gel with SYPRO Tangerine protein gel stain, which does not require acetic acid fixation, or staining the blot directly with SYPRO Ruby protein blot stain is recommended.

Diluting fluorescent stain below the recommended concentration will result in reduced staining sensitivity. Using higher staining concentrations than recommended will not result in better detection, but will instead result in increased background and quenching of the fluorescence from dye molecules crowded around the proteins.

SYPRO Red and Orange stains cannot be used to pre-stain protein samples for SDS gels. Loading solutions contain so much SDS that

the dye simply localizes in the free SDS and binds very little to the proteins.

The SDS front at the bottom of the gel stains very heavily with SYPRO stains. Unless the proteins of interest co-migrate with the SDS front, it will be advantageous to run the SDS front off the gel. Colored stains and marker dyes, as well as commercially prestained protein markers, interfere with SYPRO dye staining and quench fluorescence.

Highly colored prosthetic groups (e.g., heme) that remain bound in native gels will quench fluorescence of the SYPRO Orange and Red stains. Odd marks on stained gels can be caused by several factors. If the gel is squeezed, a mark appears that stains heavily with the SYPRO dyes. This is probably due to a localized high concentration of SDS that has difficulty diffusing out. Glove powder can also give background markings, so rinsing or washing gloves is recommended prior to handling gels. Staining with the SYPRO Orange dye occasionally results in gels with scattered fluorescent speckles.

Due to different staining properties of proteins, dual staining procedures can reveal pro-

teins with one procedure that the other has not visualized. SYPRO-stained gels can be restained with either Coomassie brilliant blue or silver stain procedures. In fact, for some silver staining methods, the authors have found that prestaining with SYPRO dyes actually increases the rate of staining and the sensitivity for detection. To fluorescently stain gels that have previously been stained with Coomassie, the Coomassie stain must be completely removed, as it will quench the fluorescence of SYPRO dyes. Soaking the gel in either 30% methanol or 7.5% acetic acid with several changes of destaining solution is effective at removing Coomassie. Once the Coomassie has been removed, the gel should be incubated in 0.05% SDS for 30 min before staining with the SYPRO stain as usual.

Triton X-100 at $\geq 0.1\%$ interferes with SYPRO dye staining. If Triton X-100 is used in the gel, the authors recommend soaking the gel in two to three changes of buffer to be sure the Triton X-100 is diluted out, and then incubating the gel in 0.05% SDS for 30 min before staining as usual.

Staining for glycoproteins

The overall specificity of glycoprotein detection by the Pro-Q Emerald 300 reagent method depends greatly upon the specificity of the oxidation reaction, which is governed in turn by the reaction conditions used (e.g., periodic acid concentration, pH, temperature, and exposure to light). Careful attention to the protocol is required to avoid oxidation of serine, threonine, and hydroxylysine residues to form aldehyde groups, which result in false-positive signals. Residual SDS in the gel will also lead to nonspecific staining. This can be avoided by adhering strictly to the fixation and wash volumes and times indicated in Alternate Protocol 6. In addition, it is advisable to stain a duplicate gel, eliminating the oxidation step (step 4), as a negative control.

Anticipated Results

The sensitivity of Coomassie blue gel staining is 0.3 to 1 μg /protein band; the sensitivity of silver staining is 2 to 5 ng/protein band. The sensitivity of both stains varies in an unpredictable manner with the protein being stained.

For fluorescent dyes, detection limits are typically ~ 500 ng protein/band in room light, ~ 50 ng protein/band with 300-nm transillumination, and ~ 1 to 2 ng protein/band in a photograph taken with Polaroid 667 black-and-white print film. The authors achieve detection limits

of 1 to 2 ng/band using a Fotodyne Foto/UV 450 ultraviolet transilluminator, which has six 15-watt bulbs that provide peak illumination at 312 nm. When using weaker illumination sources, exposures must be correspondingly longer. Although the authors' detection limits are 1 to 2 ng/band for most proteins, it should be emphasized that bands containing 5 to 10 ng/protein are more readily detected. Bands containing less than 5 to 10 ng protein require longer exposures and sharp bands for good visualization. Longer exposures can result in higher background.

Time Considerations

Coomassie blue staining requires 8 to 12 hr. Silver staining requires ~ 5 hr. Fixation may be extended for several days before Coomassie blue staining. Fixation may be extended for longer periods—up to several weeks—before silver staining.

Use of either of the rapid staining protocols considerably reduces the time required to visualize proteins. Detection of protein bands by rapid Coomassie blue staining requires ≤ 90 min from the time a minigel is run (30 to 60 min) until the gel is fixed (10 min) and placed in staining solution (5 to 10 min); however, additional time may be necessary for larger gels. Separated proteins stained with the rapid silver stain method can be visualized in ~ 35 min.

The staining time for SYPRO dyes is 10 to 60 min, depending on the thickness and percentage of the gel. For 1-mm-thick 15% polyacrylamide gels, the signal is typically optimal at 40 to 60 min of staining.

Detection of Proteins on Blot Transfer Membranes

This unit presents protocols for the staining of proteins that have been electroblotted from polyacrylamide gels to blot transfer membranes (UNIT 10.8). If the samples of interest are electrophoresed in duplicate and transferred to a membrane, half the membrane can be stained to determine the efficiency of transfer to the membrane and the other half can be used for immunoblotting (i.e., western blotting; see UNIT 10.8). Procedures are described for India ink staining (see Basic Protocol 1) and gold staining of the blots (see Alternate Protocol). Support Protocol 1 describes a method for alkali treatment that enhances subsequent staining of bound proteins. Detection limits of each staining method and compatible blot transfer membranes and gels are presented in Table 10.7.1.

Fluorescent staining methods have gained popularity because of their high sensitivity and direct compatibility with colorimetric, fluorogenic, and chemiluminescent techniques. A method is described (see Basic Protocol 2) for staining blots with SYPRO Ruby, a sensitive fluorescent stain that works equally well on both nitrocellulose and PVDF blots. Support Protocol 2 provides detail for photographing fluorescently stained blots and recording the results.

Table 10.7.1 Properties and Compatibilities of “Protein Transfer” Membrane Stains^a

Stain	Detection limit (ng)	Membrane types			Gel types	
		Nitro-cellulose	Nylon	PVDF	SDS-PAGE	Native PAGE
India ink	50	+	–	+	+	+
Gold	3	+	–	+	+	+
SYPRO Ruby	2	+	+	+	+	+

^aAbbreviations: n.d., not determined; PVDF, polyvinylidene difluoride; SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis.

INDIA INK STAINING

India ink is used to stain proteins on blot transfer membranes. The transferred proteins (≥ 50 ng) appear as black bands on a gray background.

Materials

Protein sample transferred onto blot transfer membrane, nitrocellulose or PVDF (UNIT 10.8)
Tween 20 solution (see recipe)
India ink solution (see recipe)
Plastic boxes

NOTE: Deionized, distilled water should be used throughout this protocol.

1. If desired, pretreat proteins transferred onto nitrocellulose membrane with alkali (see Support Protocol 1).
2. Place blot transfer membrane(s) in a plastic box on an orbital shaker and wash in Tween 20 solution at 37°C three times for 30 min each.

**ALTERNATE
PROTOCOL**

3. Continue to wash the membrane in Tween 20 solution at room temperature two times for 30 min each.
4. Stain the membrane in India ink solution 3 hr or overnight.
5. Rinse the membrane twice in Tween 20 solution, destain in Tween 20 solution until an acceptable background is obtained, then air dry.

Black bands appear against a gray background.

GOLD STAINING

A colloidal gold sol is used to stain proteins on blot transfer membranes. The transferred proteins (≥ 3 ng) will appear as red bands on an almost white background.

Materials

Membragold colloidal gold solution (Diversified Biotech)
Heat-sealable plastic bag

1. If desired, pretreat proteins transferred onto nitrocellulose membrane with alkali (see Support Protocol 1).
2. Place blot transfer membrane(s) in a plastic box on an orbital shaker and wash in Tween 20 solution three times at 37°C for 30 min each.

Do not attempt to stain nylon membranes.

3. Continue to wash the membrane in Tween 20 solution at room temperature three times for 5 min each.
4. Rinse well with water.
5. Stain the membrane 30 min to 1 hr at room temperature with continuous shaking in Membragold colloidal gold sol.

A heat-sealed plastic bag is a convenient container for the staining. Extended staining periods do not impair visualization.

6. Rinse the membrane briefly in water and air dry on filter paper.

**SUPPORT
PROTOCOL 1**

ALKALI ENHANCEMENT OF PROTEIN STAINING

A brief pretreatment of nitrocellulose-bound protein with alkali enhances subsequent staining with either India ink or colloidal gold.

Materials

1% (w/v) KOH
PBS (APPENDIX 2)
Glass or Pyrex dish

1. Place nitrocellulose plot or dot membrane with transferred proteins in a glass dish containing enough 1% KOH to cover the membranes. Soak 5 min at 20°C.
2. Rinse twice each time for 10 min, in PBS.

FLUORESCENT PROTEIN BLOT STAINING

The fluorescent SYPRO Ruby protein blot stain provides a rapid, simple, and highly sensitive method for detecting proteins on nitrocellulose or polyvinylidene difluoride (PVDF) membranes (blots). Staining total protein before applying specific protein detection techniques provides an assessment of protein transfer efficiency, and makes it possible to detect contaminating proteins in the sample and to compare the sample with molecular weight standards. For blots of 2-D gels, total protein staining makes it easier to localize a protein to a particular spot in the complex protein pattern. The bright, orange-red fluorescent stain can be easily visualized using UV illumination or a laser scanner. The staining procedure is simple to perform and can be completed within 1 hr. SYPRO Ruby has a sensitivity limit of 2 to 8 ng/band, making it about 60 times more sensitive than reversible stains like Ponceau S and 20 to 30 times more sensitive than Amido Black or Coomassie Brilliant Blue stains. The SYPRO Ruby protein blot stain will not stain nucleic acids and is compatible with immunodetection and colorimetric, fluorogenic, and chemiluminescent detection techniques, as well as with Edman sequencing and mass spectrometry.

Materials

Proteins electroblotted onto PVDF or nitrocellulose membrane (*UNIT 10.8*)
7% acetic acid/10% methanol
SYPRO Ruby protein blot stain (purchase from Molecular Probes; also see recipe)
Small polypropylene staining dish
Orbital shaker

NOTE: Perform all washing, staining, and other incubation steps with continuous, gentle agitation (e.g., on an orbital shaker at 50 rpm). For PVDF membranes, be sure to float the membrane face down on the solution.

After electroblotting to nitrocellulose membranes

- 1a. Completely immerse the membrane in 7% acetic acid/10% methanol and incubate at room temperature for 15 min in a small polypropylene staining dish.
- 2a. Incubate the membrane in four changes of deionized water, each time for 5 min.
- 3a. Completely immerse the membrane in SYPRO Ruby protein blot stain for 15 min.
- 4a. Wash the membrane 4 to 6 times, for 1 min each time, in deionized water, to remove excess dye.

Membranes stained with SYPRO Ruby blot stain should be periodically monitored using UV epi-illumination to determine if background fluorescence has been washed away.

After electroblotting to PVDF membranes

- 1b. Allow the membrane to dry completely.
- 2b. Float the membrane face down in 7% acetic acid/10% methanol and incubate for 15 min.
- 3b. Float the membrane for 5 min each time in four changes of deionized water, then float the membrane in SYPRO Ruby protein blot stain for 15 min.
- 4b. Wash the membrane 2 to 3 times in deionized water, each time for 1 min, to remove excess dye.

For Edman-based microsequencing, use a PVDF membrane, stain with SYPRO Ruby protein blot stain as described above, and then partially destain the blot, first washing it by placing it face down on a solution of 150 mM Tris·Cl, pH 8.8 (APPENDIX 2)/20% methanol for 10 min, with gentle agitation, then rinsing the blot four times, each time for 1 min in distilled water. Finally, air dry the blot.

5. Allow the membranes to air dry.

After staining, wet membranes should not be touched, since residue found on latex gloves may destroy the staining pattern. Use forceps to handle wet blots. Once dry, the membranes can be handled freely.

VIEWING AND PHOTOGRAPHING THE BLOT

SYPRO Ruby protein blot stain (also see Basic Protocol 2) has two excitation maxima, one at ~280 nm and one at ~450 nm, and has an emission maximum near 618 nm. Proteins stained with the dye can be visualized using a 300-nm UV transilluminator, a blue-light transilluminator, or a laser scanner. The stain has exceptional photostability, allowing long exposure times for maximum sensitivity.

UV Epi- or Transilluminator

Proteins stained with SYPRO Ruby protein blot stain are readily visualized using UV illumination. The front face of the membrane can be illuminated using a hand-held UV-B (~300 nm) light source. Alternatively, a UV light box can be placed on its side to illuminate the blots, or a top-illuminating system such as the UVP AutoChemi System or the Bio-Rad Fluor-S imager can be used to visualize the stain. Satisfactory results can also be obtained from direct UV transillumination through the blotting membrane. In either case, the use of a photographic or CCD camera and the appropriate filters is essential to obtain the greatest sensitivity. The instrument's integrating capability can make bands visible that cannot be detected by eye. It is important to clean the surface of the transilluminator after each use with deionized water and a soft cloth (like cheesecloth); otherwise, fluorescent dyes, such as SYPRO stains, SYBER stains, and ethidium bromide will accumulate on the glass surface and cause a high background fluorescence.

Using a Polaroid camera and Polaroid 667 black-and-white print film, the highest sensitivity is achieved with a 490-nm long-pass filter, such as the SYPRO protein gel stain photographic filter (cat. no. S-6656, Molecular Probes). In the authors' laboratory, blots are typically photographed using an f-stop of 4.5 for 1 sec.

Using a CCD camera, images are best obtained by digitizing at ~1024 × 1024-pixel resolution with 12- or 16-bit gray scale levels per pixel. The manufacturer of the particular camera should be contacted for recommendations on filter sets to use.

Laser-Scanning Instruments

Blots stained with the SYPRO Ruby protein blot stain can be visualized using imaging systems equipped with lasers that emit at 450, 473, 488, or 532 nm. Proteins may be analyzed immediately after staining by immunostaining, glycoprotein staining, or mass spectrometry. It is important to photograph or otherwise document the SYPRO Ruby stain before immunostaining, as over 90% of the stain is washed off the blot during the blocking step.

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

India ink solution

0.1% India ink (e.g., Pelikan 17 black) in Tween 20 solution (see recipe)

SYPRO Ruby protein blot stain

SYPRO Ruby protein blot stain (Molecular Probes) is provided in a unit size of 200 ml. The 200-ml volume is sufficient for staining 10 to 40 minigel electroblots or four large-format electroblots (20 × 20 cm). SYPRO Ruby protein blot stain may

continued

be reused up to four times with little loss in sensitivity. The reagent is stable for at least 6 months to 1 year when stored at room temperature, protected from light.

Tween 20 solution

0.3% (v/v) Tween 20 in phosphate-buffered saline (PBS; *APPENDIX 2*), pH 7.4.

COMMENTARY

Background Information

The introduction of electrophoretic transfer of separated proteins has been paralleled by the use of extremely sensitive immunoblotting techniques to detect the binding of antibodies and lectins to the transferred protein bands. "On-blot" protein staining procedures help one control the electrophoretic transfer and correlate the transferred polypeptide pattern with that detected in the overlay. An additional advantage of on-blot protein staining as compared to gel staining is that the pattern of the protein membrane stains can be directly compared to the results of the overlay assays. Comparing overlay assays with stained gels is cumbersome due to swelling or shrinking of the polyacrylamide gels.

Membranes used for the electrophoretic transfer are manufactured from nitrocellulose, nylon, or polyvinylidene difluoride (PVDF). Depending on the transfer membrane used and other considerations (e.g., the use of SDS-polyacrylamide gels or polyacrylamide gels without SDS and the level of sensitivity required), different staining procedures must be selected (Table 10.7.1).

SYPRO Ruby, in contrast to India ink and colloidal gold, is fully compatible with colorimetric, fluorogenic, and chemiluminescent immunodetection techniques. Stains such as colloidal gold often block epitopes required for subsequent immunodetection. In addition, the dark color of the colloidal gold or India ink stains makes it difficult to visualize colorimetric or fluorogenic immunodetection reagents in subsequent immunodetection assays on the membrane.

Staining of membrane-bound polypeptides by gold sol is mediated by hydrophobic interactions and by ionic interaction of negatively charged gold particles with positive groups on the proteins. The protocol listed is that described by Moeremans et al. (1985). The gold stain is very easy to perform and is the most sensitive blot membrane stain.

The protocol for India ink staining of polypeptides is based on the procedure described by Hancock and Tsang (1983).

Brief exposure to alkali described in the support protocol significantly enhances staining of proteins by either India ink or colloidal gold. Sutherland and Skerritt (1986) suggest that the alkali treatment enhances retention of proteins on the nitrocellulose surface during extensive washing of the membrane; hence more protein is available for staining.

Critical Parameters

It is mandatory that all glassware and plasticware used with the gels and blot membranes be thoroughly cleaned in order to avoid staining artifacts. All blot membranes should be handled by forceps only. The stains cannot be used for detecting polypeptides blotted onto nylon membranes, since these membranes are positively charged. Furthermore, due to its very high sensitivity, the gold stain is susceptible to impurities present in buffers and on the surface of staining boxes.

Anticipated Results

Detection limits and compatibilities of transfer membranes and gel types are summarized in Table 10.7.1.

Time Considerations

The India ink staining procedure requires ~6 hr, while gold staining can be performed in ~3 hr. An additional 30 min is required at the beginning of either protocol to perform the alkali pretreatment. SYPRO fluorescent staining is completed in <1 hr.

Immunoblotting and Immunodetection

UNIT 10.8

Immunoblotting (often referred to as western blotting) is used to identify specific antigens recognized by polyclonal or monoclonal antibodies. Protein samples are solubilized, usually with sodium dodecyl sulfate (SDS) and reducing agents such as dithiothreitol (DTT) or 2-mercaptoethanol (2-ME). Following solubilization, the material is separated by SDS-PAGE (UNITS 10.2-10.4). The antigens are then electrophoretically transferred in a tank (see Basic Protocol 1) or a semidry transfer apparatus (see Alternate Protocol 1) to a nitrocellulose, PVDF, or nylon membrane, a process that can be monitored by reversible staining (see Support Protocol 1) or by Ponceau S staining (see Support Protocol 2). Previously stained gels may also be blotted (see Alternate Protocol 2).

The transferred proteins are bound to the surface of the membrane, providing access for reaction with immunodetection reagents. All remaining binding sites are blocked by immersing the membrane in a solution containing either a protein or detergent blocking agent. After probing with the primary antibody, the membrane is washed and the antibody-antigen complexes are identified with horseradish peroxidase (HRPO) or alkaline phosphatase enzymes coupled to the secondary anti-IgG antibody (e.g., goat anti-rabbit IgG). The enzymes are attached directly (see Basic Protocol 2) or via an avidin-biotin bridge (see Alternate Protocol 3) to the secondary antibody. Chromogenic or luminescent substrates (see Basic Protocol 3 and Alternate Protocols 4 and 5) are then used to visualize the activity. Finally, membranes may be stripped and reprobed (see Support Protocol 3).

PROTEIN BLOTTING WITH TANK TRANSFER SYSTEMS

In this procedure, blotting is performed in a tank of buffer with the gel in a vertical orientation, completely submerged between two large electrode panels. In some systems up to four gels can be transferred at one time. For difficult-to-transfer proteins (>100 kDa or hydrophobic; e.g., myosin), tank blotting is preferable to semidry systems (see Basic Protocol 2) because prolonged transfers are possible without buffer depletion. However, transfers >1 hr at high power require cooling using a heat exchanger and a circulating water bath that can maintain a constant transfer temperature of 10° to 20°C.

Materials

Samples for analysis

Protein molecular weight standards (UNIT 10.2A): prestained (Sigma or Bio-Rad), biotinylated (Vector Labs or Sigma), fluorescent (e.g., BenchMark Fluorescent Protein Standards; Invitrogen), or compatible with other colorimetric and fluorescent detection method (e.g., MagicMark and MagicMark XP Western Protein standards; Invitrogen)

Transfer buffer (see recipe)

Powder-free gloves

Scotch-Brite pads (3M) or equivalent sponge

Whatman 3MM filter paper or equivalent

Transfer membrane: 0.45- μ m nitrocellulose (Millipore or Schleicher & Schuell), PVDF (Millipore Immobilon P), neutral nylon (Pall Biotodyne A), or positively charged nylon (Pall Biotodyne B; Bio-Rad Zetabind) membrane

Electroblotting apparatus (Bio-Rad, Invitrogen, Amersham, or Harvard Bioscience)

Indelible pen (e.g., Paper-Mate) or soft lead pencil

Additional reagents and equipment for one- and two-dimensional gel electrophoresis (UNITS 10.2-10.4) and staining proteins in gels (UNIT 10.6) and on membranes (see Support Protocol 1 and UNIT 10.7)

NOTE: Deionized, distilled water should be used throughout this protocol.

**BASIC
PROTOCOL 1**

**Analysis of
Proteins**

10.8.1

Supplement 66

Electrophorese the protein sample

1. Prepare antigenic samples and separate proteins using small or standard-sized one- or two-dimensional gels (UNITS 10.2-10.4). Include prestained or biotinylated protein molecular weight standards in one or more gel lanes.

The protein markers will transfer to the membrane and conveniently indicate membrane orientation and sizes of proteins after immunostaining.

MagicMark Western Protein standards allow direct visualization of protein size standards on membrane blots without the need for protein modification or special detection reagents. The standard proteins are derived from E. coli cells containing a construct with repetitive units of a fusion protein forming the size variation and an IgG binding site. The proteins can be visualized with the colorimetric, chemiluminescent, or fluorescent detection system of choice simply by processing the membrane for the specific protein. The IgG binding site will allow all the standard proteins to react with the specific primary and secondary antibodies. These protein standards do not have to be heated or reduced—they are in a ready-to-use format. Alternatively, BenchMark Fluorescent Protein Standards are visualized directly via UV transillumination on a UV transilluminator (available from UVP Inc.) when wet, or via overhead UV illumination (apparatus also available from UVP, Inc.) when dry.

A variety of gel sizes and percentages of acrylamide can be used (UNIT 10.2A). Most routinely used are either 14 cm × 14 cm × 0.75-mm gels or 8 cm × 10 cm × 0.75-mm minigels. Acrylamide concentrations vary from 5% to 20%, but are usually in the 10% to 15% range.

Assemble the immunoblot sandwich

2. When electrophoresis is complete, disassemble gel sandwich and remove stacking gel. Equilibrate gel 30 min at room temperature in transfer buffer.

IMPORTANT NOTE: Use gloves when manipulating filter papers, gels, and membranes. Oil from hands blocks the transfer.

Match the appropriate transfer buffer to the membrane (see Reagents and Solutions).

Gel equilibration is required to prevent a change in the size of the gel during transfer. Any shift in gel dimension will result in a blurred transfer pattern.

3. Assemble transfer sandwich in a tray large enough to hold the plastic transfer cassette. Fill with transfer buffer so that cassette is covered.

The transfer cassette should be assembled under buffer to minimize trapping of air bubbles. Use Figure 10.8.1 as a guide to assembly.

4. On bottom half of plastic transfer cassette, place Scotch-Brite pad or sponge, followed by a sheet of filter paper cut to same size as gel and prewet with transfer buffer.

5. Place gel on top of filter paper; the side of the gel touching the paper arbitrarily becomes the cathode side of the gel (i.e., ultimately toward the negative electrode when positioned in the tank). Remove any air bubbles between gel and filter paper by gently rolling a test tube or glass rod over surface of gel.

Any bubbles between the filter paper, gel, and membrane will block current flow and prevent protein transfer. This problem is indicated on the membrane by sharply defined white areas devoid of transferred protein.

Proteins are usually negatively charged in transfer buffer and move toward the positive anode. However, some proteins may be positively charged. An additional membrane placed on the cathode side of the gel will bind these proteins.

6. Prepare transfer membrane. Cut membrane to same size as gel plus 1 to 2 mm on each edge. Place into distilled water slowly, with one edge at a 45° angle; the water will wick up into the membrane, wetting the entire surface (if it is inserted too quickly into the water, air gets trapped and will appear as white blotches in the membrane; protein will not transfer onto these areas). Equilibrate 10 to 15 min in transfer buffer.

Figure 10.8.1 Immunoblotting with a tank blotting unit. The polyacrylamide gel containing the protein is laid on a sheet of filter paper. The uncovered side of the gel is overlaid with a sheet of membrane precut to the size of the gel plus 1 to 2 mm on each edge, then this membrane is overlaid with another sheet of filter paper. The filter paper containing the gel and membrane is sandwiched between Scotch-Brite pads. This sandwich is placed in a plastic support, and the entire assembly is placed in a tank containing transfer buffer. For transfer of negatively charged protein, the membrane is positioned on the anode side of the gel. For transfer of positively charged protein, the membrane is placed on the cathode side of the gel. Charged proteins are transferred electrophoretically from the gel onto the membrane. Transfer is achieved by applying a voltage of 100 V for 1 to 2 hr (with cooling) or 14 V overnight.

This wetting procedure works for nitrocellulose and nylon membranes only. PVDF membranes are hydrophobic and will not wet simply from being placed into distilled water or transfer buffer. For these membranes, first immerse 1 to 2 sec in 100% methanol, then equilibrate 10 to 15 min with transfer buffer. Do not let membrane dry out at any time. If this occurs, wet once again with methanol and transfer buffer as described above.

7. Moisten surface of gel with transfer buffer. Place prewetted membrane directly on top side of gel (i.e., anode side) and remove all air bubbles as in step 5.

Poor contact between the gel and membrane will cause a swirled pattern of transferred proteins on the membrane. Some proteins will transfer as soon as the gel is placed on the membrane; repositioning the gel or membrane can result in a smeared or double image on the developed blot.

The use of 0.2- μ m membranes may improve retention of smaller-molecular-weight proteins.

8. Wet another piece of Whatman 3MM filter paper, place on anode side of membrane, and remove all air bubbles. Place another Scotch-Brite pad or sponge on top of this filter paper.
9. Complete assembly by locking top half of the transfer cassette into place (Fig. 10.8.1).

It is important to orient the sandwich so that the membrane faces the anode (positively charged) side of the tank.

Transfer proteins from gel to membrane

10. Fill tank with transfer buffer and place transfer cassette containing sandwich into electroblotting apparatus in correct orientation. Connect leads of power supply to corresponding anode and cathode sides of electroblotting apparatus.

Transfer buffer should cover the electrode panels but should not touch the base of the banana plug.

11. Electrophoretically transfer proteins from gel to membrane for 30 min to 1 hr at 100 V with cooling or overnight at 14 V (constant voltage), in a cold room.

Transfer time is dependent on the thickness and the percent acrylamide of the gel, as well as the size of the protein being transferred. In general, proteins are transferred within 1 to 6 hr, but high-molecular-weight molecules may take longer. Overnight transfer at low voltage is reliable and convenient. Cooling (at 10° to 20°C) is required for transfers >1 hr at high power. Heat exchanger cooling cores using a circulating water bath are placed into the transfer unit for cooling.

12. Turn off the power supply and disassemble the apparatus. Remove membrane from blotting apparatus and note orientation by cutting a corner or marking with a soft lead pencil or Paper-Mate pen.

Many ballpoint inks come off, but Paper-Mate stays on the membrane.

Membranes can be dried and stored in resealable plastic bags at 4°C for 1 year or longer at this point. Prior to further processing, dried PVDF membranes must be placed into a small amount of 100% methanol to wet the membrane, then in distilled water to remove the methanol.

13. Stain gel for total protein with Coomassie blue (UNIT 10.6) to verify transfer efficiency. If desired, stain membrane reversibly to visualize transferred proteins (see Support Protocol 1), or irreversibly with Coomassie blue, India ink, naphthol blue, or colloidal gold (UNIT 10.7).

These staining procedures are incompatible with nylon membranes.

If membrane shows significant staining on the backside, either the gel was heavily overloaded or the membrane has poor protein-binding capacity (see Troubleshooting). In either case, protein-binding sites on the side facing the gel are saturated, allowing protein to migrate to the other side of the membrane. Nitrocellulose, in particular, will show diminished binding capacity with age or poor storage conditions (e.g., high temperature and humidity). In addition, some proteins simply do not bind well to a particular matrix. By using several membrane sheets in place of one, the protein can be detected as it passes through each consecutive sheet. This will give an indication of how efficiently the membrane binds to a particular protein.

14. Proceed with immunoprobng and visual detection of proteins (see Basic Protocols 2 and 3 and Alternate Protocols 3 and 4).

ALTERNATE PROTOCOL 1

PROTEIN BLOTTING WITH SEMIDRY SYSTEMS

Even and efficient transfer of most proteins is also possible with semidry blotting, a convenient alternative to tank transfer systems. Instead of being placed vertically into a tank filled with transfer buffer, the gel is held horizontally between buffer-saturated blotting paper that is in contact with the electrodes (Fig. 10.8.2), greatly reducing the amount of buffer required. The electrodes are close together, giving high field strengths and rapid transfer with a standard electrophoresis power supply. Prolonged transfers (>1 hr) are not recommended; tank blotting (see Basic Protocol 1) should be used for proteins that require long blotting times for efficient transfer.

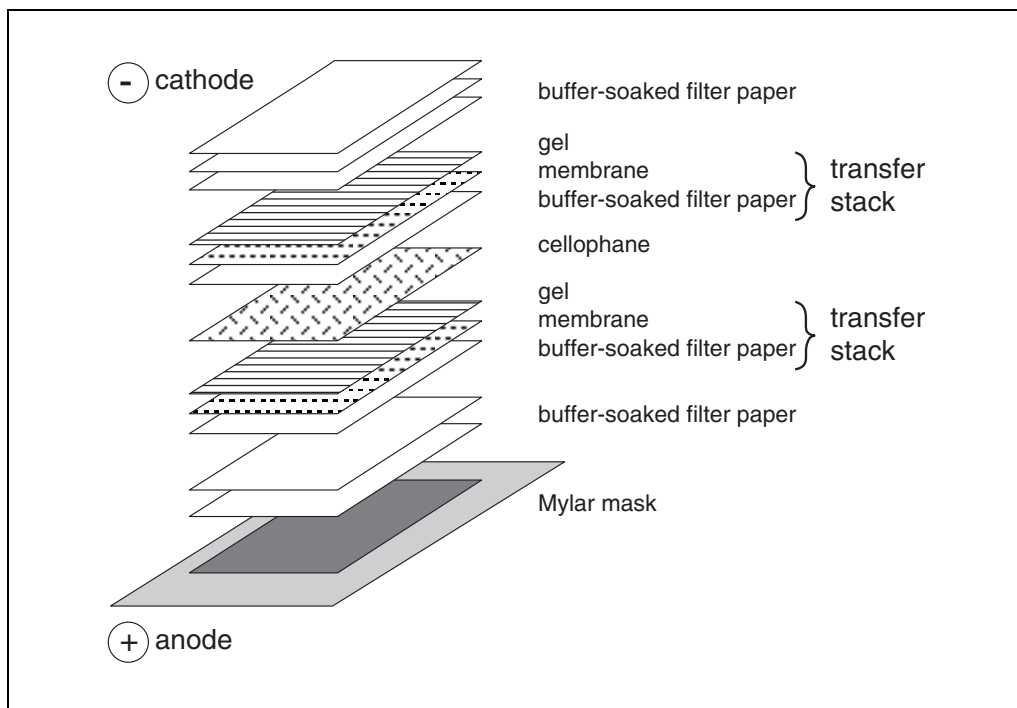

Figure 10.8.2 Immunoblotting with a semidry transfer unit. Generally, the lower electrode is the anode, and one gel is transferred at a time. A Mylar mask (optional in some units) is put in place on the anode. This is followed by three sheets of transfer buffer-soaked filter paper, the membrane, the gel, and finally, three more sheets of buffer-soaked filter paper. To transfer multiple gels, construct transfer stacks as illustrated, and separate each with a sheet of porous cellophane. For transfer of negatively charged protein, the membrane is positioned on the anode side of the gel. For transfer of positively charged protein, the membrane is placed on the cathode side of the gel. Transfer is achieved by applying a maximum current of 0.8 mA/cm^2 of gel area. For a typical minigel ($8 \times 10 \text{ cm}$) and standard-sized gel ($14 \times 14 \text{ cm}$), this means 60 and 200 mA, respectively.

Additional Materials (also see Basic Protocol 1)

- Six sheets of Whatman 3MM filter paper or equivalent, cut to size of gel and saturated with transfer buffer
- Semidry transfer unit (Hoefer, Bio-Rad, or Sartorius)

1. Prepare samples and separate proteins using small or standard-sized one- or two-dimensional gels (UNITS 10.2-10.4).

Because transfer efficiency depends on many factors (e.g., gel concentration and thickness, protein size, shape, and net charge) results may vary. Below is a guideline for 0.75-mm-thick SDS-PAGE gels transferred by semidry blotting.

Percent acrylamide (resolving gel)	Size range transferred (~100% efficiency)
5–7	29–150 kD
8–10	14–66 kD
13–15	<36 kD
18–20	<20 kD

2. Prepare transfer membrane (see Basic Protocol 1, step 6).
3. Disassemble gel sandwich. Remove and discard stacking gel.

Equilibration of the separating gel with transfer buffer is not normally required for semidry blotting, but it may improve transfer in some cases.

4. Place three sheets of filter paper saturated with transfer buffer on the anode (Fig. 10.8.2).

Most transfer units are designed so that negatively charged proteins move downward toward either a platinum or graphite positive electrode (anode).

CAPS transfer buffer, pH 10.5 (see recipe for transfer buffer) can be used in place of the Tris/glycine/methanol transfer buffer of Basic Protocol 1. CAPS buffer should be used if the protein is to be sequenced right on the membrane (Moos, 1992), as glycine will interfere with this procedure.

The filter paper should be cut to the exact size of the gel. This forces the current to flow only through the gel and not through overlapping filter paper. Some manufacturers (e.g., Hoefer) recommend placing a Mylar mask on the lower platinum anode. With an opening that is slightly less than the size of the gel, the mask forces the current to flow through the gel and not the surrounding electrode area during transfer.

5. Place equilibrated transfer membrane on top of filter paper stack. Remove all bubbles between membrane and filter paper by rolling a test tube over surface of membrane.

Any bubbles in the filter paper stack or between the filter paper, membrane, and gel will block current flow and prevent protein transfer. This problem is indicated on the membrane by sharply defined white areas devoid of transferred protein.

6. Place gel on top of membrane. Gently roll a test tube over surface of gel to insure intimate contact between gel and membrane and to remove any interfering bubbles.

Poor contact between the gel and membrane will cause a swirled pattern of transferred proteins on the membrane. Some proteins will transfer as soon as the gel is placed on the membrane; repositioning the gel or membrane can result in a smeared or double image on the developed blot.

7. Complete the transfer stack by putting the three remaining sheets of filter paper on top of gel. Roll out bubbles as described above.

Multiple gels can be transferred using semidry blotting. Simply put a sheet of porous cellophane (Hoefer) or dialysis membrane (Bio-Rad or Sartorius) equilibrated with transfer buffer between each transfer stack (Fig. 10.8.2). Transfer efficiency is dependent on the position of the transfer stack in the blotting unit and for critical applications transferring one gel at a time is recommended. The gel next to the anode tends to be more efficiently transferred when blotting more than one gel at a time.

Transfer proteins from gel to membrane

8. Place top electrode onto transfer stack.

Most units have safety-interlock features and can only be assembled one way. Consult manufacturer's instructions for details.

Once the transfer stack has been assembled with both electrodes, do not move the top electrode. This can shift the transfer stack and move the gel relative to the membrane. Some transfer will occur as soon as the gel contacts the membrane, and any shifting of the transfer stack after assembly will distort the transfer pattern.

9. Carefully connect high-voltage leads to the power supply (see UNIT 10.2 for safety precautions). Apply constant current to initiate protein transfer. Transfers of 1 hr are generally sufficient.

In general, do not exceed 0.8 mA/cm² of gel area. For a typical minigel (8 × 10 cm) and standard-sized gel (14 × 14 cm) this means ~60 and 200 mA, respectively.

Monitor the temperature of the transfer unit directly above the gel by touch. The unit should not exceed 45°C. If the outside of the unit is warm, too much current is being applied. Note that units with graphite electrodes are more prone to heating, because graphite has much more resistance to current flow than platinum or steel electrodes.

10. After transfer, turn off power supply and disassemble unit. Remove membrane from transfer stack, marking orientation as in step 12 of Basic Protocol 1. Proceed with staining and immunoprobng (see Basic Protocol 1, steps 13 and 14).

BLOTTING OF STAINED GELS

Gels stained with Coomassie blue R250 (*UNIT 10.6*) can be effectively immunoblotted by the following procedure, based on Perides et al. (1986) and Dionisi et al. (1995). Briefly, the stained gel is soaked in a series of solutions designed to increase the solubility of the proteins after staining and fixation. After transfer, the membranes are treated with 45% or 100% methanol to decrease the Coomassie blue bound to the membrane prior to processing for chromogenic development. For chemiluminescent development, removal of the Coomassie blue is generally not needed.

Materials

Destained gel containing proteins of interest (*UNIT 10.6*)
25 mM Tris base/192 mM glycine/1% SDS
25 mM Tris base/192 mM glycine/0.1% SDS

1. Soak destained gel containing proteins of interest in distilled water for 15 min.
2. Equilibrate gel with 25 mM Tris base/192 mM glycine/1% SDS for 1 hr with gentle agitation.
3. Transfer gel to 25 mM Tris base/192 mM glycine/0.1% SDS and equilibrate 30 min with gentle agitation.

To increase transfer efficiency of larger proteins, the gel should be transferred to the above solution with 6 M urea for an additional 30 min.

4. Proceed with transfer (see Basic Protocol 1, steps 2 to 12).

For the most efficient transfer and binding to the membrane, the transfer buffer should contain SDS.

5. After transfer, soak membranes for 10 to 30 min in 45% methanol (nitrocellulose) or 100% methanol (nylon or PVDF) to remove the bound Coomassie blue.

This step is not needed if using chemiluminescent reactions or radiolabeled protein A for immunodevelopment. Destaining of the nitrocellulose membrane is enhanced by adding a small ball of laboratory tissue to the methanol to absorb the Coomassie blue.

6. Proceed with immunoprobng and visual detection of proteins (see Basic Protocols 2 and 3 and Alternate Protocols 3 and 4).

REVERSIBLE STAINING OF TRANSFERRED PROTEINS

To verify transfer efficiency, nitrocellulose and PVDF membranes can be reversibly stained. This method will not work on nylon membranes.

Additional Materials (also see Basic Protocol 1)

Ponceau S solution (see recipe)

Additional reagents and equipment for photographing membranes (*UNIT 10.6*)

1. Following protein transfer to nitrocellulose or PVDF (see Basic Protocol 1 or Alternate Protocol 1), place membrane in Ponceau S solution 5 min at room temperature.

ALTERNATE PROTOCOL 2

SUPPORT PROTOCOL 1

Analysis of Proteins

10.8.7

**SUPPORT
PROTOCOL 2**

2. Destain 2 min in water. Photograph membrane if required (*UNIT 10.6*) and mark the molecular-weight-standard band locations with indelible ink.
3. Completely destain membrane by soaking an additional 10 min in water.

QUANTITATION OF PROTEIN WITH PONCEAU S

In addition to qualitatively visualizing proteins on membranes after blotting, Ponceau S provides a convenient method for quantitating the amount of protein in a given lane. By eluting the dye off the strip and reading in a spectrophotometer (OD_{525}), an internal control value of protein on a lane is obtained. This value is used to correct for any differences in protein loading from lane to lane. Comparison of the Ponceau S value to the chemiluminescent or chromogenic immunodetection value determined by densitometry provides a straightforward correction for lane-to-lane variation. This method works best for complex mixtures where the immunodetected protein represents a small proportion of the total protein (Klein et al., 1995).

Additional Materials (also see Basic Protocol 1)

Spectrophotometer and 2-ml cuvette

1. Following protein transfer to nitrocellulose, PVDF, or nylon (see Basic Protocol 1 or Alternate Protocol 1), stain membrane, photograph, and destain (see Support Protocol 1).

Membranes should be destained until the background becomes white.

2. Mark lanes with a soft pencil and cut lanes into strips.
3. Place each strip into 7 ml of distilled water for 7 min and remove the resulting solution. If any particulates are visible, centrifuge 30 min at 2000 rpm to remove them.
4. Read OD_{525} in a 2-ml cuvette.

Any variation in gel-to-gel sample loading and blotting efficiency will be reflected in a change in OD of the sample lanes when compared to the control.

The change in OD can be calibrated to a known amount of protein loaded on the control lane. This will be a relative value, however, since the transfer out of the gel and binding to the membrane is rarely 100%.

**BASIC
PROTOCOL 2**

**IMMUNOPROBING WITH DIRECTLY CONJUGATED SECONDARY
ANTIBODY**

Immobilized proteins are probed with specific antibodies to identify and quantitate any antigens present. The membrane is immersed in blocking buffer to fill all protein-binding sites with a nonreactive protein or detergent. Next, it is placed in a solution containing the antibody directed against the antigen (primary antibody). The blot is washed and exposed to an enzyme-antibody conjugate directed against the primary antibody (secondary antibody; e.g., goat anti-rabbit IgG). Antigens are identified by chromogenic or luminescent visualization (see Basic Protocol 3 and Alternate Protocol 4) of the antigen/primary antibody/secondary antibody/enzyme complex bound to the membrane. Tween 20 is a common alternative to protein-blocking agents when using nitrocellulose or PVDF filters.

Materials

Membrane with transferred proteins (see Basic Protocol 1 or Alternate Protocol 1)
Blocking buffer appropriate for membrane and detection protocol (see recipe)
Primary antibody specific for protein of interest
TTBS (nitrocellulose or PVDF) or TBS (nylon; see APPENDIX 2 for recipes)
Secondary antibody conjugate: horseradish peroxidase (HRPO)–or alkaline phosphatase (AP)–anti-Ig conjugate (Cappel, Vector Labs, Kirkegaard & Perry, or Sigma; dilute as indicated by manufacturer and store frozen in 25- μ l aliquots until use)

Heat-sealable plastic bag

Powder-free gloves

Plastic box

1. Place membrane in heat-sealable plastic bag with 5 ml blocking buffer and seal bag. Incubate 30 min to 1 hr at room temperature with agitation on an orbital shaker or rocking platform.

Usually 5 ml buffer is sufficient for two to three membranes (14 \times 14-cm size). If membrane is to be stripped and reprobed (see Support Protocol 3), blocking buffer must contain casein (for AP systems) or nonfat dry milk.

Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Dilute primary antibody in blocking buffer.

Primary antibody dilution is determined empirically but is typically 1/100 to 1/1000 for a polyclonal antibody (Fig. 10.8.3; UNIT 11.14), 1/10 to 1/100 for hybridoma supernatants (UNIT 11.8), and \geq 1/1000 for murine ascites fluid containing monoclonal antibodies (UNIT 11.10). Ten- to one-hundred-fold higher dilutions can be used with alkaline phosphatase–or luminescence–based detection systems. Both primary and secondary antibody solutions can be used at least twice, but long-term storage (i.e., >2 days at 4°C) is not recommended.

3. Open bag and pour out blocking buffer. Replace with diluted primary antibody and incubate 30 min to 1 hr at room temperature with constant agitation.

Usually 5 ml diluted primary antibody solution is sufficient for two to three membranes (14 \times 14-cm size). Incubation time may vary depending on conjugate used.

When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from plastic bag with gloved hand. Place in plastic box and wash four times by agitating with 200 ml TTBS (nitrocellulose or PVDF) or TBS (nylon), 10 to 15 min each time.

5. Dilute secondary antibody HRPO- or AP-anti-Ig conjugate in blocking buffer.

Commercially available enzyme–conjugated secondary antibody is usually diluted 1/200 to 1/2000 prior to use (Harlow and Lane, 1988).

6. Place membrane in new heat-sealable plastic bag, add diluted HRPO- or AP-anti-Ig conjugate, and incubate 30 min to 1 hr at room temperature with constant agitation.

When using plastic incubation trays, see step 3 annotation for proper antibody solution volumes.

7. Remove membrane from bag and wash as in step 4. Develop according to appropriate visualization protocol (see Basic Protocol 3 or Alternate Protocol 4).

Figure 10.8.3 Serial dilution of primary antibody directed against the 97-kDa catalytic subunit of the plant plasma membrane ATPase. Blot was developed with HRPO-coupled avidin-biotin reagents according to the second alternate protocol and visualized with 4-chloro-1-naphthol (4CN). Note how background improves with dilution.

ALTERNATE PROTOCOL 3

IMMUNOPROBING WITH AVIDIN-BIOTIN COUPLING TO SECONDARY ANTIBODY

The following procedure is based on the Vectastain ABC kit from Vector Labs (*APPENDIX 4*). It uses an avidin-biotin complex to attach horseradish peroxidase (HRPO) or alkaline phosphatase (AP) to the biotinylated secondary antibody. Avidin-biotin systems are capable of extremely high sensitivity due to the multiple reporter enzymes bound to each secondary antibody. In addition, the detergent Tween 20 is a popular alternative to protein-blocking agents when using nitrocellulose or PVDF filters.

Additional Materials (also see Basic Protocol 2)

Blocking buffer appropriate for membrane and detection protocol (see recipe)
TTBS (nitrocellulose or PVDF) *or* TBS (neutral or positively charged nylon; see *APPENDIX 2* for recipes)

Vectastain ABC (HRPO) or ABC-AP (AP) kit (Vector Labs) containing the following: reagent A (avidin), reagent B (biotinylated HRPO or AP), and biotinylated secondary antibody (request membrane immunodetection protocols when ordering)

1. Equilibrate membrane in appropriate blocking buffer in heat-sealed plastic bag with constant agitation using an orbital shaker or rocking platform. For nitrocellulose and PVDF, incubate 30 to 60 min at room temperature. For nylon, incubate ≥ 2 hr at 37°C.

TTBS is well suited for avidin-biotin systems. For nylon, protein-binding agents are recommended. Because nonfat dry milk contains residual biotin, which will interfere with the immunoassay, it must be used in the blocking step only. If membrane is to be stripped and reprobed (see Support Protocol 3), blocking buffer must contain casein (for AP systems) or nonfat dry milk.

Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Prepare primary antibody solution in TTBS (nitrocellulose or PVDF) or TBS (nylon).

Dilutions of sera containing primary antibody generally range from 1/100 to 1/100,000. This depends in large part on the sensitivity of the detection system. With high-sensitivity avidin-biotin systems, dilutions from 1/1000 to 1/100,000 are common. Higher dilutions can be used with AP- or luminescence-based detection systems. To determine the appropriate concentration of the primary antibody, a dilution series is easily performed with membrane strips. Separate antigens on a preparative gel (i.e., a single large sample well) and immunoblot the entire gel. Cut 2- to 4-mm strips by hand or with a membrane cutter (Schleicher and Schuell; Inotech) and incubate individual strips in a set of serial dilutions of primary antibody. The correct dilution should give low background and high specificity (Fig. 10.8.3).

3. Open bag, remove blocking buffer, and add enough primary antibody solution to cover membrane. Incubate 30 min at room temperature with gentle rocking.

Usually 5 ml diluted primary antibody solution is sufficient for two to three membranes (14 × 14-cm size). Incubation time may vary depending on conjugate used.

When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from bag and place in plastic box. Wash membrane three times over a 15-min span in TTBS (nitrocellulose or PVDF) or TBS (nylon). Add enough TTBS or TBS to fully cover the membrane (e.g., 5 to 10 ml/strip or 25 to 50 ml/whole membrane).

5. Prepare biotinylated secondary antibody solution by diluting two drops biotinylated antibody with 50 to 100 ml TTBS (nitrocellulose or PVDF) or TBS (nylon).

This dilution gives both high sensitivity and enough volume to easily cover a large 14 × 14-cm membrane.

6. Transfer membrane to fresh plastic bag containing secondary antibody solution. Incubate 30 min at room temperature with slow rocking, then wash as in step 4.

When using plastic incubation trays, see step 3 annotations for proper antibody solution volumes.

7. While membrane is being incubated with secondary antibody, prepare avidin-biotin-HRPO or -AP complex. Mix two drops Vectastain reagent A and two drops reagent B into 10 ml TTBS (nitrocellulose or PVDF) or TBS (nylon). Incubate 30 min at room temperature, then further dilute to 50 ml with TTBS or TBS.

Diluting the A and B reagents to 50 ml expands the amount of membrane that can be probed without greatly affecting sensitivity. Sodium azide is a peroxidase inhibitor and should not be used as a preservative. Casein, nonfat dry milk, serum, and some grades of BSA may interfere with the formation of the avidin-biotin complex and should not be used in the presence of avidin or biotin reagents (Gillespie and Hudspeth, 1991; Vector Labs).

8. Transfer membrane to avidin-biotin-enzyme solution. Incubate 30 min at room temperature with slow rocking, then wash over a 30-min span as in step 4.

9. Develop membrane according to the appropriate visualization protocol (see Basic Protocol 3 or Alternate Protocol 4).

VISUALIZATION WITH CHROMOGENIC SUBSTRATES

Bound antigens are typically visualized with chromogenic substrates. The substrates 4CN, DAB/NiCl₂, and TMB are commonly used with horseradish peroxidase (HRPO)–based immunodetection procedures, while BCIP/NBT is recommended for alkaline phosphatase (AP)–based procedures (see Table 10.8.1). After incubation with primary and secondary antibodies, the membrane is placed in the appropriate substrate solution. Protein bands usually appear within a few minutes.

Materials

Membrane with transferred proteins and probed with antibody-enzyme complex
(see Basic Protocol 2 or Alternate Protocol 3)

TBS (*APPENDIX 2*)

Chromogenic visualization solution (Table 10.8.1)

Additional reagents and equipment for gel photography (*UNIT 10.6*)

1. If final membrane wash (see Basic Protocol 2, step 7, or see Alternate Protocol 3, step 8) was performed in TTBS, wash membrane 15 min at room temperature in 50 ml TBS.
The Tween 20 in TTBS interferes with 4CN development (Bjerrum et al., 1988).
2. Place membrane into chromogenic visualization solution. Bands should appear in 10 to 30 min.
3. Terminate reaction by washing membrane in distilled water. Air dry and photograph (*UNIT 10.6*) for a permanent record.

VISUALIZATION WITH LUMINESCENT SUBSTRATES

Antigens can also be visualized with luminescent substrates. Detection with light offers both speed and enhanced sensitivity over chromogenic and radioisotopic procedures. After the final wash, the blot is immersed in a substrate solution containing luminol for horseradish peroxidase (HRPO) systems or dioxetane phosphate for alkaline phosphatase (AP) systems, sealed in thin plastic wrap, and placed firmly against film. Exposures range from a few seconds to several hours, although typically strong signals appear within a few seconds or minutes.

Additional Materials (*also see Basic Protocol 3*)

Luminescent substrate buffer: 50 mM Tris·Cl, pH 7.5 (for HRPO; *APPENDIX 2*) *OR*
dioxetane phosphate substrate buffer (for alkaline phosphatase; see recipe)

Nitro-Block solution (AP reactions only): 5% (v/v) Nitro-Block (Applied
Biosystems) in dioxetane phosphate substrate buffer, prepared just before use

Luminescent visualization solution (Table 10.8.1)

Clear plastic wrap

Additional reagents and equipment for autoradiography (*APPENDIX 3A*)

NOTE: See Troubleshooting section for suggestions concerning optimization of this protocol, particularly when employing AP-based systems.

1. Equilibrate membrane in two 15-min washes with 50 ml substrate buffer.
For blots of whole gels, use 50 ml substrate buffer; for strips, use 5 to 10 ml/strip.
2. *For AP reactions using nitrocellulose or PVDF membranes:* Incubate 5 min in Nitro-Block solution, followed by 5 min in substrate buffer (volumes as in step 1).

Nitro-Block enhances light output from the dioxetane substrate in reactions using AMPPD, CSPD, or Lumigen-PPD concentrate. It is required for nitrocellulose and recommended for PVDF membranes. It is not needed for Lumi-Phos 530, AP reactions on nylon

Table 10.8.1 Chromogenic and Luminescent Visualization Systems^a

System	Reagent ^b	Reaction/Detection	Comments ^c
Chromogenic			
HRPO-based	4CN	Oxidized products form purple precipitate	Not very sensitive (Tween 20 inhibits reaction); fades rapidly upon exposure to light
	DAB/NiCl ₂ ^d	Forms dark brown precipitate	More sensitive than 4CN but potentially carcinogenic; resulting membrane easily scanned
	TMB ^e	Forms dark purple stain	More stable, less toxic than DAB/NiCl ₂ ; may be somewhat more sensitive ^e ; can be used with all membrane types; kits available from Kirkegaard & Perry, TSI, Moss, and Vector Labs
AP-based	BCIP/NBT	BCIP hydrolysis produces indigo precipitate after oxidation with NBT; reduced NBT precipitates; dark blue-gray stain results	More sensitive and reliable than other AP-precipitating substrates; note that phosphate inhibits AP activity
Luminescent			
HRPO-based	Luminol/H ₂ O ₂ / <i>p</i> -iodophenol	Oxidized luminol substrate gives off blue light; <i>p</i> -iodophenol increases light output	Very convenient, sensitive system; reaction detected within a few seconds to 1 hr
AP-based	Substituted 1,2-dioxetane-phosphates (e.g., AMPPD, CSPD, Lumigen-PPD, Lumi-Phos 530 ^f)	Dephosphorylated substrate gives off light	Protocol described gives reasonable sensitivity on all membrane types; consult instructions of reagent manufacturer for maximum sensitivity and minimum background (see Troubleshooting)

^aAbbreviations: AMPPD or Lumigen-PPD, disodium 3-(4-methoxy-1,2-dioxetane-3,2'-tricyclo[3.3.1.1^{3,7}]decan-4-yl)phenyl phosphate; AP, alkaline phosphatase; BCIP, 5-bromo-4-chloro-3-indolyl phosphate; 4CN, 4-chloro-1-naphthol; CSPD, AMPPD with substituted chlorine moiety on adamantane ring; DAB, 3,3'-diaminobenzidine; HRPO, horseradish peroxidase; NBT, nitroblue tetrazolium; TMB, 3,3',5,5'-tetramethylbenzidine.

^bRecipes and suppliers are listed in Reagents and Solutions except for TMP, for which use of a kit is recommended.

^cSee Commentary for further details.

^dDAB/NiCl₂ can be used without the nickel enhancement, but it is much less sensitive.

^eMcKimm-Breschkin (1990) reported that if nitrocellulose filters are first treated with 1% dextran sulfate for 10 min in 10 mM citrate-EDTA (pH 5.0), TMB precipitates onto the membrane with a sensitivity much greater than 4CN or DAB, and equal to or better than that of BCIP/NBT.

^fLumi-Phos 530 contains dioxetane phosphate, MgCl₂, CTAB, and fluorescent enhancer in a pH 9.6 buffer.

membranes, or HRPO-based reactions on any type of membrane. Lumi-Phos 530 is not recommended for nitrocellulose membranes.

3. Transfer membrane to visualization solution. Soak 30 sec (HRPO reactions) to 5 min (AP reactions; volumes as in step 1).

Alternatively, lay out a square of plastic wrap and pipet 1 to 2 ml visualization solution into the middle. Place membrane on the plastic so that the visualization solution spreads out evenly from edge to edge. Fold wrap back onto membrane, seal, and proceed to step 5.

4. Remove membrane, drain, and place face down on a sheet of clear plastic wrap. Fold wrap back onto membrane to form a liquid-tight enclosure.

To insure an optimal image, only one layer of plastic should be between the membrane and film. Sealable bags are an effective alternative. Moisture must not come in contact with the X-ray film.

5. In a darkroom, place membrane face down onto film.

Do this quickly and do not reposition; a double image will be formed if the membrane is moved while in contact with the film. A blurred image is usually caused by poor contact between membrane and film; use a film cassette that insures a tight fit.

6. Expose film for a few seconds to several hours.

Typically, immunoblots produce very strong signals within a few seconds or minutes. However, weak signals may require several hours to an overnight exposure. If no image is detected, expose film 30 min to 1 hr, and if needed, overnight (see Troubleshooting).

7. If desired, wash membrane in two 15-min washes of 50 ml TBS and process for chromogenic development (see Basic Protocol 3).

Chemiluminescent and chromogenic immunoblotting can be easily combined on a single blot to provide a permanent visual marker of a known protein. First probe membrane with the chemiluminescent reactions to record on film. If stripping and reprobing are needed, then process by wetting and NaOH treatment (see Support Protocol 3). For the last reaction, use chromogenic development to produce a permanent visual record of the blot. Alternatively, once the film record of the chemiluminescent blot is recorded, the blot can be rinsed briefly with distilled water and placed in the appropriate chromogenic solution for chromogenic development of the blot. This results in a permanent reference stain on the blot for comparison to the more easily scanned and quantitated film record.

ALTERNATE PROTOCOL 5

VISUALIZATION WITH CHEMILUMINESCENT, FLUORESCENT, OR CHROMOGENIC SUBSTRATES

Specialized kits are available that provide significant signal amplification and can accommodate the chemiluminescent, fluorescent, or chromogenic development of a substrate. The Vectastain ABC-AmP Western Blotting Immunodetection Kit (Vector Laboratories) features a reagent that is a preformed complex between streptavidin and biotinylated alkaline phosphatase. The substrate is either the chromogenic substrate for alkaline phosphatase, BCIP/NBT (5-bromo-4-chloro-3-indolyl phosphate/nitroblue tetrazolium), which produces a blue-purple precipitate, or a chemiluminescent/fluorescent substrate that provides very high sensitivity and has sustained light-emission characteristics. Blots can be exposed to film several times over an 8-hr period for the optimization of band intensities or resolution. In addition to providing an amplified signal, the reagent produces a very low background on both nitrocellulose and PVDF membranes. These kits have been developed to produce maximum sensitivity with minimal background staining.

Materials

- Membrane with transferred proteins (see Basic Protocol 1 or Alternate Protocol 1)
- Primary antibody (from mouse or rabbit) specific for protein of interest
- Vectastain ABC-AmP Chromogenic *or* Chemiluminescent Western Blotting Immunodetection Kit (Vector Laboratories) containing:
 - 10× casein solution (250 ml)
 - Vector biotinylated secondary antibody (0.25 ml): anti-mouse IgG (for mouse primary antibodies) *or* anti-rabbit IgG (for rabbit primary antibodies)
 - Vectastain ABC-AmP reagent A (0.5 ml)
 - Vectastain ABC-AmP reagent B (0.5 ml)
 - Substrate: chemiluminescent/fluorescent substrate (100 ml) *and* BCIP/NBT chromogenic substrate kit (stock reagents for 200 ml)
- PBS: 10 mM sodium phosphate buffer, pH 7.5 (APPENDIX 2) containing 150 mM NaCl
- 0.1 M Tris·Cl, pH 9.5 (APPENDIX 2)

Staining trays

X-ray film (e.g., Kodak BioMax)

UV transilluminator or UV imaging trans- and epi-CCD acquisition system (UVP, Inc.)

NOTE: The components supplied in each Vectastain ABC-AmP Western Blotting Immunodetection Kit provide sufficient reagents to develop approximately twenty 100-cm² blots. The volumes of the reagents in the protocol below are optimized for the development of a 100-cm² membrane. Volumes may be proportionally adjusted for blots of a different size. All kit reagents may be used immediately following dilution. For optimal results, it is recommended that all diluted reagents from the kit be used the same day that they are prepared. Vectastain ABC-AmP Kit stock reagents should be stored under refrigeration and kept in the box in which they are supplied.

Block membrane

1. For a 100-cm² (10 × 10-cm) blot, prepare 120 ml of 1× casein solution by adding 12 ml of 10× casein solution (provided with Vectastain kit) to 108 ml distilled water. Block membrane by incubating in 10 ml of 1× casein solution 5 min at room temperature with gentle agitation. Save remaining 1× casein to be used in subsequent steps.

In rare cases, some nonspecific bands may develop. This can usually be eliminated by increasing the concentration of NaCl to 0.3 to 0.5 M in the Vectastain ABC-AmP reagent (see step 5, below). Some enzymes isolated from tissues may have covalently attached biotin as a cofactor. If high salt does not prevent the Vectastain ABC-AmP reagent from binding to particular bands, use an avidin/biotin blocking step (Vector Laboratories, cat. No. SP-2001) between steps 1 and 2 in this protocol.

2. Incubate the membrane for 30 min (or for a time established to be optimal for the concentration of primary antibody used) with gentle agitation at room temperature in an appropriate concentration of primary antibody diluted in PBS.
3. Wash the membrane in 10 ml of 1× casein solution three times, each time for 4 min at room temperature with gentle agitation.
4. Prepare the biotinylated secondary antibody solution by adding 10 μl of biotinylated anti-mouse IgG or anti-rabbit IgG (provided with the Vectastain kit; choice depends on species from which primary antibody was obtained) to 10 ml of 1× casein solution (final concentration 1.5 μg/ml). Incubate membrane 30 min at room temperature with gentle agitation in 10 ml of the biotinylated secondary antibody solution. At end of incubation, wash in 1× casein solution as in step 3.
5. Prepare the Vectastain ABC-AmP reagent by adding 20 μl of reagent A and 20 μl of reagent B (both provided with the kit) to 10 ml of 1× casein solution. Incubate the membrane in 10 ml of the Vectastain ABC-AmP reagent for 10 min at room temperature with gentle agitation. At end of incubation, wash with 1× casein solution as in step 3.

Incubate membrane in substrate solution

For chemiluminescent and/or fluorescent signal detection, follow steps 6a to 10a. For chromogenic signal detection, follow steps 6b to 8b. It is recommended that the membrane be transferred to a different staining tray for the substrate development step.

To detect chemiluminescent (and/or fluorescent) signal

- 6a. Equilibrate membrane for 5 min in 0.1 M Tris·Cl, pH 9.5. Remove excess buffer by holding membrane vertically and touching edge of membrane to absorbent paper.
- 7a. Place membrane target-side-up on plastic wrap on a level surface. Pipet 5 ml of substrate on to membrane surface. Incubate 5 min under subdued light or in dark.
- 8a. Rinse membrane in 0.1 M Tris·Cl, pH 9.5, for a few seconds, then remove excess buffer by holding membrane vertically and touching edge of membrane to absorbent paper.
- 9a. Place membrane between two pieces of acetate, plastic wrap, or clear sheet protector. Expose membrane to X-ray film (e.g., KODAK BioMax film) for the appropriate time.

If necessary, background may be further reduced by washing membrane in 0.1 M Tris·Cl, pH 9.5, for 5 min at room temperature and removing excess buffer before exposure to film.
- 10a. *Optional:* To obtain fluorescent signal, following step 9a, wash membrane in 0.1 M Tris·Cl, pH 9.5, for 5 min at room temperature. Remove excess buffer. Place membrane target-side-up on a UV transilluminator (254 to 365 nm) or UV imaging trans- and epi-CCD acquisition system, and observe results.

To detect chromogenic signal

- 6b. Equilibrate membrane from step 6 for 5 min in 0.1 M Tris·Cl, pH 9.5.
- 7b. Prepare chromogenic reagent by adding 4 drops of reagent from each of the three dropper bottles in the BCIP/NBT substrate kit (provided with Vectastain kit) into 10 ml of 0.1 M Tris·Cl, pH 9.5. Incubate membrane in the substrate solution at room temperature with gentle agitation until the appropriate density of colored bands develops.

Incubation times may vary from 30 min up to several hours.
- 8b. Briefly rinse the membrane in PBS and air dry. Store blot protected from light.

**SUPPORT
PROTOCOL 3**

STRIPPING AND REUSING MEMBRANES

This stripping procedure works with blotted membranes from one- and two-dimensional gels as well as with proteins blotted from previously stained gels (Suck and Krupinska, 1996). Reprobing PVDF membranes that have been developed with chemiluminescent reagents is simple and straightforward. All residual antibodies are removed from the membrane by first rewetting it in water and then briefly treating it with NaOH. Although repeated reprobing can lead to loss of signal, up to five reprobings generally are feasible. The blot should have been previously blocked with 5% nonfat dry milk prior to treatment.

Materials

0.2 M NaOH

1. Wash blot 5 min in distilled water.

In order to effectively reprobe the membranes, casein (for AP systems) or nonfat dry milk must be used as the blocking agent. Chromogenic development leaves a permanent stain on the membrane that is difficult to remove, and should not be used when reprobing. The stain can interfere with subsequent analysis if reactive bands from sequential immunostainings are close together.

2. Transfer to 0.2 M NaOH and wash 5 min.
3. Wash blot 5 min in distilled water.
4. Proceed with immunoprobng procedure (see Basic Protocol 2 and Alternate Protocol 3).

Casein or nonfat dry milk is recommended as blocking agent when reprobing membranes.

REAGENTS AND SOLUTIONS

Deionized, distilled water should be used to prepare all solutions. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4. For selection of appropriate chromogenic or luminescent solutions, and for definition of abbreviations, see Table 10.8.1.

Alkaline phosphate substrate buffer

100 mM Tris·Cl, pH 9.5 (APPENDIX 2)
100 mM NaCl
5 mM MgCl₂

BCIP/NBT visualization solution

Mix 33 μl NBT stock (100 mg NBT in 2 ml at 70% DMF, stored <1 year at 4°C) and 5 ml alkaline phosphate substrate buffer (see recipe). Add 17 μl BCIP stock (100 mg BCIP in 2 ml of 100% DMF, <1 year at 4°C) and mix. Stable 1 hr at room temperature.

Recipe is from Harlow and Lane (1988). Alternatively, BCIP/NBT substrates may be purchased from Sigma, Kirkegaard & Perry, Moss, and Vector Labs.

Blocking buffer

Colorimetric detection

For nitrocellulose and PVDF: 0.1% (v/v) Tween 20 in TBS (TTBS; APPENDIX 2).

For neutral and positively charged nylon: Tris-buffered saline (TBS; also see APPENDIX 2) containing 10% (w/v) nonfat dry milk. Prepare just before use.

TTBS can be stored ≤1 week at 4°C.

Luminescence detection

For nitrocellulose, PVDF, and neutral nylon (e.g., Pall Biodyne A): 0.2% casein (e.g., Hammarsten grade or I-Block; Applied Biosystems) in TTBS (APPENDIX 2). Prepare just before use.

For positively charged nylon: 6% (w/v) casein/1% (v/v) polyvinyl pyrrolidone (PVP) in TTBS (APPENDIX 2). Prepare just before use.

With constant mixing, add casein and PVP to warm (65°C) TTBS. Stir for 5 min. Cool before use.

4CN visualization solution

Mix 20 ml ice-cold methanol with 60 mg 4CN. Separately mix 60 μl of 30% H₂O₂ with 100 ml TBS (APPENDIX 2) at room temperature. Rapidly mix the two solutions and use immediately.

DAB/NiCl₂ visualization solution

5 ml 100 mM Tris·Cl, pH 7.5 (APPENDIX 2)
100 μl DAB stock (40 mg/ml in H₂O, stored in 100-μl aliquots at -20°C)
25 μl NiCl₂ stock (80 mg/ml in H₂O, stored in 100-μl aliquots at -20°C)
15 μl 3% H₂O₂
Mix just before use

CAUTION: *Handle DAB carefully, wearing gloves and mask; it is a carcinogen.*

Suppliers of peroxidase substrates are Sigma, Kirkegaard & Perry, Moss, and Vector Labs.

Dioxetane phosphate substrate buffer

1 mM MgCl₂
0.1 M diethanolamine
0.02% sodium azide (optional)
Adjust to pH 10 with HCl and use fresh

Traditionally, the AMPPD substrate buffer has been a solution containing 1 mM MgCl₂ and 50 mM sodium carbonate/bicarbonate, pH 9.6 (Gillespie and Hudspeth, 1991). The use of diethanolamine results in better light output (Applied Biosystems Western Light instructions).

Alternatively, 100 mM Tris·Cl (pH 9.5)/100 mM NaCl/5 mM MgCl₂ can be used (Sandhu et al., 1991).

Dioxetane phosphate visualization solution

Prepare 0.1 mg/ml AMPPD or CSPD (Applied Biosystems) or Lumigen-PPD (Lumigen; see Table 10.8.1) substrate in dioxetane phosphate substrate buffer (see recipe). Prepare just before use. Lumi-Phos 530 (Boehringer Mannheim or Lumigen) is a ready-to-use solution and can be applied directly to the membrane.

This concentration (240 μM) of AMPPD substrate is the minimum recommended by Applied Biosystems Western Light. Ten-fold lower concentrations can be used but require longer exposures.

Luminol visualization solution

0.5 ml 10× luminol stock [40 mg luminol (Sigma) in 10 ml DMSO]
0.5 ml 10× *p*-iodophenol stock [optional; 10 mg (Aldrich) in 10 ml DMSO]
2.5 ml 100 mM Tris·Cl, pH 7.5 (APPENDIX 2)
25 μl 3% H₂O₂
H₂O to 5 ml
Prepare just before use

*Recipe is from Schneppenheim et al. (1991). Premixed luminol substrate mix (Mast Immunosystems; Amersham ECL; Du Pont NEN Renaissance; Kirkegaard & Perry LumiGLO) may also be used. *p*-Iodophenol is an optional enhancing agent that increases light output. Luminol and *p*-iodophenol stocks can be stored for ≤6 months at −20°C.*

Ponceau S solution

Dissolve 0.5 g Ponceau S in 1 ml glacial acetic acid. Bring to 100 ml with water. Prepare just before use.

Transfer buffer

Add 18.2 g Tris base and 86.5 g glycine to 4 liters of water. Add 1200 ml methanol and bring to 6 liters with water. The pH of the solution is ~8.3 to 8.4. For use with PVDF filters, decrease methanol concentration to 15%; for nylon filters, omit methanol altogether.

CAPS transfer buffer can also be used. Add 2.21 g cyclohexylaminopropane sulfonic acid (CAPS; free acid), 0.5 g DTT, 150 ml methanol, and water to 1 liter. Adjust to pH 10.5 with NaOH and chill to 4°C. For proteins >60 kDa, reduce methanol content to 1% (Moos, 1992).

COMMENTARY

Background Information

Immunoprecipitation has been widely used to visualize the antigens recognized by various antibodies, both polyclonal and monoclonal. However, there are several problems inherent with this method, including the requirement for radiolabeling of antigen, co-

precipitation of tightly associated macromolecules, occasional difficulty in obtaining precipitating antibodies, and insolubility of various antigens (Talbot et al., 1984).

To circumvent these problems, electroblotting (Towbin et al., 1979)—subsequently popularized as western blotting or im-

munoblotting (Burnette, 1981)—was conceived. Immunoblotting is a rapid and sensitive assay for the detection and characterization of proteins that works by exploiting the specificity inherent in antigen-antibody recognition. It involves the solubilization and electrophoretic separation of proteins, glycoproteins, or lipopolysaccharides by SDS-PAGE (UNIT 10.2) or urea-PAGE, followed by quantitative transfer and irreversible binding to nitrocellulose, PVDF, or nylon. This technique has been useful in identifying specific antigens recognized by polyclonal or monoclonal antibodies and is highly sensitive (1 ng of antigen can be detected).

Protein blotting has important clinical applications—it is the confirmatory test for human immunodeficiency virus Type 1 (HIV-1). SDS-PAGE-separated virus proteins are blotted onto nitrocellulose and processed with patient sera. After washing and incubating (using a Tween 20/nonfat dry milk diluting and washing solution) with an anti-human IgG coupled to HRPO or alkaline phosphatase, the antigens are identified by chromogenic development. Typically, the prepared blots and all reagents needed for the test are purchased commercially (Bio-Rad Novapath; Organon Teknika Cappel HIV-1 Western Blot Kit; Du Pont/Biotech HIV Western Blot Kit).

Electroblotting of previously stained gels is a convenient way to visualize and document the gel prior to immunoblotting. Transfer efficiencies at all molecular weights will be lower with fixed and stained gels. This is particularly true of proteins >50 kDa (Perides et al., 1986). The additional incubation in 6 M urea will significantly increase transfer efficiency of all proteins and is required for proteins >50 kDa.

Ponceau S staining provides an easy method for calibrating and quantitating the amount of material on a nitrocellulose or PVDF blot. An alternative to this method is to use an internal protein control with a separate antibody probe, but these tend to be expensive and time-consuming to use. Other applications for Ponceau S calibration include monitoring transfer efficiency under varied conditions for optimization of tank and semidry blotting.

Immunoblotted proteins can be detected by chromogenic or luminescent assays (see Table 10.8.1 for a description of the reagents available for each system, their reactions, and a comparison of their advantages and disadvantages).

Luminescent detection methods offer several advantages over traditional chromogenic procedures. In general, luminescent substrates increase the sensitivity of both HRPO and phosphatase systems without the need for radioisotopes. Substrates for the latter have only recently been applied to protein blotting (see Gillespie and Hudspeth, 1991; Sandhu et al., 1991; Bronstein et al., 1992). Luminescent detection can be completed in as little as a few seconds; exposures rarely go more than 1 hr. Depending on the system, the luminescence can last for 3 days, permitting multiple exposures of the same blot. Furthermore, the signal is detected by film, and varying the exposure can result in more or less sensitivity. Luminescent blots can be easily erased and reprobed because the reaction products are soluble and do not deposit on the membrane (see below). Compared to chromogenic development, the luminescent image recorded on film is easier to photograph and to quantitate by densitometry.

Alkaline phosphatase-based luminescent protocols that achieve maximum sensitivity with minimum background can be complex, and the manufacturer's instructions should be consulted (see Reagents and Solutions). The procedure described in Alternate Protocol 4 gives reasonable sensitivity on nitrocellulose, PVDF, and nylon membranes with a minimum of steps.

Alternate Protocol 5 describes a new product that can be used in chromogenic, chemiluminescent, or fluorescent detection schemes. Vectastain's DuoLuX Chemiluminescent/Fluorescent Substrate is a novel acridan-based substrate that can be used not only in immunoblots, as described here, but also in nucleic acid detection methods (e.g., Southern, northern, western or dot blotting, colony lifts, and ELISA). The substrate is available for either alkaline phosphatase (AP) or horseradish peroxidase (HRP) development. The choice of enzyme will depend on the application. Generally, signal development is faster when using HRP. Thus, HRP may be preferred when digital imaging systems are used or when abundance of target reduces the need for a high signal-to-noise ratio. However, for applications where optimal sensitivity is required, AP is recommended, as it will provide a higher signal-to-noise ratio than HRP.

The DuoLuX Chemiluminescent/Fluorescent Substrate has very high sensitivity and prolonged light-emission characteristics. This enables image documentation with either

film or digital imaging systems. Unlike some chemiluminescent substrates, blots can be re-exposed to film as often as necessary over many hours. Because many digital imaging systems require a longer exposure time than film, the faster signal development of HRP relative to AP may be preferred when using these systems. PVDF, nitrocellulose, or nylon membranes can be used, although the chemiluminescent signal develops faster on nylon and PVDF.

In addition to its chemiluminescent properties, the reaction product is also fluorescent. Fluorescence can be recorded with a digital imaging system or a conventional camera months after chemiluminescence has faded. For fluorescence detection, nitrocellulose is recommended. Acquisition of fluorescent signal requires a much shorter exposure time than chemiluminescence, often a fraction of a second.

Critical Parameters

First and foremost, the antibody being used should recognize denatured antigen. Nonspecific binding of antibodies can occur, so control antigens and antibodies should always be run in parallel. Time of transfer and primary antibody and conjugate dilutions should always be optimized.

A variety of agents are currently used to block binding sites on the membrane after blotting (Harlow and Lane, 1988). These include Tween 20, PVP, nonfat dry milk, casein, BSA, and serum. A 0.1% (v/v) solution of Tween 20 in TBS (TTBS), a convenient alternative to protein-based blocking agents, is recommended for chromogenic development of nitrocellulose and PVDF membranes (Blake et al., 1984). In contrast to dry milk/TBS blocking solution (BLOTTO), TTBS is stable and has a long shelf life at 4°C. Furthermore, TTBS generally produces a clean background and permits subsequent staining with India ink. However, even with the application of such standard blocking procedures as 5% to 10% milk protein or 0.05% to 0.1% Tween 20, background can still be a significant problem. If this happens, using a blocking protein (e.g., goat, horse, or rabbit normal serum) from the same species as the primary antibody can reduce the background, presumably by reducing cross-reactivity between the primary antibodies and the blocking agent. If a secondary antibody detection is used, the blocking protein (i.e., normal serum) should be from the same species as the second-

dary antibody. Combinations of blocking agents can also be effective. Thus, 0.1% human serum albumin (HSA) and 0.05% Tween 20 in TBS is recommended when probing Immobilon-P membranes with human serum (Craig et al., 1993). However, this can also lead to overall loss of antigen signal, requiring a ten-fold increase in the primary antibody (serum) concentration to achieve an adequate background free antigen signal.

When using chemiluminescent detection for immunoblotting, high background frequently occurs, particularly for strong signals (Pampori et al., 1995). Several methods are available for reducing the background from chemiluminescent reactions. These include changing the type and concentration of blocking agents (see above), optimizing antibody concentrations, letting the reaction proceed for several minutes before exposing to film, or simply limiting the exposure time of the film on the blot. These procedures are not always successful, however, and can lead to inconsistent results. An alternative approach is to reduce the concentration of reagents ten-fold. This effectively removes the background and has a number of advantages which include lower cost, increased signal-to-noise ratio, and reduced detection of cross-reacting species.

Two types of nylon membrane are used for western transfer—neutral (e.g., Pall Biodyne A) and positively charged (e.g., Pall Biodyne B). Although the positively charged membranes have very good protein-binding characteristics, they tend to give a higher background. These membranes remain positively charged from pH 3 to pH 10. Neutral nylon membranes are also charged, having a mix of amino and carboxyl groups that give an isoelectric point of 6.5. Because of their high binding capacity, positively charged membranes are popular for protein applications using luminescence.

Nylon membranes require more stringent blocking steps. Here 10% nonfat dry milk in TBS is recommended for chromogenic development. During luminescence development, however, background is a more significant problem. Compared to dry milk, purified casein has minimal endogenous alkaline phosphatase activity (AP activity leads to high background) and is therefore recommended as a blocking agent for nitrocellulose, PVDF, and nylon membranes. Positively charged nylon requires much more stringent blocking with 6% (w/v) casein and 1% (v/v) poly-

vinylpyrrolidone (PVP). Because nonfat dry milk and casein may contain biotin that will interfere with avidin-biotin reactions, subsequent steps are done without protein-blocking agents when using these systems. If background is a problem, highly purified casein (0.2% to 6%) added to the antibody incubation buffers may help.

If reprobing is desired, blots can be air dried and stored at 4°C for 3 months after chemiluminescence detection. After drying, store in a sealed freezer bag until use. Repeated probing will lead to a gradual loss of signal and increased background. However, this will depend in part on the properties of the sample.

If the primary procedure is problematic due to loss of sensitivity or an increase in the background, then two possible alternative procedures for stripping membranes are recommended. The first uses 2-mercaptoethanol and SDS (Kaufmann et al., 1987; Tesfaigzi et al., 1994). Briefly, the membranes are incubated in 2% SDS/100 mM Tris·Cl, pH 7.4/100 mM 2-mercaptoethanol for 30 min at 70°C, effectively removing primary and secondary antibodies. As with the primary procedure recommended above, the repeated probing should be done with caution due to the potential loss of detection signal, and 5% nonfat dry milk is required as a blocking agent. The milk blocking agent facilitates antibody removal from the blot (Kaufmann et al., 1987). The second uses guanidine·HCl. For nylon and PVDF membranes (do *not* use with nitrocellulose), incubate the immunoblot in 7 M guanidine·HCl for 10 min at room temperature. (The short wash time is critical, as guanidine·HCl is a very strong denaturant, so do not leave the filter in this solution >15 min.) Pour off excess guanidine·HCl and then rinse the membrane several times in 1× TTBS (UNIT 10.8). Reblock the membrane and proceed with your standard immunoblotting procedure. Membranes stripped using this procedure can generally be reused three or four times.

In Alternate Protocol 5, extensive washing will reduce signal strength; do not extend the wash time unless high background is experienced. If background is excessive, repeat steps 6a through 9a with a wash time of 5 to 10 min in step 8a (optimal wash time is dependent on the degree of background previously detected and, therefore, may require optimization). The long emission lifetime of the substrate allows the user to re-expose the same blot until optimal signal to noise is achieved. Blotting

can be done onto either nylon or nitrocellulose. Nylon requires shorter exposure times and is, therefore, preferred for chemiluminescent applications. However, because of nylon's intrinsic fluorescence, nitrocellulose is preferred for fluorescence detection.

Troubleshooting

There are several problems associated with immunoblotting. The antigen is solubilized and electrophoresed in the presence of denaturing agents (e.g., SDS or urea), and some antibodies may not recognize the denatured form of the antigen transferred to the membrane. The results observed may be entirely dependent on the denaturation and transfer system used. For example, zwitterionic detergents have been shown to restore the antigenicity of outer membrane proteins in immunoblotting (Mandrell and Zollinger, 1984). Gel electrophoresis under nondenaturing conditions can also be performed (UNIT 10.2).

Other potential problems include high background, nonspecific or weak cross-reactivity of antibodies, poor protein transfer or membrane binding efficiency, and insufficient sensitivity. For an extensive survey and discussion of immunoblotting problems and artifacts, see Bjerrum et al. (1988).

If no transfer of protein has occurred, check the power supply and electroblot apparatus to make sure that the proper electrical connections were made and that power was delivered during transfer. In addition, check that the correct orientation of filter and gel relative to the anode and cathode electrodes was used.

If the transfer efficiency using the tank system appears to be low, increase the transfer time or power. Cooling (using the unit's built-in cooling cores) is generally required for transfers >1 hr. At no time should the buffer temperature go above 45°C. Prolonged transfers (>1 hr) are not possible in semidry transfer units due to rapid buffer depletion.

Alternatively, the transfer buffer can be modified to increase efficiency. Adding SDS at a concentration of 0.1% to the transfer buffer improves the transfer of all proteins out of the gel, particularly those above 60 to 90 kD in size. Lowering the concentration of methanol will also improve the recovery of proteins from the gel. These procedures are tradeoffs. Methanol improves the binding of proteins to PVDF and nitrocellulose, but at the same time hinders transfer. With SDS present, transfer efficiency is improved, but

the SDS can interfere with protein binding to the membrane. Nylon and PVDF membranes are particularly sensitive to SDS interference. If needed, 0.01% to 0.02% SDS may be used in PVDF membrane transfer buffers (Milipore, 1990). SDS and methanol should not be used in the transfer buffer for nylon (Peluso and Rosenberg, 1987).

Gel cross-linking and thickness also have a profound effect on the transfer efficiency. In general, 0.5- to 0.75-mm-thick gels will transfer much more efficiently than thicker gels (e.g., 1.5 mm thick). Gels with a higher acrylamide percentage will also transfer less efficiently. Proteins can be particularly difficult to transfer from gradient gels, and a combination of longer transfer times, thin gels, and the addition of SDS to the transfer buffer may be needed.

If the protein bands are diffuse, check the transfer cassette. The gel must be held firmly against the membrane during transfer. If the transfer sandwich is loose in the cassette, add another thin sponge or more blotter paper to both sides.

Occasionally, a grid pattern will be apparent on the membrane after tank transfer. This is caused by having either the gel or the membrane too close to the sides of the cassette. Correct this by adding more layers of filter paper to diffuse the current flowing through the gel and membrane. Use a thinner sponge and more filter paper if necessary.

If air bubbles are trapped between the filter and the gel, they will appear as clear white areas on the filter after blotting and staining. Take extra care to make sure that all bubbles are removed.

Insufficient blocking or nonspecific binding of the primary or secondary antibody will cause a high background stain. A control using preimmune serum or only the secondary antibody will determine if these problems are due to the primary antibody. Try switching to another blocking agent; protein blocking agents may weakly cross-react. Lowering the concentration of primary antibody should decrease background and improve specificity (Fig. 10.8.3).

Due to the nature of light and the method of detection, certain precautions are warranted when using luminescent visualization (e.g., Harper and Murphy, 1991). Very strong signals can overshadow nearby weaker signals on the membrane. Because light will pipe through the membrane and the surrounding plastic wrap, overexposure will produce a

broad diffuse image on the film. The signal can also saturate the film, exposing the film to a point whereby increased exposure will not cause a linear increase in the density of the image on the film.

With the alkaline phosphatase substrate AMPPD, nitrocellulose, PVDF, and nylon membranes require 2, 4, and 8 to 12 hr, respectively, to reach maximum light emission. In addition, PVDF is reported to give a stronger signal than nitrocellulose (Applied Biosystems Western Light instructions). Positively charged nylon requires special blocking procedures to minimize background (Gillespie and Hudspeth, 1991). These procedures include using a blocking and primary antibody solution containing 6% casein, 1% polyvinylpyrrolidone-40 (PVP-40), 3 mM NaN₃, 10 mM EDTA, and PBS, pH 6.8. Prior to use, the casein must be heated to 65°C to reduce alkaline phosphatase activity in the casein itself. In addition, maximum sensitivity has been observed when free biotin or biotinylated proteins are removed by pretreating the casein with avidin-agarose (Sigma).

Anticipated Results

Immunoblotting should result in the detection of one or more bands. Although antibodies directed against a single protein should produce a single band, degradation of the sample (e.g., via endogenous proteolytic activity) may cause visualization of multiple bands of slightly different size. Multimers will also form spontaneously, causing higher-molecular-weight bands on the blot. If simultaneously testing multiple antibodies directed against a complex protein mixture (e.g., using patient sera against SDS-PAGE-separated viral proteins in AIDS western blot test), multiple bands will be visualized.

For immunoblot or protein dot blot chemiluminescent applications, the sensitivity using HRP is ~1 pg of target protein. For chemiluminescent western blots, DuoLuX Chemiluminescent/Fluorescent Substrate (see Alternate Protocol 5) can be used on either nitrocellulose or PVDF membranes.

Time Considerations

The entire immunoblotting procedure can be completed in 1 to 2 days, depending on transfer time and type of gel. Gel electrophoresis requires 4 to 6 hr on a regular gel and 1 hr on a minigel. Transfer time can be 1 hr (high-power transfer) to overnight. Blocking, conjugate incubation, and washing each take

30 min to 1 hr. Finally, substrate incubation requires 10 to 30 min (chromogen) and a few seconds to several hours (luminescence).

For the DuoLuX Chemiluminescent/Fluorescent Substrate (see Alternate Protocol 5), optimal exposure times can vary from 5 sec to 15 min. It is recommended that initial exposures be taken between 1 and 5 min. Band intensities or resolution can then be optimized by lengthening or shortening exposure times based on the initial results.

PURIFICATION OF PROTEINS BY CONVENTIONAL CHROMATOGRAPHY

Purification of proteins by conventional chromatography is usually achieved by using a combination of chromatographic methods, including gel filtration, ion-exchange, immunoaffinity, and affinity chromatography. With the possible exceptions of immunoaffinity and affinity chromatography, it is rarely possible to purify a protein from a mixture of proteins in a single chromatographic step. Hence, it will usually be necessary to utilize separate, sequential steps involving different modes of chromatography (e.g., gel filtration *and* ion-exchange). In turn, each type of chromatography requires an informed choice of matrix—considering bead shape, size, and porosity, in addition to functional group type, charge, distribution, and density—as well as elution conditions (i.e., pH, ionic strength, and gradient shape). The goal is to isolate a specific protein, and simultaneously reduce contaminants to levels that will not interfere with structural or functional analyses, in the minimum number of chromatographic steps.

Gel filtration (*UNIT 10.9*) separates proteins on the basis of differences in molecular size. Gel filtration matrices differ in porosity and chemical composition (i.e., hydrophobicity and charge). The former property leads to selective exclusion of proteins that are not small enough to penetrate the matrix pores, which is the physical basis of gel filtration. The latter property leads to mixed-mode separation effects—glycoproteins might interact with sugar-based polymeric matrices or negatively charged proteins might be repulsed by a matrix with a partial negative charge. The choice of gel filtration matrix is based on the molecular size of the protein being purified, as well as the expected range of molecular sizes of the contaminating proteins, since the effect of composition is unpredictable. Gel filtration is ideally suited to separating a desired protein from proteins that are either much larger or much smaller. It is a poor choice for separating proteins with similar molecular sizes, and therefore is never the method of choice for beginning a multistep purification from a complex mixture of proteins. However, gel filtration is excellent for removing low-molecular-size contaminants, such as salts and unbound detergents, from a purified protein in preparation for structural or functional analysis.

In general terms, the most versatile chromatographic separation method is ion-exchange chromatography (*UNIT 10.9*), since it relies on subtle differences between both the number of charges and the distribution of charge groups, under a given set of pH and solvent conditions, on the surface of the desired protein and all other contaminating proteins. Most proteins carry a net negative charge at pH values above their isoelectric point, and a net positive charge when below it. As a general rule, one may assume that most proteins are negatively charged at neutral pH and that anion-exchange chromatography is the method of choice for their purification; in the occasional cases when a desired protein is positively charged, cation-exchange chromatography should be used. It is important to realize that all chromatographic separations are mixed-mode separations, because chromatographic matrices have different porosities, leading to molecular sieving whereby large proteins may be excluded from the matrix while small molecules are included. Hence, small molecules will elute more slowly than larger molecules. In addition, matrices differ in chemical composition and in their hydrophilicity or hydrophobicity. The selection process for a matrix is largely empirical, but a thorough understanding of ion-exchange chromatography, as described in the Strategic Planning section of *UNIT 10.10*, will help an investigator make a judicious initial choice of chromatographic matrix and elution conditions.

Immunoaffinity chromatography (*UNIT 10.11A*) is a highly selective chromatographic method for purifying proteins to homogeneity, or markedly simplifying a protein-con-

taining mixture, prior to gel filtration or ion-exchange chromatography. The selectivity of immune recognition makes it possible, under favorable conditions, to purify a protein in a single step. However, this form of chromatography relies on the existence of a monoclonal or polyclonal antibody specific for the native structure of the protein being purified. It is also important to keep in mind the likelihood of nonspecific protein binding of contaminating proteins to the immunoaffinity matrix, to its coupled antibody, and to the protein-antibody complex. An empirical choice of elution buffer—with regard to pH, ionic strength, and detergent concentration—must be made for each purification to minimize these effects.

Metal-chelate affinity chromatography (*UNIT 10.11B*) is another highly selective method, which relies on the binding affinity of short sequences of amino acids (such as polyhistidine) to nickel chelates tethered to a chromatographic matrix. Such polyamino acid sequences, or tags, are incorporated into expressed proteins by genetic engineering of the protein genes as a means of simplifying purification. As in other forms of chromatography, mixed-mode separation will occur simultaneously and may complicate the separation.

Chromatographic purification of membrane proteins may require the addition of low concentrations of nonionic detergents (*APPENDIX 11*) to solubilize the protein and to decrease its hydrophobic interaction with chromatographic matrices. The choice of detergent depends on its critical micelle concentration, UV properties, and cost.

The simplest way of monitoring the effectiveness of a purification is to assess the electrophoretic patterns before and after a given purification by gel electrophoresis (*UNIT 10.2*), and the presence of the desired protein by either a biological or immunological assay. It is important to think carefully about the design of the assay or mode of detection, since an unnecessarily complicated assay or analysis greatly augments the tedium of chromatographic separations.

John Smith

Gel-Filtration Chromatography

Gel filtration (GF) separates proteins solely on the basis of differences in molecular size. Separation is achieved using a porous matrix to which the molecules, for steric reasons, have different degrees of access (smaller molecules have greater access and larger molecules less). The matrix is packed into a chromatographic column, the sample mixture applied, and the separation accomplished by passing an aqueous buffer (the mobile phase) through the column. Protein molecules that are confined in the volume outside the matrix beads will be swept through the column by the mobile phase and the sample is thus eluted in decreasing order of size. The protein zones eluted are detected by an in-line UV monitor and fractions are collected for subsequent specific analysis or further preparation steps.

GF is often used to condition samples prior to further purification by adsorptive techniques. It is also frequently used in the final polishing stage to remove a few remaining contaminants with surface properties similar to the target protein (e.g., for polishing monomers from oligomers).

Three basic protocols are provided in this unit, corresponding to the major applications of gel filtration. GF is used for desalting or group separation (see Basic Protocol 1), in which the target protein and contaminating solutes differ substantially in molecular size. It is also used for protein fractionation (see Basic Protocol 2), where proteins with only a small size difference must be separated. A third application is in characterizing the molecular dimensions of proteins (see Basic Protocol 3). A Support Protocol is also provided for calibrating GF columns to be used in estimating molecular size.

NOTE: Among the items referred to in this unit, Sephadex, Sephacryl, Superdex, Superose, and HiLoad are trademarks of Amersham Pharmacia Biotech; Bio-Gel and Bio-Sil are trade marks of Bio-Rad; and Toyopearl and TSK SW are trademarks of Toyo Soda.

STRATEGIC PLANNING

Selecting Matrix and Column for Desalting

The exclusion limit—i.e., the smallest-sized protein molecule that will be excluded from the pores of the matrix—is the most important factor in selecting a matrix for desalting. If the protein is able to permeate the matrix, flow-dependent zone broadening will occur, reducing the resolution. On the other hand, gels of very small pore size generally contain more matrix, and thus have smaller separating volumes. A gel of sufficiently small exclusion limit, but not smaller, should therefore be selected. Another factor to take into consideration is the particle size of the matrix. This should not be too small because the pressure drop over the column is inversely proportional to the square of the particle size; this factor is especially important for gravity flow columns.

The selection of column dimensions (i.e., the bed volume of the column) is influenced by the amount of sample that is to be processed. Columns for desalting are typically short and wide to accommodate large sample volumes and keep the processing time short. Because the zone broadening of the column will have a limited effect on the peak width in desalting as compared to other applications of gel filtration—e.g., protein fractionation—short columns run at high flow rates are used for large-scale desalting. The typical length of columns for laboratory use is ~10 cm.

Columns for desalting vary greatly in size and sophistication, ranging from Pasteur pipets plugged with glass wool to prepacked high-performance GF columns. The scale of

operation for which they are used also varies widely, with applications ranging from micropreparative cleanup of a 50- μ l reduction/alkylation mixture using a 0.9-ml column to industrial de-ethanolization of 12 liters of human serum albumin using a 75-liter column. Incidentally, columns for both these procedures may be packed with Sephadex G-25—of course, of different particle size.

Some gel-filtration media suitable for laboratory-scale desalting are listed in Table 10.9.1, and some empty columns that can be used with these media are listed in Table 10.9.2. A partial compilation of disposable prepacked columns for desalting is found in Table 10.9.3. This table also contains information about spin columns for use with a centrifuge. Spin columns require special techniques, and they are presently not widely used for desalting proteins; therefore no protocols for their use have been included in this unit. More information about spin columns can be obtained from the suppliers.

Selecting Matrix and Column for Protein Fractionation

Suitability of a gel for protein fractionation may be judged from “typical runs” made with synthetic protein mixtures, the results of which are published by suppliers. The solute of interest should ideally be eluted in the first part of the chromatogram, but not too close to the void volume. A matrix with a distribution coefficient (see Basic Protocol 3) of ~0.2 to 0.4 has been reported to yield maximum resolution (Hagel, 1989). This corresponds to an elution volume of ~1.5 to 2 times the void volume. A long bed and a matrix with a large pore volume will increase the peak-to-peak distance between the proteins and thus increase the resolution of the system (also see Critical Parameters). Another way to increase resolution is to employ a GF matrix of small particle size, which will reduce the zone width of the protein bands. The flow rate will also affect resolution. As in the case of desalting, the maximum sample volume that can be processed depends upon the bed volume and the pore volume of the packed bed. Thus, there are many parameters to consider when optimizing protein fractionation by GF. In the worst case, a suitable matrix may have to be found by trial and error.

Commercial prepacked columns for protein fractionation often sacrifice column length and pore volume in favor of small particle size. This results in columns that are optimized for fast separation at the expense of some reduction in the maximum sample volume that can be loaded. Therefore, traditional columns packed in the laboratory are often still a

good alternative for purification of large volumes of sample. If time is critical in the separation (e.g., in proteinase removal), fast column operation is of course advantageous. Matrices of large particle size will permit protein fractionation at low operating pressure. Some matrices suitable for protein fractionation are listed in Table 10.9.4, and some empty columns suitable for use with these media are listed in Table 10.9.5. Table 10.9.6 lists some prepacked columns for protein fractionation. Columns and media are selected on the basis of the difficulty of the separation (i.e., how small the size difference is between the proteins to be separated) and whether scaleup will be required (i.e., the availability of

a variety of columns with different diameters that can be packed with bulk media facilitates linear scaleup).

A matrix of small particle size will permit preparation of columns of high efficiency (i.e., low zone broadening) at the expense of high pressure drops and greater cost. Also, smaller particles generally have smaller pore volumes. The net effect of the relationships between these parameters is that the prepacked columns listed in Table 10.9.6 have resolving power of the same order of magnitude, although protein fractionation may be carried out faster on the columns that have particles of small size.

A final factor to consider in choosing a matrix for protein fractionation is the likelihood of matrix-solute interactions (e.g., as in the case of lectins on gels containing glucose-type structures).

Selecting Matrix and Column for Molecular Size Determination

A matrix with high resolving power is recommended for determination of molecular size as well as for protein fractionation (see Table 10.9.4, Table 10.9.5, and Table 10.9.6 for

^aData as reported by the manufacturers.

^bIn general, matrices of natural polymers (e.g., Superdex, Sephacryl, or Superose) have larger pore volumes than silica-based materials (e.g., TSK SW, Protein-Pak, Bio-Sil SEC, or GF-250/450).

^cSelectivity of materials decreases with increased width of the fractionation range and also with decreased pore volume.

^dAbbreviations: BR, Bio-Rad; DU, DuPont; PB, Amersham Pharmacia Biotech; TH, Toso Haas; WA, Waters. Addresses and phone numbers of suppliers are provided in APPENDIX 4.

matrices and columns suitable for both these applications). However, certain other criteria that are important for selecting a matrix and column for size determination differ from those for protein fractionation. First, when analyzing samples containing several proteins of varying molecular size (e.g., protein digests) a matrix of sufficient separation range is needed. As selectivity inherently limits separation range, optimal separation range may not be achieved using a matrix of high selectivity. Second, because peak broadening is not critical as long as the peaks are resolved, short (e.g., 30-cm) columns operated at high flow rates may be used. However, in situations where the effluent is continuously monitored with a mass-sensitive detector (see Basic Protocol 3), complete resolution between peaks is essential. In this case the criteria used for protein fractionation may be applied.

**BASIC
PROTOCOL 1**

DESALTING (GROUP SEPARATION)

Desalting, or group separation, is used to separate the target protein from low-molecular-mass contaminants. The purpose might be to remove salt prior to lyophilization, or to remove low-molecular-mass reagents—e.g., a reductive cleavage mixture from a preparation step or polybuffer from chromatofocusing. Desalting is also used to change from one buffer to another—e.g., to decrease ionic strength prior to ion-exchange chromatography (UNIT 10.10). The pore size of the matrix is selected to exclude the protein of interest while allowing maximum permeation of the contaminants. This is beneficial in three ways. First, because the protein does not penetrate into the pores, little dilution of the sample will take place except where the sample volume is very small. Second, because the protein is unable to diffuse into the pores, no flow-sensitive zone broadening that results from slow mass-transfer will take place. Hence, the flow rate may be kept high during the desalting. Third, because the protein and the low-molecular-mass solutes are maximally separated, very large sample volumes may be applied before contamination of the protein band becomes evident. Thus, very large sample volumes may be applied and desalted in a short time without dilution of the sample.

The procedure described here uses a closed column system and a pump; annotations explain variations needed in some of the steps if an open-bed column and gravity flow are used. The GF matrix is swelled, the column is packed, and the void volume and total volume of the column are determined in preliminary runs using high- and low-molecular-weight solutes. This information is used to determine the maximum sample volume to apply for the unknown protein to be desalted. Guidelines for estimating approximate sample volumes to use for desalting are also given. Alternative steps are provided for using this procedure either to determine elution volume or to desalt a protein for preparative purposes (or further analysis). Elution volumes must be determined to ascertain the exact void volume and total volume of a column in preparation for desalting. It is also necessary to measure the elution volume for certain protein analyses—e.g., for determining molecular size (also see Basic Protocol 3).

Materials

- GF matrix (Table 10.9.1) or prepacked GF column (Table 10.9.3) with appropriate exclusion limit for protein of interest (also see Strategic Planning and Critical Parameters)
- GF desalting buffer (see recipe)
- Colored marker: 0.2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B₁₂
- Void marker (see recipe)
- Total liquid volume marker (see recipe)
- Protein sample to be desalted
- 90°C water bath (optional)

Figure 10.9.1 Equipment used for gel filtration. (A) Simple setup for desalting using an open-bed column made with a Pasteur pipet. (B) Column and attachments. (C) Complete automated chromatography system. Courtesy of Amersham Pharmacia Biotech.

- Buchner or sintered-glass funnel
- GF chromatography column (see Critical Parameters and Table 10.9.2) with column extension (optional), adaptors, and buffer reservoir (Fig. 10.9.1)
- Carpenter's level
- Peristaltic pump (Fig. 10.9.1)
- 0.22- μm filter: any 0.22- μm filter for buffer; protein-compatible for sample
- Detector (optional; Fig. 10.9.1)
- Chart recorder (optional; Fig. 10.9.1)
- Sample applicator: sample application loop (e.g., Superloop, Amersham Pharmacia Biotech) or syringe
- Fraction collector (optional; Fig. 10.9.1)

NOTE: Small-scale desalting of multiple samples may be carried out using spin columns and a centrifuge. At present, spin columns are primarily used for preparing microliter-sized samples of oligonucleotides; however, they are equally useful for small-volume protein samples. As the procedure is different from that described here, manufacturer's instructions should be consulted (see Table 10.9.3 for suppliers).

Prepare gel

If GF matrix is supplied dry:

- 1a. Calculate the amount of dry matrix needed from the swelling factor given by the manufacturer and the approximate bed volume of the column to be packed. Add the calculated amount of dry gel to a volume of GF desalting buffer equal to twice the calculated final gel volume (i.e., twice the approximate bed volume of the column).
- 2a. Carefully stir suspension with a glass rod. Let gel swell overnight at room temperature or for 3 hr in a 90°C water bath, stirring as needed to keep gel in suspension.

Do not use a magnetic stirrer, as this may break fragile gel particles.

- 3a. Allow gel bed to settle, then remove fines and broken beads by decanting the hazy solution. Repeat decantation (4 or 5 times if necessary) until bed settles as a sharp zone, then dilute so that final slurry is 50% (v/v) settled gel and 50% (v/v) GF buffer.

Careful removal of fine particles will prevent the nets that support the column end pieces from becoming blocked, and will also permit a higher flow rate through the column.

If GF matrix is supplied preswollen:

- 1b. Wash gel with an excess of GF buffer on a Buchner or sintered-glass funnel to remove storage buffer.

With some products, the gel slurry is obtained by simply shaking the gel bottle, and this can be used to pack the column without further preparation. If this type of gel is used, skip steps 1b to 3b and proceed directly to step 4.

Gel particles may adhere to the glass wall of the funnel; therefore, to avoid contamination from other types of gels (e.g., ion-exchange media), it is important to ensure that glassware used is clean.

- 2b. If gel contains fines, remove by decantation as in step 3a.
- 3b. Dilute so that final slurry is 50% (v/v) settled gel and 50% (v/v) GF buffer.

Pack column

4. Examine column to ensure that it is clean and that the support nets are undamaged. If necessary, supply column with new support nets.
5. Mount column on a stable laboratory stand, using a carpenter's level to ensure that it is vertical. Equip column with an extension that together with the column will hold the complete volume of the gel slurry (i.e., twice the volume of the settled gel).

If <50% of the column volume is to be packed, there is no need for a column extension.
6. Remove air from outlet tubing and end piece of column by injecting GF buffer into outlet tubing (using syringe or peristaltic pump) until support net is covered with 0.5 cm of buffer. Close outlet of column.
7. Inject GF buffer into inlet tubing of adaptor until net is wetted, while holding outlet upwards to ensure that air easily escapes from net. Place adaptor in a beaker containing GF buffer until it is time to use it.
8. Swirl gel slurry from step 3a or b and pour entire slurry into column along a glass rod tilted toward the inner wall of the column or column extension. Fill the remaining space with GF buffer by carefully pouring buffer along glass rod so as to cause minimum disturbance of the gel layer. Put lid on column extension (or put top adaptor on column).

Small columns (e.g., 1-cm i.d., 5-cm length) to be used for preliminary experiments where optimum resolution is not critical may be quickly prepared by adding the gel slurry to the

chromatographic tube, letting the gel settle by gravity, and washing the bed with one column volume of GF buffer before applying the sample.

9. Fill buffer reservoir with GF buffer and place at a level higher than the pump. Connect reservoir to pump using a large-i.d. tube.

This step is to ensure a free flow of buffer to the pump head.

10. Purge pump with GF buffer and attach outlet from pump to inlet of column or column extension. Open outlet of column and start pump at flow rate recommended by manufacturer for the gel/column combination used. Continue flow until height of gel bed becomes constant (typically 1 to 4 hr).

If no manufacturer's recommendation is available, use a flow rate 50% higher than that to be used in the separation.

If column is to be packed by gravity flow—i.e., by attaching the buffer reservoir directly to the inlet of the column—the actual flow rate must be monitored (e.g., by continuously weighing the effluent, or in the simplest case, by using a graduated cylinder) or controlled by a pump placed after the column. In the latter case it is necessary to check that the free gravity flow exceeds the pump flow—i.e., that the pump is serving to reduce the flow to a constant value.

The flow rate caused by gravity depends upon the hydrostatic pressure, determined by the difference in height between the air inlet in the buffer reservoir and the outlet tubing from the column. However, because the pressure drop over the column increases with the height of the packed bed, the free gravity flow rate will decrease during packing if the hydrostatic pressure is kept constant. Gravity flow rate may be increased by lowering the outlet tube or raising the buffer reservoir.

11. Turn pump off, close column outlet, remove column extension, adjust bed height if necessary, and adjust inlet adaptor so that it is flush with the bed surface.

Avoid trapping air under the support net.

Adjustment of the bed height is recommended only to remove excess gel. This is done by carefully swirling the upper part of the gel surface with a spatula and sucking the excess slurry out with a Pasteur pipet or tubing attached to a pump. If a crater or uneven surface is produced, the gel should be swirled so that a sharp bed surface is obtained before adjusting the inlet adaptor atop the bed. If the bed is too short the column should be repacked, although in most cases the old gel can be reused and added to new slurry prepared as in steps 1a to 3a or 1b to 3b before repacking.

12. Reattach column to pump, open column outlet, and resume flow conditions used in step 10 for 1 hr to stabilize column bed height. Readjust the adaptor so that it is flush with the new bed surface.

In some cases it is desirable to lower the inlet adaptor a few millimeters into the gel surface to make sure that there is contact between adaptor and gel.

Stabilizing the bed at a higher flow rate than that to be used during the separation will prevent the bed from shrinking as a result of “after-packing” during the run. If a gap appears between the adaptor and the bed surface, step 12 must be repeated at an increased flow rate before experiments are carried out. A space between the adaptor and the bed surface will act as a mixing chamber; the effect on separation will depend on the separation problem at hand.

13. Inspect packed bed visually for cracks, trapped air, and particle aggregates by observing the light scattered from a light source held behind the column. Chromatograph a colored marker (2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B₁₂) as in steps 20 to 23, and ascertain that the zone produced is horizontal and sharp.

Quality of the packed bed need not be as high for desalting as for protein fractionation (see Basic Protocol 2); therefore evaluation of the packed bed may be performed by visual

inspection. However, it is important for it to be free of cracks and for a colored sample to produce a sharp horizontal zone.

Air bubbles would be a major problem and should be avoided at all costs (see Troubleshooting).

If column is to be stored, GF buffer containing 0.02% (w/w) sodium azide or 20% (v/v) ethanol as antibacterial agents should be prepared, then 2 column volumes of this mixture should be pumped through the column. The outlet is then closed and the column stored in the buffer/antibacterial agent at room temperature for several months. See recipe for GF buffer for precautions concerning azide.

Prepare and test the GF system

14. Calculate amount of GF buffer necessary for the run and filter this amount plus a 50% excess through a 0.22- μm filter. Adjust pH if necessary and pour filtered buffer into buffer reservoir.

If the column is going to be used for a prolonged time, it is good practice to continuously deaerate the GF buffer by heating the buffer slightly with heat from a light bulb, or to use a degasser.

15. Assemble GF system according to manufacturer's instructions or Figure 10.9.1, placing detector and chart recorder (if used) in line but leaving column off line. Attach buffer reservoir to pump and purge pump with GF buffer with column off line.

If the system is run by gravity flow alone, the risk of the column running dry may be eliminated by placing the end of the outlet tubing higher than the inlet adaptor or placing a loop of the tubing from the reservoir with its bend at a lower level than the outlet.

Detection of salt may be accomplished in line by conductivity or off line by flame photometry or conductimetry. Colorimetric detection of proteins is readily done at 280 or 254 nm; the latter wavelength provides higher sensitivity. Refer to UNITS 10.6-10.8 for specific methods of protein detection.

16. Connect outlet of pump to column via the injection valve, run system with GF buffer at flow-rate settings to be used for separation, collect fractions with fraction collector, and note actual flow rate of the pump (e.g., by weighing collected fractions or measuring them with a graduated cylinder).

If the concentration of the solute is detected by in-line monitoring, use of a two-channel recorder set at different sensitivities (e.g., 100% and 10% full-scale) is recommended to ensure that the peaks of unknown solutes are not off-scale.

The actual flow rate of the system must be determined with the column installed, because the flow rate from a peristaltic pump or similar device depends upon the back-pressure of the system.

Determine separating volume of column

17. Determine the void volume of the system (V_0) by running a void marker and obtaining the elution volume according to steps 20 to 23.

The sample volume for determination of void volume and total liquid volume (steps 17 and 18) is not critical and may typically be 1% to 2% of the bed volume. However, correction of the calculated elution volume is needed if large sample volumes are applied (see annotation to step 23a). See Figure 10.9.2 for graphical depiction of void and total liquid volume.

The markers for void volume and total liquid volume may be mixed and run together.

Void volume (V_0) is typically 30% to 33% of the bed volume of a nonrigid (e.g., agarose) gel and 36% to 40% of the bed volume of a rigid (e.g., silica) gel.

18. Determine the total liquid volume of the system (V_l) by running a total liquid volume marker and obtaining the elution volume according to steps 20 to 23.

Total liquid volume (V_l) is typically 85% to 95% of the geometric bed volume ($\pi r^2 L$, where r is the inner radius of the column) for a nonrigid gel and 70% to 80% of the bed volume for a rigid gel. Because solute-matrix interactions may occur, it is advisable to check that the total liquid volume is smaller than the bed volume and perhaps run several different total liquid volume markers to confirm the result.

19. Calculate the separating volume of the column (V_i) as $V_t - V_o$.

The separating volume (V_i) is the amount of liquid that will pass through the column from the point where large proteins begin to emerge to the point where small solutes are eluted. It is equal to the pore volume of the bed, which is typically 50% to 65% of the bed volume of a nonrigid gel and 30% to 50% of the bed volume of a rigid gel.

Prepare, apply, and chromatograph the sample

20. Dissolve sample to be desalted in GF buffer. Filter through a 0.22- μm protein-compatible filter.

If possible, let sample solution reach room temperature before being applied to column to reduce viscosity effects. This is more important for large sample volumes.

The influence of the sample volume on the resolution (see Critical Parameters) is related to the need for column efficiency (see Basic Protocol 2). Too large a sample volume may ruin the separation of closely eluting proteins in a separation where high efficiency and narrow peaks are required. This is of primary interest in protein fractionation (see Basic Protocol 2), whereas in desalting, conditions are chosen to yield maximum separation of the protein from contaminants. To this end, column efficiency is less important, and very large sample volumes may be applied. See Critical Parameters for guidelines on optimal sample concentration.

When GF is performed for analytical purposes, the sample concentration should be as small as possible within the sensitivity of the detection method employed. For preparative purposes, on the other hand, the concentration should be as high as possible. The limiting factor in the latter case is the viscosity of the sample divided by the viscosity of the GF buffer (relative viscosity). At relative viscosities >1.5 , the hydrodynamic instability of the trailing edge of the zone may cause distortion of the protein zone (resulting from invasion of less viscous eluant into the more viscous zone; called "viscous fingering"), which will ruin the separation. It is generally safe to use protein concentrations up to 50 mg/ml and in some cases up to 70 mg/ml, whereas concentrations of 100 mg/ml often result in viscous

Figure 10.9.2 Chromatogram illustrating the separating volume (V_i) of gel filtration as determined by the void volume (V_o) and the total liquid volume (V_l). The total bed volume (V_c) is equal to the total liquid volume plus the matrix volume. Column efficiency is calculated as $N = 5.54(V_r/W_h)^2$, where N is the efficiency of the column in terms of number of theoretical plates, V_r is the elution volume of the peak, and W_h is the peak width at half peak height. The symmetry of the peak is calculated at 10% peak height as b/a , where b is the width of the trailing part of the peak and a is the width of the leading part of the peak.

fingering. However, when large sample volumes are applied—e.g., in desalting—the low dilution factor will result in a high concentration of protein in the peak, hence lower concentrations than these may be required to avoid viscosity effects.

21. Open outlet from column, turn on pump, and let two bed volumes of GF buffer pass through the column. Turn on detector and recorder and allow baseline to stabilize.
22. Load sample applicator with the appropriate volume of sample for desalting, not exceeding the separating volume determined in step 19. Switch the sample application valve to the load position and put a start mark on the chart recorder paper (or start a stopwatch if no chart recorder is used).

Smaller sample volumes are used for protein fractionation than for desalting, and much smaller sample volumes are used for analysis.

Before injecting, flush injector loop with excess sample to avoid trapping air bubbles, which otherwise may end up in the top of the column.

If the separating volume of the column has not been determined, the maximum sample volume may be estimated as ~50% of the bed volume for nonrigid media and ~30% of the bed volume for rigid media. For a first attempt at desalting, 50% of these volumes should be applied (i.e., 25% and 15% of the bed volume for nonrigid and rigid media, respectively).

If an open-bed column is used, gently add GF buffer to the top of the column with a Pasteur pipet or similar device, then open the outlet from the column and continue adding GF buffer until two bed volumes of buffer have passed through. Let the last portion of buffer penetrate the gel without the gel surface becoming dry; this is facilitated by using a top filter on the bed. Gently apply the sample to the clear gel surface or the top filter using a micropipet (or a Pasteur pipet if large volumes of sample are to be desalted).

- 23a. *To determine elution volume:* Pass GF buffer through the system at the appropriate flow rate and follow detector response with recorder while collecting fractions. Construct a chromatogram and calculate elution volume as the time from the start point to the apex of the peak for the protein (or other solute) multiplied by the flow rate of the pump (as determined in step 16).

If large sample volumes are being applied, the correct elution volume of the peak is obtained by subtracting half the applied sample volume from the apparent elution volume.

For determination of void volume as in step 17, the fractions that emerge between the point where a volume of buffer equal to 25% of the bed volume has passed through the column and the point where buffer volume equal to 50% of the bed volume has passed through the column are analyzed (either in line by monitoring detector response or off line by another method; see annotation below). For determination of the total liquid volume as in step 18, fractions emerging between the point where a buffer volume equal to 75% of the bed volume has passed through and that where 125% has passed through are analyzed. To determine the elution volume of an unknown protein sample (as in determining molecular size; see Basic Protocol 3), fractions emerging between the point where a buffer volume equal to 25% of the bed volume has passed and that where 125% has passed through are analyzed. Allowing 125% to pass through will permit the entire peak to be traced.

If fractions are to be collected for subsequent off-line analysis to determine where elution occurs (e.g., by photometry at 280 nm to detect Blue Dextran 2000 or proteins, or conductivity to trace the salt peak), start and stop the fraction collector to sample fractions at the volumes stated above. The fraction size should be large enough to permit accurate assay of the solute of interest; often 1 ml or 2% of the bed volume (whichever is smallest) is a suitable fraction size. The prefraction (i.e., the amount of liquid eluted from the point of sample application to the start of fraction collection for analysis) should be sampled in a vessel of known weight. The elution volume is calculated from the volume of the fractions by adding half the volume of the peak fraction and the volume of the prefraction, then subtracting half the sample volume. For dilute aqueous buffers (e.g., 0.5 M) a density of 1

may be assumed for converting weight to volume. If the experiment will take a long period of time, it is advisable to minimize evaporation by sealing the fraction cups with Parafilm.

If an open-bed (gravity flow) column is used, carefully add a volume of GF buffer that corresponds to the void volume of the column reduced by half the sample volume—unless the sample volume is <4% of the bed volume, in which case add 1 void volume of buffer. If the column is operating correctly, the effluent collected should contain no protein. Add GF buffer in ≤ 1 -ml increments if the column has a bed volume <50 ml, collect fractions, assay for proteins, and calculate elution volumes as described above.

- 23b. *To desalt a protein:* Pass a volume of GF buffer equal to the void volume reduced by half the applied sample volume through the column, and collect a waste fraction. Place a vessel that can hold 1.5 times the applied sample volume under the column, then add a volume of GF buffer equal to the applied sample volume. Collect the desalted protein.

Depending upon the efficiency of the desalting system, these quantities may have to be adjusted (i.e., the volume collected in the second fraction may need to be decreased in order to preclude contamination from substances that elute later). If system effects (e.g., mixing after the column) are substantial or the column is badly packed (e.g., contains cracks in the bed), it will be necessary to pass more GF buffer through the column than the void volume minus half the sample volume before sampling the protein (see Critical Parameters). Figure 10.9.3 shows a sample chromatogram of optimized desalting of 400 ml hemoglobin.

The desalting step may be continuously monitored by simultaneous in-line detection of the protein zone by absorbance at 280 nm and in-line detection of the salt peak by conductivity.

24. Wash column with ≥ 1 column volume of GF buffer containing an antibacterial agent. Close column outlet and store column.

See recipe for GF buffer for acceptable antibacterial agents.

Figure 10.9.3 Chromatogram illustrating desalting of proteins by gel filtration. A 4×85 -cm column packed with Sephadex G-25 is used. The sample consists of 400 ml hemoglobin (protein peak; solid line) in NaCl (salt peak; broken line). Note that the sample volume is close to the pore volume of the packed matrix, i.e., 490 ml. No correction for sample volume has been made. Calculation from the figure yields $V_0 = 560 \text{ ml} - 200 \text{ ml} = 360 \text{ ml}$, which is 31% of the geometric column volume (V_c). Reproduced from Flodin (1961) with permission of the *Journal of Chromatography*.

PROTEIN FRACTIONATION

Protein fractionation refers to the separation of proteins of similar molecular size for purification purposes. The objective may be to separate dimer and higher aggregates from a pharmaceutically active protein or peptide. Requirements for the column and system are therefore substantially higher for protein fractionation than for desalting.

The same materials and methodology described for desalting are used for protein fractionation. However, selection of matrix and column (see Strategic Planning) is more critical in this procedure, as are the quality of the column packing and control over experimental conditions (e.g., temperature and flow rate). The protocol includes steps for determining the column efficiency to evaluate the fitness of a packed column for use in protein fractionation.

Materials

GF matrix (see Table 10.9.4) or prepacked GF column (see Table 10.9.6) with appropriate selectivity for protein of interest (also see Strategic Planning and Critical Parameters)

GF fractionation buffer (see recipe)

Colored marker: 0.2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B₁₂

Low-molecular-weight marker (e.g., 5 mg/ml acetone or 2 M sodium chloride)

Protein sample to be fractionated

GF chromatography column (see Critical Parameters and Table 10.9.5)

Prepare column

1. Prepare GF matrix as in steps 1a to 3a or 1b to 3b of Basic Protocol 1 using GF fractionation buffer wherever GF buffer is indicated.

It is generally difficult to prepare columns of maximum efficiency using a GF medium with a small (e.g., 10- μ m) particle size. The need to scale up the procedure should be considered when selecting medium and column (see Strategic Planning and Critical Parameters).

The GF fractionation buffer must be selected in light of the method planned for testing purity of the final protein fraction (step 11), as this may put special restrictions on the buffer (e.g., sodium azide absorbs light at 254 nm and will also interfere with the anthrone reaction used for assaying carbohydrates).

2. Pack the column (see Basic Protocol 1, steps 4 to 12).

Because protein fractionation puts high demands on the quality of the packed column, care must be taken in selecting columns of proper design. Columns for protein fractionation are typically 30 to 100 cm long, depending upon the difficulty of the separation and the particle size of the medium used. Columns used must be constructed so that parts coming into contact with buffer and sample are made of appropriate materials. Long tubings and other sources of dead space or mixing chambers should be avoided. The pressure resistance of the column should be compatible with the expected pressure drop of the bed. See Strategic Planning and Critical Parameters for details concerning column selection.

3. Check quality of column packing visually (see Basic Protocol 1, step 13).

4. Assemble and test the system (see Basic Protocol 1, steps 14 to 16).

Place system and column in an environment not subject to temperature variations (e.g., the column should not be exposed to direct sunlight). If the system is to be used in a cold room, the influence of temperature on viscosity must be considered. Zone broadening of proteins and the pressure drop of the system are proportional to the viscosity of the buffer, and the flow rate will have to be adjusted accordingly.

Successful, reproducible protein fractionation requires a constant flow rate. This may be achieved using a peristaltic or high-precision pump whose flow rate is regularly checked. Continuous monitoring of the effluent is necessary to ensure proper sampling of the fraction

of interest. Detection may be carried out at 280 or 254 nm to trace proteins containing aromatic amino acids, or at lower wavelength (e.g., 214 or 206 nm) to measure absorption by peptide bonds. Other parts of a protein fractionation system that might be of use include a fraction collector (although in the simplest case it is possible to collect the fraction of interest by using a switch valve) and a chromatography controller, which permits automatic fractionation of the protein of interest.

Evaluate column

5. Chromatograph a colored marker (2 mg/ml Blue Dextran 2000 or 0.2 mg/ml vitamin B₁₂; see Basic Protocol 1, steps 20 to 23) and ascertain that the zone produced is horizontal and sharp.

A volume of marker solution 1% to 4% of the bed volume should be applied. The zone produced by a colored sample must be horizontal and sharp for packing to be considered acceptable.

If the supplier recommends a different method than this for evaluating column packing, that method should ordinarily be used.

6. Chromatograph a low-molecular-weight marker (e.g, 5 mg/ml acetone or 2 M sodium chloride; see Basic Protocol 1, steps 20 to 23) and construct a chromatogram to determine the column efficiency.

The sample volume applied in this step may contribute considerably to the peak width and result in a falsely low value for column efficiency. It is therefore recommended that the sample volume not exceed 0.9%, 0.5%, and 0.4% of the bed volume for columns packed with GF matrices having average particle diameter of 100 μm , 30 μm , and 10 μm respectively (Hagel, 1985).

7. Calculate the number of theoretical plates per column according to the equation $N = 5.54(V_r/W_h)^2$, where N = number of theoretical plates per column, V_r = elution (retention) volume of peak, and W_h = width of the peak at half peak height. See Figure 10.9.2 for a graphical depiction of these variables.

The efficiency of the column corresponds to the number of theoretical plates under given experimental conditions.

8. Calculate the asymmetry factor of the peak according to the equation $A_s = (b/a)$, where a is the width of the leading part of the peak and b is the width of the tailing part of the peak at 10% peak height.

9. Compare the plate number and asymmetry factor obtained for the column with the acceptance limits for these parameters in the manufacturer's documentation.

If no data for expected column performance is given, calculate the plate height (H) according to the equation $H = L/N$, where L is the length of the packed bed and N is the number of theoretical plates calculated in step 7. As a rule of thumb, H should be about three times the average particle diameter of the matrix for a good column and twice the average particle diameter for an excellent column. Plate heights of five times the average particle diameter or more are generally not accepted for high-resolution chromatography. The asymmetry factor should be 1.0 ± 0.2 .

The flow rate used will influence the broadening of the solute peak; suggested flow rates for GF matrices of different particle size are given in Table 10.9.7.

Perform chromatography and evaluate results

10. Dissolve, apply, and chromatograph protein sample to be fractionated (see Basic Protocol 1, steps 20 to 23).

Start by applying a small fraction of the sample to get a rough idea of the separation and to calculate optimum conditions for the actual run. A sample volume of ~1% to 4% of the bed volume has been found to be optimal for protein fractionation using a medium of 30- μm

particle size, depending upon the processing rate (i.e., amount of substance processed per unit time) of the system (Hagel et al., 1989). As a general rule, a sample volume of 2% of the bed volume can be applied. A chromatogram illustrating protein fractionation where dimers and higher aggregates are separated from the target monomeric form of the protein is given in Figure 10.9.4.

Optimum sample volume depends upon many experimental factors; discussion of optimization strategies have been published (Hagel et al., 1989; Hagel and Janson, 1992). In general, the larger the bead size used, the larger the sample volume that may be applied before the initial resolution is lost. This is due to the fact that smaller bead sizes normally result in more efficient columns that produce narrower peaks; hence the influence of sample volume on peak width is more detrimental.

Table 10.9.7 Practical Velocities for Protein Fractionation or Size Determination^a

Solute molecular mass	Nominal eluant velocities (cm/hr) at a support particle size of (μm):						
	2	5	10	15	30	50	100
1,000	507	203	101	68	34	20	10
5,000	293	117	59	39	20	12	6
10,000	234	94	47	31	16	9	5
15,000	195	78	39	26	13	8	4
50,000	137	55	27	18	9	6	3
75,000	121	48	24	16	8	5	2
100,000	109	44	22	15	7	4	2
200,000	86	34	17	11	6	3	2
300,000	76	30	15	10	5	3	2

11. Check the purity of the collected fraction(s).

Suitable methods of determining purity include HPLC (see UNITS 10.12-10.14) and electrophoresis (see UNITS 10.2-10.4).

DETERMINATION OF MOLECULAR SIZE

The third important application of gel filtration is in determining molecular size. To accomplish this, a GF column is calibrated with reference samples of known molecular size (see Support Protocol). Gel filtration is then carried out on an unknown protein solute as in Basic Protocols 1 and 2, and the molecular size of that solute is then inferred from the calibration curve, which relates elution volumes or distribution coefficients on the calibrated column to the molecular sizes of the different reference samples. If the relationship between the molecular size and mass is known, the mass of the solute may be calculated. However, because the shapes of biological molecules vary considerably (e.g., proteins may be spherical or ellipsoidal, or in some cases more or less rod-shaped), the calculation of molecular mass (M_r) from elution volume must be done with great care. If the shape of the molecule under study is not known, the experiment will yield only its estimated solvated size. The influence of solute shape on size may be exemplified by the fact that the radius of gyration (one estimate of size) is proportional to $M_r^{1/3}$ for spherical molecules (e.g., some proteins), to $M_r^{1/2}$ for molecules shaped like flexible coils (e.g., dextrans and denatured proteins), and to M_r for rod-shaped molecules (e.g., fibrous proteins and DNA fragments of intermediate length). Thus, gel filtration is very suitable for estimating the molecular size but generally not the molecular mass of unknown solutes.

Materials

- GF matrix or prepacked GF column (see Table 10.9.4, Table 10.9.6, Strategic Planning, and Critical Parameters)
- GF fractionation buffer (see recipe; note variations for size determination)
- GF chromatography column (Table 10.9.5)
- High-precision pump
- Protein sample for size determination

1. Prepare gel, pack column, then assemble and test GF system (see Basic Protocol 1, steps 1 to 16) using GF fractionation buffer wherever GF buffer is indicated.

For high-precision analytical gel filtration, the temperature of the chromatographic bed is often kept constant by using a jacketed column and circulating water from a temperature-controlled water bath. This makes the instrument setup more complicated, and the need for this precaution must be assessed on a case-by-case basis (e.g., if the column is calibrated at every other run, as is possible with high-speed gel filtration, there is little need for temperature control).

A high-precision pump must be used to ensure accurate and constant flow rate, which is of utmost importance for achieving reliable results in molecular size determinations. In addition to a UV detector for determining protein concentration, a detector for viscosity and/or light scattering—e.g., one employing multiple-angle laser light scattering (MALLS)—may be used for assay of molecular size or (indirectly) molecular mass. A mass spectrometry detector—e.g., one employing electrospray ionization mass spectrometry (ESI-MS)—may be used for assay of molecular mass.

If denatured standards are to be used in the calibration to eliminate the influence of molecular shape (see Support Protocol), 6 M guanidine hydrochloride (see recipe for GF buffers in Reagents and Solutions) is used as the GF fractionation buffer in this and subsequent steps.

Once a column has been calibrated (see Support Protocol), it is important to check column performance by determining the elution volume of one of the reference samples used for calibration as part of the routine testing of the system.

2. Determine the void volume (V_0) and the total liquid volume (V_t) for the system (see Basic Protocol 1, steps 17 and 18).

3. Calibrate column (see Support Protocol). Check flow rate during calibration by sampling effluent and weighing fractions.

Calibration of the column (and chromatography of the sample) may be carried out under denaturing conditions to eliminate the effects of molecular shape. Variations in procedure are described in the Support Protocol.

There are no general restrictions on the flow rate as long as the protein of interest separates from contaminating solutes (ideally, baseline separation should be achieved). A high flow rate will not influence the qualitative information sought—i.e., the position of the peak maximum. Thus, qualitative information may be obtained by very fast gel filtration; however, at high flow rates the danger of shear effects on elongated solutes must be considered. If a high-precision pump is used, there is less need to check the flow rate for every run (though in the author's experience this is a good practice because any pump may malfunction). If constant flow rate can be taken for granted, time may be substituted for volume in the calculations.

For both the calibration (see Support Protocol) and the run to determine molecular size of the unknown sample, the elution volume should generally be corrected for the contribution from the sample volume (see Basic Protocol 1, step 23a). However, if the sample volume is kept constant throughout the entire investigation it may arbitrarily be regarded as a part of the dead volume of the system, and no correction is necessary.

4. Apply, elute, and chromatograph unknown sample (see Basic Protocol 1, steps 20 to 23). Prepare a chromatogram and calculate elution volume. Check flow rate by sampling the effluent and weighing fractions.

The same applied sample volume should be used for the unknown sample as for the size standards (see Support Protocol).

If denatured standards were used in the calibration to eliminate the effects of molecular shape (see Support Protocol), the sample must be denatured. Elution is then carried out using 6 M guanidine hydrochloride as the GF buffer.

Often the calculations are performed on a time basis using an integrator or chromatography software (Amersham Pharmacia Biotech).

5. Calculate molecular size of unknown sample components using the calibration graph constructed in performing the support protocol.

If two different detectors were used for the reference standards and the sample (e.g., a refractive index detector for calibration with dextran standards and a UV detector for the protein sample), a correction factor for the difference in volume between the two detectors must be used in the calculations.

The estimate of molecular size will be correct only if there are no sample-matrix or sample-sample interactions (in fact, gel filtration has been used to study these self-association processes). The size estimate will be an apparent gel-filtration size which, together with data about the molecular mass (e.g., from mass spectrometry), will yield information about molecular shape.

6. Continue to run GF buffer through column until the next run is to be made.

It is important to continue flushing the column to maintain column characteristics and avoid the need for recalibration (see Critical Parameters). If the next run is not to be made for a long time, the flow rate may be reduced and buffer recirculated through a filter to the buffer reservoir (see Critical Parameters). Before reusing the column after a long period of rest, the validity of the calibration curve should be checked by running two or three reference samples covering the range of interest and calculating their molecular size from the old calibration curve. The apparent size should agree with the assigned size within $\pm 5\%$ error.

COLUMN CALIBRATION

Molecular size standards for column calibration should ideally be of the same shape and type as the molecules under study (e.g., globular proteins, fibrous proteins, or peptides). In cases where this requirement cannot be met, the column can be calibrated with other suitable reference substances of known size (e.g., dextrans). An apparent size may thus be assigned to the unknown and the actual size then inferred from the relationship between the shape of the different molecules. It is thus possible to use dextran as a reference for the estimation of Stokes radius for globular proteins (Hagel, 1993). However, a general shape parameter governing separation of all types of molecules by gel filtration has not yet been found (Dubin et al., 1990).

When protein standards are used, the calibration curve will reflect small natural variations in the molecular shapes of proteins, which will decrease the precision of the curve. However, the procedure described here is very simple and will readily yield an apparent molecular mass or molecular weight, which in many cases is quite satisfactory.

The influence of protein shape on the calibration curve may be eliminated by disruption of noncovalent bonds with denaturing solvents (e.g., guanidine hydrochloride). Disulfide bonds are broken by reductive cleavage with a reagent such as DTT, and reoxidation is prevented by carboxymethylation. This treatment converts the shape of sample and reference proteins to random coils. The physical size of a random coil is larger than that of a compact molecule of equal mass; therefore a more porous gel is needed to separate the former species. Detergents may also be used to denature proteins. However, it must be noted that a protein-detergent complex is larger than the protein and that ionic detergents will introduce charged groups. Also, information about size or molecular mass obtained using detergent-denatured proteins may not be relevant to the native protein. As these types of treatment are frequently used to prepare proteins for analytical electrophoresis, the reader is referred to *UNITS 10.3 & 10.4* for further details.

The influence of variation in shape on the calibration curve may also be eliminated by using as molecular size standards reference substances from a homologous class of nonprotein polymers—e.g., dextran or polyethylene glycol. Dextran has been used extensively as reference substance for calibration of gel-filtration columns. Calibration can be done by running a number of narrow fractions or one sample of broad size distribution.

Additional Materials (also see *Basic Protocol 3*)

- Calibration standards (see recipe and Table 10.9.8)
- 6 M guanidine hydrochloride (see recipe for GF buffer)
- In-line refractive-index detector

For calibration with native proteins

- 1a. Calibrate the column using protein standards (see Table 10.9.8) as in steps 20 to 23 of *Basic Protocol 1* and construct a chromatogram.

It is practical to mix a number of the calibration standards and chromatograph them simultaneously so that the calibration may be completed in a few runs (see example in Figure 10.9.5).

- 2a. Plot the elution volume (V_r ; i.e., the volume on the chromatogram from the injection point to the apex of the peak for a particular size standard) versus the logarithm of the molecular size, $\log_{10}R$, where R is the molecular radius of the calibration standard.

Table 10.9.8 gives the molecular radii of commonly used calibration standards. A sigmoid curve should be obtained that is approximated by a straight line in the middle section (see Fig. 10.9.5).

If the sample volumes are not held constant, the elution volume must be normalized by setting the injection point at half injected volume.

The calibration curve is often made system-independent by plotting distribution coefficient (K_D) versus $\log_{10}R$. The distribution coefficient is calculated as

$$K_D = (V_r - V_o)/(V_i - V_o),$$

where V_r is the elution volume for a particular peak, V_o is the void volume for the column, and V_i is the total liquid volume for the column.

For substances belonging to a homologous series (e.g., dextrans), it is meaningful to plot elution volume versus the logarithm of the molecular mass ($\log_{10}M_r$). Where substances of

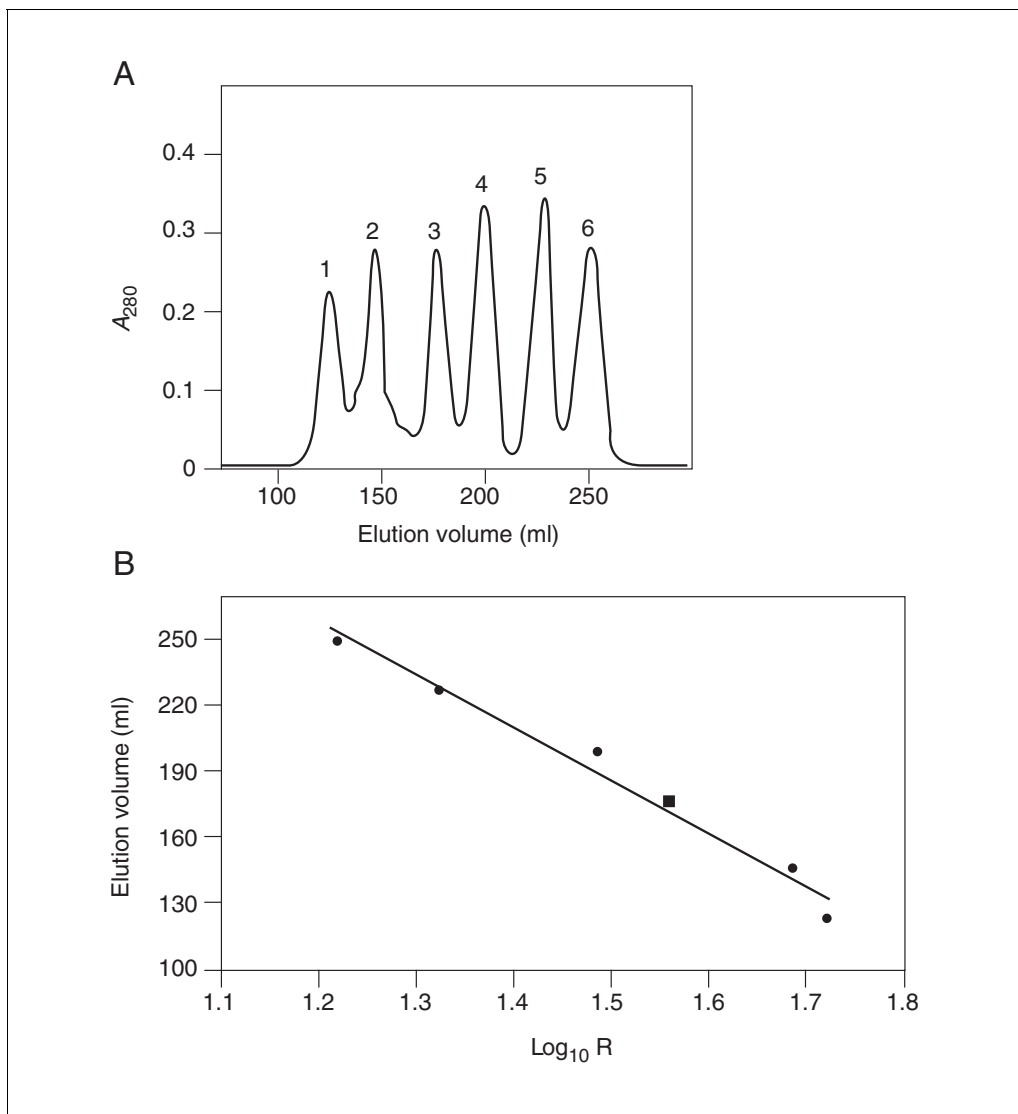

Figure 10.9.5 Calibration of GF column for determination of protein size. A K 26/70 column packed with Sephadex G-200 SF is used. **(A)** Chromatogram obtained for six size standards: 1, catalase; 2, aldolase; 3, bovine serum albumin; 4, ovalbumin; 5, chymotrypsinogen A; 6, ribonuclease A. **(B)** Calibration curve obtained by plotting the logarithms of the molecular radii ($\log_{10}R$) of the standards (x axis) versus the elution volumes for peaks 1, 2, 4, 5, and 6 from panel A (filled circles). The curve was used for evaluating the size of bovine serum albumin (filled square; elution volume corresponds to peak 3 in panel A), giving an apparent size of 34.8 Å. The excellent agreement with the nominal molecular size value of 35.5 Å may be incidental. Repeating the procedure for peak 4 in panel A showed that a deviation of ~3 Å from the nominal value may be expected for proteins of globular shape. Panel A reproduced from Pharmacia Biotech (1991) with permission from the publisher.

different chemical nature are being used to calibrate the column, the preferable way to calibrate the column is by using the hydrodynamic volume, V_h . This is calculated according to the equation $V_h = (\eta)(M_r)/Nv$, where η is the intrinsic viscosity, M_r is the relative molecular mass, N is Avogadro's number (6.02×10^{23} molecules per mole), and v is a shape factor, which for a spherical solute is 2.5.

It is wise to check the accuracy of the calibration by deleting one point at a time from the calibration data set and calculating the size or mass of the protein represented by that point from the calibration curve obtained with the remaining data. The average absolute difference from the nominal value indicates the accuracy of the calibration (see Fig. 10.9.5).

For calibration with denatured standards

- 1b. Denature calibration standards according to a standard denaturing protocol.
- 2b. Carry out steps 1a and 2a above, using a column equilibrated in 6 M guanidine hydrochloride and using 6 M guanidine hydrochloride as the GF buffer in the cross-referenced steps of Basic Protocol 1.

Where denatured standards are used, denaturing conditions must be maintained in chromatography of the sample (see Basic Protocol 3).

For calibration with nonprotein polymer standards

- 1c. Using an in-line refractive index detector, run system until a stable baseline is obtained. Chromatograph a number of dextran calibration standards (see Basic Protocol 1, steps 20 to 23) that will give calibration points surrounding the protein under study, to obtain their elution volumes or distribution coefficients.

The proper number and size of calibration standards to be run may be quickly found by running first the unknown sample and then the necessary calibration samples that will be eluted close to the unknown protein.

Apply each standard individually or as a mixture of two dextrans of high and low molecular mass.

Using a two-channel recorder set at two different sensitivities may prevent the peak from running off scale.

- 2c. Plot the elution volume (V_r) or distribution coefficient (K_D) versus the logarithm of the viscosity radius of dextran ($\log_{10}R_{vis}$).

The viscosity radius of dextran, R_{vis} , is related to the molecular mass (M) according to the equation $R_{vis} = 0.271 \times M^{0.498}$. Because dextran is a polydisperse polymer, the value of M used here is the molecular mass of dextran that corresponds to the peak apex, sometimes denoted M_p .

When two different detectors are used for calibration and chromatography of the sample—e.g., a refractive index detector for dextran standards and a UV detector for the protein sample—the difference in volume between the two detectors must be taken into account in calculation of elution volume.

Another procedure where the entire separation range of interest was calibrated in one run, using an integral calibration method, has been described (Hagel and Andersson, 1991; Hagel, 1993). Unfortunately, this simple and powerful method cannot yet be performed on routine basis because it requires data for the molecular mass distribution of the sample, and this information is, at the moment, not readily available in most cases.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

GF buffers

For desalting: Use a volatile buffer—e.g., 0.05 M ammonium hydroxide, 0.05 M acetic acid, 0.05 M ammonium acetate, or 0.5 M ammonium bicarbonate—unless the step is for buffer exchange, in which case use the desired final buffer.

Distilled (Milli-Q-purified or equivalent) water may be preferred to buffer as an eluant in some cases. This will yield adequate results with noncharged solutes; however, ionic interactions with the small amount of charged groups on the gel surface may disturb the purification of slightly charged molecules when water alone is used. Addition of a volatile bacteriostatic agent—e.g., chlorhexidine—may sometimes provide enough ionic strength to suppress such interactions.

For protein fractionation: Use 0.05 M sodium or potassium phosphate ($pK_a = 2.1, 7.2, 12.4$), 0.05 M Tris·Cl ($pK_a = 8.1$), or 0.05 M sodium or potassium acetate ($pK_a = 4.8$).

The buffering capacity of these buffers is adequate at a pH within ± 0.5 units of the pK_a value. If the protein is to be freeze-dried, use of a volatile buffer or water is advantageous.

It is sometimes necessary to add 0.1 M sodium chloride to completely eliminate ionic interactions. If parts of the system that come into contact with the buffer are composed of steel, the sodium chloride should be replaced with 0.05 M sodium sulfate to prevent halide-induced corrosion. In some cases the ionic strength of the buffer will affect the sample, e.g., by disrupting aggregates. This effect can be eliminated only by changing the ionic strength.

For determining molecular size: Use the same buffers as for protein fractionation but select one that will preclude solute-matrix interactions (see Support Protocol). If the column is to be used for a long period, add preservatives to prevent bacterial growth. Make sure the buffer is compatible with the detection step (e.g., use a buffer with low salt content if mass spectrometry will be used for detection).

If calibration is to be conducted under denaturing conditions, 6 M guanidine hydrochloride is used as the GF buffer. Guanidine hydrochloride is a better denaturing agent than urea.

For all buffers: Add antimicrobial agent if buffer will be used for a long time, adjust the pH of the buffer, filter through a 0.22- μ m filter, then recheck pH and readjust if necessary.

It is also recommended to degas the buffer prior to prolonged use. It is common practice to prepare fresh buffer once a week, but if an antimicrobial agent has been added it may be stored for 1 month or more. Antimicrobial agents used for GF buffers include ethanol added to a concentration of 20% (v/v), sodium azide added to a concentration of 0.02% to 0.05% (w/v), or chlorhexidine added to a concentration of 0.002% (w/v). Ethanol is not recommended for use with Sephadex gels as organic solvents cause the bed to shrink when used with this matrix.

IMPORTANT NOTE: Sodium azide is a very potent antimicrobial agent and therefore widely used. However, handling of azide, especially the dry powder, requires special attention; please refer to information from the supplier for safety precautions. Frequent exposure to the dry powder may be avoided by preparing a stock solution (e.g., 20% w/v) from which aliquots (e.g., 1 ml azide stock solution to 1 liter GF buffer) may be drawn conveniently with a micropipet. Azide may form explosive salts in lead-pipe waste disposal systems; collect the effluent in waste bottles.

Calibration standards

Table 10.9.8 provides a compilation of commercially available molecular size calibration standards and their suppliers. Some of these are available as kits (e.g., from Amersham Pharmacia Biotech). Protein standards should be prepared in the GF buffer that will be used in the molecular size determination. To prolong the life of the column, samples should be filtered through a protein-compatible filter prior to injection. The exact concentration to be prepared depends on the additives present (e.g., sucrose as stabilizer), detector sensitivity, and the zone broadening of the column. Concentrations of proteins in the range from 1 to 5 mg/ml are frequently used for calibration. It is possible to mix several standards to calibrate the separation range of interest in a few runs (it is seldom necessary to calibrate the entire separation range of the column).

Table 10.9.8 also lists some dextran fractions that are useful for calibrating the column in hydrodynamic volume, which makes comparing solutes of different shape easier.

Total liquid volume marker

5 mg/ml acetone, 10 mg/ml sodium azide, 0.1 mg/ml cytidine, 10 mg/ml sodium nitrate, and 2 M sodium chloride have been used for determination of total volume. A negative pulse from injection of water can also be used. In cases where interactions between matrix and solute must be eliminated, deuterium oxide can be used.

Acetone and cytidine are detected by UV absorbance at 280 nm, azide at 254 nm, and nitrate at 254 nm. Sodium chloride can be detected by flame photometry, conductivity, a sodium or chloride electrode, or precipitation of chloride with silver nitrate solution. A negative pulse from injection of water is detected by measuring the absorbance or refractive index of the buffer or by monitoring the conductivity of the effluent. Deuterium oxide is detected with a refractive-index detector.

Void marker

A suitable substance for determining void volume is a protein of the correct size (not too large and not too small), which may be selected by running a series of large proteins and observing which of them start to permeate the matrix. Other substances that have been used include 2 mg/ml Blue Dextran 2000 and DNA.

Blue Dextran 2000 has the advantage of being visible to the eye. Disadvantages are that small amounts of free dye may stick to the gel and a broad permeating peak may be visible in addition to the sharp excluded peak if the pore size of the gel is large enough (e.g., as with Sepharose 4B). This occurs because of the polydispersity of dextran. If the molecule is too large, so-called secondary exclusion effects, in which the sample is excluded from the narrow space where beads intersect, will yield a falsely low void volume. However, this phenomenon is only important in high-precision gel filtration and rarely has to be considered in desalting.

COMMENTARY

Background Information

Although separation of molecules according to size had been noticed in the mid-1950s (Lindqvist and Storgårds, 1955; Lathe and Ruthven, 1956), the discovery of gel filtration (GF) may be attributed to Porath and Flodin (1959), who realized the potential of the technique and were the first to report using it to desalt proteins. Their discovery provided the basis for a new separation technology that rapidly gained widespread acceptance owing to the commercial availability of a suitable cross-linked gel-filtration matrix—Sephadex—in-

roduced in 1959. Remarkably enough, after 35 years this matrix is still one of the premier choices for desalting of proteins (see Table 10.9.1). The use of gel filtration for determination of molecular size of proteins was described later (Andrews, 1970). Gel filtration was also rapidly established as an important tool for determining the molecular mass distribution of polymers in aqueous (Granath and Flodin, 1961) and organic solutions (Moore, 1964), for which suitable methods were lacking at that time. Moore used cross-linked polystyrene-based media for his application, naming the

Table 10.9.8 Molecular Size Standards for Calibration of Gel Filtration Columns

Standard	Molecular mass (M_r)	$\log_{10}(M_r)$	Molecular size (radius, Å) ^a	Supplier ^a
<i>Proteins^b</i>				
Thyroglobulin, bovine thyroid	669,000	5.825	85.0	PB
Ferritin, horse spleen	440,000	5.643	61.0	PB
Catalase, bovine liver	232,000	5.365	52.2	PB
Gamma globulin, bovine	158,000	5.199	—	BR
Aldolase, rabbit muscle	158,000	5.199	48.1	PB
Transferrin	81,000	4.908		SI
Albumin, bovine serum	67,000	4.826	35.5	PB
Ovalbumin, chicken	44,000	4.643	—	BR
Ovalbumin, hen egg	43,000	4.633	30.5	PB
Chymotrypsinogen A, bovine pancreas	25,000	4.398	20.9	PB
Myoglobin, equine	17,500	4.243	—	BR
Ribonuclease A, bovine pancreas	13,700	4.137	16.4	PB
<i>Non-protein standard</i>				
Vitamin B ₁₂	1,350	3.130	—	BR
<i>Dextrans^c</i>				
Dextran T-10	8,100		23	PB
Dextran T-40	23,600		40	PB
Dextran T-70	33,000		50	PB
Dextran T-500	370,000		150	PB
Dextran 1	1,080		9	PC
Dextran 5	4,440		18	PC
Dextran 12	9,980		26	PC
Dextran 25	21,400		39	PC
Dextran 50	43,500		55.3	PC
Dextran 80	66,700		68.4	PC
Dextran 150	123,600		93.1	PC

^aAbbreviations and symbols: —, Not stated by manufacturer; BR, Bio-Rad; PB, Amersham Pharmacia Biotech; PC, Pharmacosmos; SI, Sigma. Addresses and phone numbers of suppliers are provided in APPENDIX 4.

^bThe size of proteins may vary according to the source of information and the methodology used for determination—e.g., a value of 67.1 Å has also been assigned to ferritin (de Haen, 1987).

^cDextran is a polydisperse polymer and values given here—e.g., peak molecular mass—may vary from lot to lot. In cases where peak molecular mass is not stated by the supplier, the column is calibrated as elution volume versus $M = (M_w/M_n)^{1/2}$, where M_w is the weight-average molecular mass and M_n is the average molecular mass. The molecular size of dextran is calculated according to the equation $R_{vis} = 0.271 \times M^{0.498}$, where R_{vis} is the viscosity radius and M is the molecular mass (Hagel, 1989).

technique gel-permeation chromatography. Thus, within a few years after the discovery of gel filtration, applications of the technique basically covered the present range.

During the following years, the focus was directed to investigating the mechanism behind gel filtration. Theories suggesting that the separation was regulated exclusively by diffusion of molecules were soon replaced by the explanation, accepted today, that the process is driven by loss of conformational entropy when free

permeation of the matrix by a solute is hindered by steric factors (Casassa, 1967). Of course, diffusion affects peak width and thus also the degree of separation, but diffusion does not influence the elution volume of a solute. The definite impact of steric exclusion on the separation has led to the proposal to rename the technique “steric exclusion chromatography” (ASTM, 1978), but this term has not gained wide acceptance. Another generic designation sometimes used in the literature is size-exclu-

sion chromatography (SEC). It is important to realize that all of these designations refer to the same basic separation principle, which the majority of protein chemists refer to as gel filtration.

Development of gel-filtration media was focused for a long period on natural polymers or hydrophilic polymers. The late 1970s saw the introduction of silica-based materials, which combined rigidity and small particle size to enable fast gel filtration. A few years later, natural polymers of enhanced rigidity were introduced, which made it possible to pack columns with matrices of 10- μm bead size. To distinguish these media from the traditional type, the designation of high-performance size-exclusion chromatography (HPSEC) was introduced. However, it has been recently pointed out that the advantage of HPSEC media lies not in performance (i.e., traditional media packed in long columns may have equal or even better resolving capacity) but in speed of operation (Hagel, 1992). In addition, none of these materials have the outstanding selectivity shown by some of the traditional matrices (e.g., Sephadex and Bio-Gel P). Therefore, development of matrices for gel filtration has now been directed toward increasing their selectivity, which is done by decreasing the apparent width of the pore-size distribution of the matrix. Development is also geared toward tailoring the apparent pore size of matrices for the separation of molecules in specific interesting areas of application (e.g., for polishing of recombinant peptides). Recently, some of these modern media have become available for separation of peptides and proteins of moderate size (Hagel, 1993).

Even though the theoretical framework for the separation mechanism in gel filtration is well understood, there are still some uncertainties as to which molecular size estimate the elution volume reflects (Dubin et al., 1990). It is generally agreed that Stokes radius is a poor measure of molecular size, especially if different types of molecules are being studied. The hydrodynamic volume seems to be a general size parameter for polymers, globular proteins, and DNA of a certain length (Potschka, 1987). It appears that more work needs to be done to resolve this fundamental issue.

Until recently, development of instrumentation for gel filtration has been modest. High-precision pumps and automated systems for injection, fraction collection, and calculation were introduced more than a decade ago. New equipment and technology being introduced includes multiple-angle laser light scattering

(MALLS) detectors and in-line viscosity detectors, which provide information about the shape and size of molecules, and electrospray ionization mass spectrometry (ESI-MS), which has the power to provide in-line detection of molecular mass. ESI-MS combined with high-resolution gel-filtration columns provides a very powerful system for characterizing protein dimensions. Molecular size of solutes may also be determined with an in-line light-scattering or viscosity detector combined with a concentration-sensitive detector. It is now possible to obtain the exact molecular mass of small-to-medium-sized proteins by connecting an in-line mass spectrometer to the GF column. The advantages of using a mass-sensitive detector are that the system does not need to be calibrated, fluctuations in flow rate are not detrimental, and solute-matrix interactions or solute-solute interactions will not affect the molecular mass obtained. In this case, the column acts as a high-resolution separating device to resolve the sample components prior to determination of molecular mass by mass spectrometry.

Critical Parameters

Optimization and scaleup of desalting

Optimization of desalting starts with selection of a matrix of suitable exclusion limit with maximum pore volume and proper particle size. The bed volume is dictated by the sample volume to be purified. The actual elution protocol to be used depends upon the dispersion of the chromatography system, which in turn is related to the particle size and the column length. The particle size will influence the pressure drop over the column; this may be a limiting factor determining the maximum possible flow rate, the maximum column length, and the possibility of scaling up to columns of large diameters (i.e., the pressure specification is often reduced for columns of large diameter). However, in this case the column length can be traded off for an increase in column diameter to keep the bed volume high (also see Strategic Planning, Selecting Matrix and Column for Desalting).

To maximize the sample volume that can be applied to a column

A gel matrix should be selected from which the protein is excluded (see Strategic Planning) and in which the contaminants are eluted close to the total liquid volume (see Basic Protocol 1). It should also have a small matrix volume.

The maximum sample volume that can be applied to a column is directly related to the pore volume of the packed bed (V_i). The pore volume is proportional to the geometric column volume. As a rule of thumb, the maximum sample volume that may be applied for desalting is 25% to 40% of the bed volume for the materials listed in Table 10.9.1. The lower figure applies to small columns (e.g., <10-ml bed volume) and the higher figure to large columns (e.g., 100-ml bed volume). After the bed length is determined on basis of the acceptable pressure drop (which is proportional to the bed length), the sample capacity is maximized by increasing the diameter of the column. This is done because the applicable volume is directly proportional to the cross-sectional area of the column. Limitations in applicable column length may be eliminated by using columns in series ("stacked columns").

The maximum volume that theoretically can be applied for desalting is equal to the separating volume of the system, which is calculated by subtracting the void volume from the total volume (see Basic Protocol 1 for steps to determine these quantities). To account for extra zone-broadening effects, it is generally advisable to apply not more than 80% of the separating volume or even less—e.g., 50%—for small columns in which eddy dispersion (see discussion below) will contribute proportionally more to the zone broadening.

To optimize the yield of desalting

Sampling of the protein fraction must be adjusted according to the zone broadening of the sample (i.e., the width of the protein zone). For a well-packed column with a plate height (see Basic Protocol 2) roughly equal to two particle diameters, this parameter may be estimated as the sample volume plus the dispersion of the zone that occurs through different pathways in the packed bed—i.e., eddy dispersion. The peak width (w_b) is described by Equation 10.9.1, where V_t is the total liquid volume of the column, d_p is the particle size of the matrix, and L is the length of the packed bed. Thus, for a 5-ml NAP-5 column (0.9 × 2.8-cm bed dimensions) packed with Sephadex G-25 medium-particle matrix, which has a particle size of 175 μm, eddy dispersion adds ~0.6 ml to the sample volume. This is roughly equal to the maximum sample volume (i.e., the separation volume; see Basic Protocol 1) and thus the eluted fraction is twice the sample volume. However, for a much larger 4 × 85-cm column packed with Sephadex G-25 coarse-particle

matrix, which has an estimated particle size of 300 μm, the eddy dispersion adds ~100 ml to the originally applied sample volume of 400 ml, giving a protein zone of 500 ml (see Fig. 10.9.3). If G-25 medium-particle matrix were used, the smaller particle size would in this case theoretically decrease the protein zone from 500 to 475 ml, at the expense of a pressure drop over the column three times higher than with the coarser medium.

$$w_b = 4(V_t) \left(\frac{2d_p}{L} \right)^{\frac{1}{2}}$$

Equation 10.9.1

To minimize the time of the separation

Use the highest possible flow rate for the desalting step. High flow rates are suitable for desalting because eddy dispersion effects are rather insensitive to flow rate. The limiting factors on the flow rate are the rigidity of the matrix and the pressure limitations of the system used. Because media with small pore volume are generally more rigid than those with large pore volume, the disadvantage of a smaller separating volume may be offset by increasing the applicable flow rate to keep productivity high when working with the former type of medium. Incomplete removal of fine particles from the medium prior to packing may reduce the flow rate of the column after use as a result of partial blockage of the outlet filter. Operating the column with the flow direction reversed may help to increase the applicable flow rate in such situations.

The total process time for repetitive runs to desalt large volumes may be further minimized by utilizing the dead time of the void fraction. To do this, samples are added, not after total liquid volume + sample volume + eddy dispersion volume, but after subtracting the void volume from the total process volume (i.e., the next sample is added before the salt peak of the previous sample has emerged). The saving in time may be in the range of 20% to 30%, but this practice can only be recommended for well-understood processes.

$$R_s = \frac{1}{4} \log_{10} \left(\frac{M_{r1}}{M_{r2}} \right) b \left[\frac{1}{\left(\frac{V_o}{V_i} + K_D \right)} \right] \left(\frac{L}{H} \right)^{\frac{1}{2}}$$

Equation 10.9.2

Optimization and scaleup of protein fractionation

There are two basic ways to optimize the resolution of a separation. One is to increase the peak-to-peak distance and the other is to decrease the peak widths. The resolution for gel filtration is described by Equation 10.9.2, where M_{r1} and M_{r2} are the molecular masses of the two sample components being separated, b is the slope of the selectivity curve ($-\partial K_D/\partial \log M_r$), V_o is the void volume of the column, V_i is the pore volume of the bed, L the bed height, and H the plate height of the column (i.e., the term $L/H = N$, the plate number). The impact of these parameters will be described below.

To increase the peak-to-peak distance

1. A matrix of high selectivity should be chosen. The most important factor for optimizing protein fractionation is selectivity, which is the inherent ability of the matrix to resolve proteins of similar size. This factor is a function of the pore-size distribution of the matrix. Selectivity is often illustrated by a plot of the elution volumes of a series of reference substances versus the logarithm of the molecular size or molecular mass of those substances. A function of the elution volume (e.g., the distribution coefficient; see Basic Protocol 3) may be substituted for the elution volume in constructing a selectivity curve. The steeper the selectivity curve (i.e., the greater the absolute value of the slope b , defined above), the better the resolvability of proteins differing in size. The selectivity of different gels can be judged from the fractionation range stated by the manufacturer. Gels with a small fractionation range (in terms of $\log M_r$) will generally have higher selectivity than gels with a large fractionation range.

2. A gel of high pore volume should be selected. The pore volume of a matrix is often related to the particle size. Smaller particles need to resist a higher friction force from the high flow rates that are used with matrices of smaller bead size; therefore the matrix volume is generally larger and pore volume smaller when using these matrices. A traditional soft-gel matrix may have up to 98% pore volume, whereas rigid matrices such as silica may have as low a pore volume as 52% (of the bead volume).

3. A column of sufficient length (L) should be selected. The resolution between peaks is proportional to the square root of the column length. The column length chosen for protein

fractionation is usually optimized with respect to the particle size of the matrix—i.e., a 100-cm column is often chosen where the particle size is 100 μm , a 60-cm column where the bead size is 30 μm , and a 30-cm column where the bead size is 10 μm .

To decrease peak width

1. A material that yields a small void volume (V_o) should be selected. Reducing the void volume will decrease the dispersion of the protein band (as will minimization of all extra column dead volumes). Irregularly shaped or rigid particles generally yield beds with larger void volumes than spherical, nonrigid beads.

2. A material of small particle size should be used, as this will affect the plate height (H ; also see Basic Protocol 3). Zone broadening of proteins within a column is directly proportional to the square of the particle size. Therefore, smaller particles will yield smaller peak widths unless very large sample volumes are applied or large system effects are causing dispersion of zones.

3. The separation should be run at optimum flow rate, as this will affect the plate height (see Basic Protocol 3). Zone broadening is caused by dispersion within the void volume of the chromatographic bed, or by nonequilibrium effects that occur in the separation process itself when the mobile-phase velocity in the extra-particle space is too high as compared with the diffusivities of the proteins and the diffusion distances in the matrix. Flow rates that will allow minimum zone broadening and complete equilibrium will in most cases be impractically low. Table 10.9.7 lists practical flow rates for different solute molecular weights and matrix particle sizes, which represent compromises with regard to these parameters.

Dissolving the sample

Care must be taken to assure that the sample is completely dissolved in the GF buffer. Conditions must be chosen so that spontaneously formed aggregates are dissolved and aggregates that are to be removed are not dissolved merely to reaggregate in the fraction tube. Because gel filtration permits rather free choice of pH, ionic strength, and additives, it is generally not difficult to find suitable conditions.

Solute-matrix interactions

Solute-matrix interactions are generally to be avoided. Even though mixed-mode separations (i.e., separations on the basis of both molecular size and the solute-matrix interac-

tion) have sometimes given good resolution, one must be concerned about the reproducibility of such mechanisms. Solute-matrix interactions may be specific or nonspecific, and the chemical basis may be an ionic or hydrophobic interaction. In the case of specific solute-matrix interactions, the only thing to do is to change the matrix to one based on a different chemistry. Ionic interaction can be suppressed by addition of an electrolyte; hydrophobic interaction can be reduced by adding an organic modifier (e.g., methanol, acetonitrile, or isopropanol) or by reducing the ionic strength of the buffer. Of course, avoidance of solute-matrix interactions is a prerequisite for estimating molecular size using a calibrated column (see Basic Protocol 3 and Support Protocol). Solute-matrix interactions can be uncovered by varying the composition of the mobile phase or temperature and noting the effect. Because ideal gel filtration is driven by entropy, temperature should not affect the elution volume of proteins (unless the temperature change affects protein size or the pore size).

Column maintenance

Column life is drastically reduced by introduction of air into the column, deposition of material on the bed surface, and use of flow rates that exceed the maximum recommended flow rate. To protect valuable columns from air it is advisable to use an air trap, to degas the buffer, or to use a deaerator. Deposition of material is minimized by filtering both sample and buffer through a 0.22- μm filter prior to application. Exceeding the maximum flow rate or pressure (e.g., by failing to compensate for viscosity effects at low temperatures) will result in the bed becoming compressed. This may be avoided by using a flow or pressure sensor to shut down the pump if the limit is exceeded. To maintain the calibration of a column for molecular size determinations (see Basic Protocol 3 and Support Protocol), the flow through the column should never be turned off completely, but may be reduced (e.g., to one-tenth) and the effluent recycled to the buffer reservoir through a filter. The buffer should be treated with preservatives and must be discarded when the column is put back in service. According to the author's experience, the lifetime of a column may be expected to exceed several years and calibration may remain valid for up to 1 year if the appropriate precautions are taken.

A parameter that reflects the possibility of bed compression is the void fraction—i.e., the void volume divided by the bed volume. This

parameter is 0.26 for beds made up of tetrahedral, closely packed spheres and 0.40 for beds made up of randomly packed spheres. Experimentally determined void fractions vary from 0.30 to 0.47 because of the surface and packing properties of the matrix and the particle shape. Void fractions <0.30 may indicate compression of beads.

Flow rate

Flow rate must be carefully controlled, especially if the column is used for characterization of molecular size as in Basic Protocol 3. The actual flow rate of a pump seldom agrees with the nominal flow rate, so it is essential that the flow rate be checked regularly.

Troubleshooting

Gel filtration is a comparatively uncomplicated separation technique and troubleshooting is straightforward. Provided that the critical aspects of the technique (see Critical Parameters) are kept under control, gel filtration can be expected to be relatively trouble-free. Problems that may arise most frequently are compression of the bed and consequent decrease in flow rate, air bubbles in the column, tailing or leading peaks, and peaks that elute in the "wrong place."

Bed compression and decreased flow rate

Compression of the bed most likely results from the maximum flow rate being exceeded during packing (see Critical Parameters). It may also arise from excessive packing of the column, which creates an inhomogeneously packed bed with a denser layer in the lower part of the column that will eventually collapse even at a moderate flow rate. A column found to have a compressed bed must be repacked.

Compression may also result from partial clogging of the inlet filter and the upper part of the bed. To save the column in such a case, the adaptor should be removed, the filter cleaned, contaminated upper matrix removed, the upper part of the bed swirled, and the bed restabilized (see Basic Protocol 1, step 11). If the column still does not perform as expected, it must be repacked.

Decrease in the flow rate often accompanies compression of the bed. If the gel contains fines, these may block parts of the outlet net, causing a decrease in flow rate. Reversing the direction of flow may restore normal conditions. If this is not successful, the column should be repacked after exhaustive decantation of fines (see Basic Protocol 1, steps 3a and 2b).

Air bubbles in column

Small air bubbles in the column may be due to failure to deaerate the buffer or to the introduction of bubbles during sample injection. Moving the column from a cold room directly to a warmer laboratory will also release air bubbles in the column and should be avoided. An attempt may be made to remove the bubbles by pumping deaerated buffer through the column in the reverse direction. Heating the buffer slightly is sometimes successful, as the temperatures of the buffer and gel will equilibrate, allowing the warmer buffer to dissolve some air. This may have to be done at least overnight and perhaps for several days to be fully successful. A large air pocket situated right under the adaptor that has not been taken up by the buffer may be removed using the procedures for readjusting the adaptor to the bed surface (see Basic Protocol 1, step 11).

Tailing and leading peaks

Tailing peaks indicate a large dead volume somewhere in the system, solute-matrix interactions, or a bed that is packed too loosely. To check the system for extra dead volumes, another column or a dummy column of small volume should be packed and a sample run to see if the problem reproduces itself. If it does not, the problem can be attributed to the column, and a sample of a different substance should then be run to ensure that the effect is not caused by solute-matrix interactions. If the tailing problem is still noted, the defect probably lies in the column packing, and an attempt should be made to stabilize the bed at a higher flow rate (see Basic Protocol 1, step 11). If this does not help, the column should be repacked at a higher flow rate. Before doing this, however, it should first be ascertained that the tailing is really seen with the sample to be run under the actual conditions under which it is to be run. Slight tailing of a small solute may be negligible when compared to a large diffusion-regulated zone broadening of a protein. Tailing may also be caused by partial separation of a small amount of a solute of slightly smaller size or slightly different surface properties.

Leading (fronting) peaks indicate solute-matrix interactions or cracks in the bed. Solute-matrix interactions (e.g., ionic-exclusion effects) are detected by running a different substance and/or using a different buffer. If the problem is related to the column packing (i.e., cracks in the bed), the column must be repacked at a lower flow rate. As with tailing peaks, however, the actual sample should first be run

under the actual conditions to be used to determine whether the effect of fronting on the separation is serious. Fronting may also be caused by partial separation of a small amount of slightly larger contaminant.

Peaks that elute in the wrong place

Peaks that elute prior to the void volume indicate ionic-exclusion effects. To suppress these effects, the ionic strength of the GF buffer should be increased. Solutes that elute after the total liquid volume indicate adsorptive effects. These may be masked by adding an organic modifier or by increasing or decreasing the ionic strength of the buffer (see Critical Parameters for discussion of solute-matrix effects).

Anticipated Results

Results from gel filtration are in general very predictable. Guidelines for optimization and scaleup are presented in Hagel et al. (1989) and Hagel and Janson (1992).

Time Considerations

Gel filtration using media of small particle size may generally be carried out in half an hour. Gel filtration using traditional larger-particle matrices are typically run for 5 hr. Desalting is very fast: e.g., 1.4 ml of sample may be desalted in 30 sec.

Preparation (i.e., swelling) of the gel will take 3 hr to overnight, depending on the procedure chosen. Packing of the column takes 1 to 4 hr, and the subsequent stabilization of the packed bed takes 1 hr. Thus, a column is typically prepared in a day, and testing of the packing quality is carried out overnight.

Ion-Exchange Chromatography

Ion-exchange chromatography separates biomolecules on the basis of charge characteristics. Charged groups on the surface of a protein interact with oppositely charged groups immobilized on the ion-exchange medium. As illustrated in Figure 10.10.1, the charge of a protein depends on the pH of its environment (the operating pH). The pH at which the net charge of a protein is zero (i.e., where the number of positive charges equals the number of negative charges) is known as the isoelectric point (pI). When the operating pH is greater than the pI, the protein will have a net negative charge, and should bind to anion-exchange media, which are positively charged. When the operating pH is less than the pI, the protein will have a net positive charge, and should bind to cation-exchange media, which are negatively charged.

The Strategic Planning section outlines the basic steps in planning and carrying out ion-exchange chromatography to separate proteins. Basic Protocol 1 describes batch adsorption of protein to an ion-exchange medium followed by elution using a step gradient of increasing salt concentration. This technique accommodates a wide range of sample volumes and is most often used in the initial capture stage of protein purification. Batch techniques have minimal system requirements. The Alternate Protocol describes use of a buffer of a different pH to elute via step gradient. Basic Protocol 2 describes adsorption of protein to an ion-exchange medium in a column, followed by elution with a linear gradient. Basic Protocol 2 provides a higher resolution than Basic Protocol 1, and is therefore used in the intermediate purification and final polishing stages of protein separation. Support Protocol 1 describes a pilot experiment to determine initial conditions for batch or column chromatography (i.e., pH required for binding, change in pH or salt concentration required for elution, and available capacity of a medium). Support Protocol 2 describes a means of calculating the dynamic capacity of an ion-exchange column, Support Protocol 3 describes methods for producing continuous gradients of pH and salt concentration to elute proteins from ion-exchange columns, Support Protocol 4 describes

Figure 10.10.1 Net charge of a protein as a function of pH, showing the pH ranges in which protein is bound to anion or cation exchangers. The pH range over which the protein is stable may be only a small fraction of the binding range; this must also be taken into consideration when choosing an ion-exchange medium.

regeneration of used ion-exchange media, and Support Protocol 5 details storage of ion-exchange media.

STRATEGIC PLANNING

There are a number of basic steps in developing an ion-exchange method for protein purification. First, an appropriate ion-exchange medium must be selected, as well as the optimal operating pH and buffer system for the medium and sample (see following discussions on *Selecting an Ion-Exchange Medium* and *Selecting a Buffer System*). It is then necessary to decide whether batch or column chromatography is appropriate given the purity, protein concentration, and physical characteristics of the sample, the sample volume to be used, and the availability of suitable equipment (see following discussion on *Selecting Batch Versus Column Purification*). Next, pilot experiments are conducted to determine conditions for binding and eluting the protein (see Support Protocol 1). It is also necessary to make sure that the capacity of the medium is sufficient to isolate the desired quantity of protein (see Support Protocol 1 and Support Protocol 2). When these initial conditions have been determined, the medium and sample are prepared, the sample is bound to the medium, unbound sample components are washed away, and bound sample components are selectively eluted and collected (see Basic Protocol 1, Basic Protocol 2, or Alternate Protocol). The medium may then be cleaned and regenerated (see Support Protocol 5). Finally, results are evaluated and conditions optimized if necessary (see *Critical Parameters*).

Selecting an Ion-Exchange Medium

A wide variety of ion-exchange media are commercially available, but no miracle medium exists that is best for every protein purification. Criteria for selecting an ion-exchange medium include the specific requirements of the application, the pI and molecular size of the sample components (i.e., target protein and contaminants), and the available equipment (e.g., pumps and columns).

It is necessary to begin by selecting either anion or cation exchange. This requires knowledge of the pI and pH stability of the target protein. If the pI of the target protein is known, an anion-exchange medium with an operating pH above the pI of the target protein or a cation-exchange medium with an operating pH below the pI of the target protein should be selected. If the pI of the target protein is unknown, it is desirable to determine it before beginning. The optimal operating pH can be determined empirically (see Support Protocol 1). Because the pI for most proteins is below pH 7 (Gianazza and Righetti, 1980), it is reasonable to select an anion-exchange medium and an operating pH of 8.5 to start, then evaluate the results and optimize conditions as necessary.

It is also useful to know the pI and binding characteristics of the contaminants present in the protein solution. For example, if the pH of the binding buffer is higher than the pI of a major contaminant, that contaminant will not bind to an anion-exchange medium. If the starting material is crude cell lysate, DNA will be present and generally needs to be removed from the protein. Since DNA is anionic, it binds tightly to anion-exchange media and typically is not eluted with the salt and pH conditions used during protein purification.

Selecting a Buffer System

A buffer system must be selected for the desired pH range. As with selection of an ion-exchange medium, there are several factors that must be considered in selecting a buffer system, including the type of ion exchange to be performed, the pH stability of the sample and the pH range to be used, the required buffering capacity, and, finally, the cost.

^cChange in pK_a per °C (i.e., $\partial\text{pK}_a/\partial T$).

Anionic buffers (e.g., acetate and phosphate) are preferred for cation exchange and cationic buffers (e.g., Tris-Cl, ethanolamine, and piperazine) are preferred for anion exchange. It is important to ensure that the buffering ion will have the same charge as the ion exchanger, and hence will not be bound. A constant buffering capacity and pH will thus be maintained during the ion-exchange experiment. Table 10.10.1 lists a variety of buffers useful for anion and cation exchange. Additives to be included in the buffers (e.g., detergents or protease inhibitors) should also carry the same charge as the ion-exchange medium, to preclude binding.

Selecting Batch Versus Column Purification

If the sample volume is large in relation to the size of the pumps and columns available in the laboratory, batch adsorption techniques (see Basic Protocol 1) are appropriate for the capture stage of purification. Batch methods, in which the sample and medium are directly mixed without use of a column, are employed to reduce the sample volume and

total protein content prior to column chromatography. Batch techniques are also very useful for capture of the target protein from extremely crude samples (e.g., cell lysates and samples containing particulates and/or aggregates). In batch methods the flow and packing characteristics of the medium are of minor importance, but economy and capacity are of primary importance. Ion-exchange media suitable for batch purification at the capture stage of protein purification are presented in Table 10.10.2.

High resolution is required in the intermediate purification and polishing stages of protein purification, and this can only be achieved using column chromatography. However, higher-than-necessary resolution is frequently traded off for greater throughput (i.e., amount of material processed in a defined time). The packing and flow characteristics of the medium are of primary importance when using column chromatography. Columns packed with smaller beads usually require higher operating pressures than columns packed with larger beads. However, smaller beads offer higher resolution, resulting from the increased efficiency that comes with decreasing bead size. Larger beads are desirable for applications requiring higher throughput. A medium with the smallest bead size that will provide the necessary throughput (and whose operating pressure can be accommodated by available equipment) should be selected. Table 10.10.3 lists a variety of media suitable for column purification at various stages in the purification process. See *APPENDIX 4* for contact information of suppliers of these media, all of whom provide technical support for selection and use of specific media.

Capacity of Ion-Exchange Media

The amount of ion-exchange medium required for a particular application will be determined by the protein capacity of the medium (i.e., the amount of protein that can be bound to the matrix) at the chosen pH. The amount of medium required will in turn determine the size of column required. The capacity of an ion-exchange medium is dependent on a variety of factors, including charge and molecular size of the components in the sample and experimental conditions employed.

Analysis of Proteins

10.10.7

The number of charged groups on a specified amount of matrix that can participate in ion exchange is termed **ionic** or **total** capacity. However, ion-exchange media are porous and the ion-exchange groups are usually distributed throughout the bead. The amount of protein that will bind is dependent on the ability of the sample components to diffuse into the bead, and this ability is related to the molecular weight and shape of the components and the pore structure of the matrix (see *UNIT 10.9*). In addition, large molecules such as proteins and nucleic acids can bind to multiple ion-exchange groups (or sterically hinder other molecules from binding) depending on the shape and surface-charge distribution of the protein, as well as the spatial orientation of the exchange ligands on the matrix. These factors are taken into account in the available and dynamic capacity of a matrix or column.

Available capacity is defined as the amount of a specific protein that will bind to an ion-exchange medium at a defined pH, salt concentration, and sample concentration in a batch purification process. When medium is packed in a column, the amount of a specific protein that will bind is dependent on many of these factors, as well as on the column dimensions and flow rate. The capacity of a column operating under defined conditions is termed the **dynamic capacity**. The dynamic capacity is typically less than the available capacity for the same sample under the same operating conditions.

Ion-exchange media in which the charge state of the ligand is sensitive to the operating pH are termed weak ion exchangers. The usable pH range of weak ion exchangers is narrower than that of strong ion-exchange media, in which the charge on the ligand used for exchange is constant (i.e., insensitive to pH). Ion-exchange media with DEAE (diethylaminoethyl) or CM (carboxymethyl) groups as the ligand for exchange are considered weak ion exchangers. Because the ionic capacity of weak ion-exchange media is variable, strong ion-exchange media are recommended for pilot experiments (see Support Protocol 1).

When selecting ion-exchange media for batch or column purifications, the amount of medium should be estimated from the manufacturer-supplied capacity data for a protein similar in size to the target protein to be purified. Be aware of what type of capacity (i.e., ionic, available, or dynamic) is being reported and the experimental conditions under which the reported capacity was determined (see Table 10.10.3). A general recommendation is to begin pilot experiments at ~10% of the published capacity data, then determine the capacity for your system.

Preparing Solutions

All aqueous solutions for use in ion-exchange chromatography should be prepared with distilled or deionized water (Milli-Q purified or equivalent). Solutions and samples for column chromatography should be filtered, degassed, and equilibrated to the appropriate temperature prior to use. Special attention must be given to any additives to be included in the buffer to be sure that they will not bind to the column (see preceding discussion on Selecting a Buffer System). If the chosen additives increase the viscosity of the mobile phase, the flow rate should be decreased.

Chromatography Systems

Column techniques typically result in higher resolution than batch techniques, and should be used during the intermediate purification and polishing stages of a purification procedure. However, to achieve high resolution, an appropriate chromatography system is required. A chromatography system may be described simply by the functional operations required to perform a chromatographic separation. The minimum functions required (Fig. 10.10.2) include a buffer delivery system capable of gradient formation, a mechanism for introducing sample into the system, the column itself (properly packed with the appro-

Table 10.10.4 Scale-Up Calculations for Ion-Exchange Column Chromatography

Scale	1×	10×	100×
<i>Sample</i>			
Sample concentration (mg/ml)	1	1	1
Sample load (mg)	10	100	1000
Sample volume (ml)	10	100	1000
<i>Column</i>			
Column diameter (cm)	0.5	1.6	5
Cross-sectional area (cm ²)	0.2	2	20
Bed height (cm)	5	5	5
Bed volume (ml)	1	10	100
<i>Flow rate</i>			
Volumetric flow (ml/min) ^a	2	20	200
Linear velocity (cm/hr)	300	300	300
<i>Gradient</i>			
Gradient volume (ml)	20	200	2000

^aLinear flow (cm/hr) multiplied by the cross-sectional area of the column (cm²) equals the volumetric flow rate (ml/hr); cm/hr × cm² = cm³/hr = ml/hr.

appropriate ion exchanger), an in-line UV monitor suitable for use at 280 nm, a chart recorder, and a fraction collector to preserve the separation. Additional unit operations may include system controllers for automated operation as well as data-acquisition systems. The equipment required to perform each of these unit operations is ultimately determined by the chromatography medium and column selected. Specifically, the operating pressure and flow characteristics of the packed column will be the most important factors for selecting equipment to fit the column, or for selecting columns to fit existing equipment.

It is highly recommended that prepacked columns be used and that the manufacturer be consulted prior to purchase as to equipment requirements for proper operation. This will save time and money and increase the probability of success. If columns are to be packed in the laboratory, the manufacturer's packing instructions for the medium should be followed and column efficiency and function should be tested with representative standards prior to use with the actual sample. There is no single packing methodology that is optimal for all types of media. Table 10.10.3 lists a variety of ion-exchange media available in prepacked columns and/or in bulk for packing in the laboratory. Several manufacturers offer inexpensive disposable ion-exchange columns, suitable for many applications, that can be operated using only a syringe.

Scale-Up Conditions

Ion-exchange separations are typically developed and optimized on a small scale before the entire sample is committed. It is thus important to choose an ion exchanger that will allow simple and convenient scale-up, so that methods established on a small column can be applied more or less directly to a larger one.

Scaling up in ion-exchange chromatography can be approached in two different ways—either the same ion-exchange medium can be used in a larger-diameter column with the same bed height, or a different medium having the same charged group immobilized on a matrix with a higher throughput can be substituted for the medium used in the small-scale separation.

The former approach, using the same medium throughout, is the simplest. Scaling up a separation with the same medium and bed height used in the small-scale optimization is achieved by employing simple scale factors to adapt the flow, gradient volume, and sample load to the increased volume of a larger-diameter column. The scale factor for the required increase in flow rate is the ratio of the cross-sectional area of the larger column to that of the smaller column (i.e., the factor by which the total flow of solution through the column must be increased so that the same linear velocity used in the small-scale experiment is maintained). The increase in gradient volume and sample loading are directly proportional to the increase in column volume. Table 10.10.4 shows an example of changes that must be made to various parameters for a 10- and 100-fold increase in scale.

BATCH ADSORPTION AND STEP-GRADIENT ELUTION WITH INCREASING SALT CONCENTRATION

This protocol describes adsorption of a protein to an ion-exchange medium by direct mixing of the protein-containing sample and the medium (in this case, an anion-exchange gel). This batch purification is in contrast to column purification (see Basic Protocol 2), in which the gel is packed in a column and the sample is passed through it. Batch adsorption is particularly useful where large volumes of sample are involved, which is usually the case in the capture stage of protein purification (*UNIT 8.1*). The equipment used here is sufficient for sample volumes up to 1.5 liter. Larger samples may be divided and processed with parallel apparatuses, or processed sequentially on a single apparatus. Different-sized funnels and side-arm flasks may be used when appropriate.

Once the starting conditions have been determined (see Support Protocol 1), the range of pH and salt concentration where binding and elution occur is well defined. Conditions for batch adsorption and elution used in this procedure are based on the results, presented in Figure 10.10.3, of a test tube pilot experiment performed as described in Support Protocol 1. Buffer volumes and equipment were chosen on the basis of a sample volume of 1 liter containing 50 to 1000 mg of total protein.

Elution of sample components adsorbed to an ion-exchange medium can be achieved either by increasing the salt concentration of the mobile phase, as in this protocol, or by changing its pH (see Alternate Protocol). In batch techniques, discontinuous (step) gradients are used for elution. Column chromatography (see Basic Protocol 2) allows the use of either step or continuous gradients. Formation of continuous gradients requires special equipment (see Basic Protocol 2 and Support Protocol 3).

The number of incremental steps to include in a step gradient must be judged empirically based on the resolution achieved. Ideally (as in the procedure described here), three steps should be used in which all weakly bound materials are desorbed and eluted in the first gradient step using wash buffer, the target protein is eluted in the second gradient step using elution buffer, and all strongly adsorbed materials are eluted in the third gradient step using regeneration buffer. A minimum increment of 50 mM NaCl is recommended for experiments using step-gradient elution with increasing salt concentration. Steps in the gradient may be added, omitted, or modified as determined empirically.

Materials

QAE Sephadex A-25 (Amersham Pharmacia Biotech) or equivalent
anion-exchange gel

Binding buffer: 20 mM Tris·Cl, pH 7.5 (or other buffer as determined empirically;
see Support Protocol 1)

Protein sample to be purified

Wash buffer: 20 mM Tris·Cl (pH 7.5)/100 mM NaCl (or other buffer/salt solution
as determined empirically; see Support Protocol 1)

Elution buffer: 20 mM Tris-Cl (pH 7.5)/350 mM NaCl (or other buffer/salt solution as determined empirically; see Support Protocol 1)

Regeneration buffer: 20 mM Tris-Cl (pH 7.5)/2 M NaCl (also see Support Protocol 5)

Boiling water bath (optional)

500-ml sintered-glass filter funnel, medium porosity

Three 2000-ml side-arm flasks

Conductivity meter

Swell and equilibrate ion-exchange gel

1. Add 10 g QAE Sephadex A-25 to 1 liter binding buffer and swell 2 days at room temperature or 2 hr in a boiling water bath.

The volume of swollen gel will be ~70 ml.

2. Mount 500-ml sintered-glass filter funnel on 2000-ml side-arm flask and apply suction.

Centrifugation (~5000 × g, 1 min) may be used instead of filtration to collect the gel, and may be preferred for processing small sample volumes. It is also possible to simply allow the gel to settle under gravity, then decant or aspirate the supernatant; this may be preferable for very large-scale operations.

3. Gently swirl swollen gel to resuspend. Pour gel slurry into funnel as fast as the fluid level in funnel permits, allowing buffer to collect in flask. Continue until all gel has been collected. Release suction after all buffer has been removed.

IMPORTANT NOTE: *Never use a magnetic stir-bar to resuspend chromatography medium. This can damage beads by grinding them against the bottom of the vessel, resulting in fine particles that can slow the filtration process.*

4. Add 200 ml binding buffer to funnel and resuspend gel using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer.

5. Repeat step 4 at least three times to ensure equilibration.

The gel is considered equilibrated when the pH and salt concentration of the eluant are the same as those of the binding buffer. If the procedures here are followed, there is little need to measure pH and salt concentration of the eluant because the gel is swollen and washed in binding buffer and the chance of error is very small. The worst-case scenario is that the target protein will not bind (see Troubleshooting). The repeated washings are more for the removal of fines than for adjustment of pH or salt concentration.

6. Add enough binding buffer (~100 ml) to produce an ~50% (v/v) slurry and allow gel to stand in funnel until sample has been prepared.

Adsorb sample to gel

7. Adjust pH and salt concentration of protein sample to initial optimal values.

For a pilot experiment to determine optimal initial values for pH and salt concentration, see Support Protocol 1.

Samples prepared by salt precipitation may require desalting prior to ion exchange (see UNIT 10.9). The sample can be dialyzed against the binding buffer. Also, the salt concentration of a sample can be reduced by adding distilled water until a desired salt concentration is achieved, as measured by a conductivity meter.

8. Combine gel and sample in 2000-ml beaker or wide-mouth flask.

The ~50% gel slurry is swirled and poured from the funnel; transfer may be aided with a rubber policeman, spoon, stirring rod, or wash bottle containing binding buffer.

9. Gently mix sample and gel by swirling every 15 min or shake on a platform shaker at sufficient rate to maintain gel in suspension. Allow 1 to 2 hr for binding at room temperature or 3 to 4 hr at 4°C.

IMPORTANT NOTE: Excessive shaking may result in foaming and possible denaturation of the target protein.

10. Collect gel by filtration as in step 3. Save filtrate for assay.

This filtrate is saved in case the target protein did not bind. All filtrates should be kept until the fraction containing the target protein has been identified. Storage conditions depend on the stability of the target protein; as a general rule they should be refrigerated to minimize microbial growth. Bacteriostatic agents may be added for prolonged storage.

11. Add 100 ml binding buffer to funnel and resuspend gel using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Repeat three or four times, pooling all washings with the filtrate from step 10.

The gel containing the bound sample may be packed in a column for subsequent elution steps (see Basic Protocol 2).

Elute with step gradient of increasing salt concentration

12. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

13. Add an equal volume of wash buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Save filtrate.

The wash buffer is the first step of the gradient. The filtrate will contain sample components that were weakly adsorbed to the gel (see annotation to step 10).

14. Measure absorbance of filtrate at 280 nm using wash buffer as blank.

15. Repeat steps 13 and 14 until the last filtrate shows no significant absorbance at 280 nm. Pool and save the filtrates.

16. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

17. Add an equal volume of elution buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand 5 min, then apply suction to remove buffer. Save filtrate.

The elution buffer is the second step of the gradient. The filtrate will contain the sample components that were more strongly adsorbed to the gel and should include the target protein.

18. Measure the absorbance of the filtrate at 280 nm using elution buffer as a blank.

19. Repeat steps 17 and 18 until the last filtrate shows no significant absorbance at 280 nm. Pool and save the filtrates for assay and subsequent purification of the target protein.

If gel is to be reused, continue with remaining steps. Otherwise, discard the gel.

Regenerate ion-exchange medium for reuse

20. Transfer the sintered-glass funnel to the top of a clean 2000-ml side-arm flask.

21. Add an equal volume of regeneration buffer to gel in funnel and resuspend using a stirring rod. Allow resuspended gel to stand for 5 min, then apply suction to remove buffer. Repeat five times and discard filtrates.

The regeneration buffer removes strongly bound materials from the gel. See Support Protocol 5 for additional considerations in regenerating ion-exchange media.

22. Repeat step 11 for a total of five washes to reequilibrate the gel with binding buffer.
23. Check the pH and conductivity of the last filtrate to ensure that the gel is properly equilibrated.

See Support Protocol 5 for information on storing ion-exchange media.

pH-BASED STEP-GRADIENT ELUTION

The net charge of a protein is pH dependent. Therefore, altering the pH of the mobile phase to make it closer to the pI of a protein can change its net charge, causing it to desorb and elute from an ion exchanger (see Figure 10.10.1). Continuous pH gradients are very difficult to produce at constant salt concentration because charge characteristics of sample components, buffering ions, and ion-exchange media depend on the pH of the system. pH-based step gradients are much easier to produce and more reproducible. For anion-exchange media, elution occurs when the pH is decreased. For cation exchange, the pH is raised for elution.

The first basic protocol can be modified for pH-gradient elution by selecting a buffer at a pH suitable for elution, based on results obtained in a pilot experiment (see Support Protocol 1). This elution buffer is then used in steps 17 to 19 of the first basic protocol. Incubation times and buffer volumes should be increased by 20% when using pH elution.

When scouting methods for ion exchange, it is best to start with changes in salt concentration (see Basic Protocol 1) as this technique is simpler and more reproducible. Elution with pH change is only recommended when the ion-exchange behavior of the sample is well known and the resolution required cannot be attained with a change in salt concentration. pH elution may also be appropriate in cases where it provides a superior ionic/pH environment for loading in the next chromatographic step. A combination of increasing salt concentration and pH change may also be used for elution.

COLUMN CHROMATOGRAPHY WITH LINEAR GRADIENT ELUTION

Column chromatography is generally preferred to batch chromatography (see Basic Protocol 1), especially where high resolution is required, although it accommodates smaller sample volumes. Column chromatography requires specialized equipment to achieve high resolution, including a column containing the medium and a fluid-delivery system appropriate for the pressure and flow rate at which the column is to be operated. It is the technique preferred for the intermediate purification and polishing stages of protein purification. Also in contrast to the first basic protocol, this technique uses a linear gradient for elution. Although more difficult to produce than step gradients (see Basic Protocol 1), linear gradients lead to better resolution (see Support Protocol 3).

The example presented here uses a RESOURCE Q anion-exchange column from Amersham Pharmacia Biotech, which may be used with either FPLC (fast protein liquid chromatography) or HPLC (high-performance liquid chromatography) systems. Optimal conditions for other columns should be obtained from the manufacturer. Procedures mentioned in the protocol steps should be carried out according to the manufacturer's instructions for the particular chromatography system being used.

NOTE: All buffers, media, and other system components should be filtered, degassed, and equilibrated to the same temperature before use.

**ALTERNATE
PROTOCOL**

**BASIC
PROTOCOL 2**

**Analysis of
Proteins**

10.10.13

Materials

Liquid chromatography system (FPLC or HPLC)

Elution buffer: binding buffer (see Basic Protocol 1 and Support Protocol 1) containing 1 M NaCl

Binding buffer (see Basic Protocol 1 and Support Protocol 1)

RESOURCE Q chromatography column (1-ml packed bed volume; Amersham Pharmacia Biotech)

Protein sample to be purified

Conductivity meter

0.22- μ m filter

Prepare chromatography system

1. Set up the liquid chromatography system according to manufacturer's instructions, without the column in-line.
2. Test system performance by running a blank gradient ranging from 0% to 100% elution buffer in 20 ml at a constant flow rate of 5 ml/min.

See Figure 10.10.2 for a diagram of a typical column chromatography system. The gradient is formed by placing binding and elution buffer in the appropriate buffer reservoirs (see Support Protocol 3 for detailed discussion of continuous gradient formation).

Figure 10.10.2 Liquid column chromatography system with gradient maker.

Stability of the column at extremes of pH must be considered when choosing binding and elution buffers. The working stability of the RESOURCE Q column is pH 2 to 12, and the stability for cleaning is pH 1 to 14.

The flow rate for the test should be appropriate for the column to be connected. For the RESOURCE Q column, the recommended flow rate is 1 to 10 ml/min and the maximum operating pressure is 4 bar.

3. Test for system leaks and ascertain monitor stability according to system documentation. Test accuracy of gradient composition using conductivity meter.

Adding 0.1% (v/v) acetone to the elution buffer used in step 2 will allow observation of gradient composition at 280 nm using the UV monitor. Do not include acetone in the elution buffer used for the chromatographic run.

Prepare column

4. Purge system with binding buffer to remove any air, then install column in system.

New columns may require precycling prior to use; consult product documentation. Used columns may require cleaning or removal of storage solution prior to use (see Support Protocol 4).

5. Wash column with $5 V_c$ (5 ml for RESOURCE Q column) of elution buffer at a flow rate of 5 ml/min and check for leakage.

V_c refers to the packed bed volume of a column and is calculated according to the equation $V_c = \pi r^2 \times L$, where r is the radius of the column and L is the bed height (i.e., the height of the packed medium in the column). As the RESOURCE Q column used here has a packed bed volume of 1 ml, the column is washed with 5 ml of elution buffer. Consult product literature to find V_c for other columns.

6. Equilibrate column with 5 to 10 V_c of binding buffer at 5 ml/min. Collect one fraction at the end of the equilibration stage and measure pH and conductivity to ensure the pH and salt concentration of the fraction are the same as that of binding buffer.

If the pH and salt concentration of the fraction are not the same as that of the binding buffer, continue passing binding buffer through the column until equilibration is complete.

Purify protein sample and regenerate column

7. Adjust pH and salt concentration of sample to binding conditions determined in Support Protocol 1. Filter sample prior to injection using a 0.22- μ m filter to remove particulates that may clog system or column.

For initial experiments, a sample containing 25 mg total protein is appropriate.

For columns packed with beads of average diameter $\geq 90 \mu\text{m}$, a 1- μm filter may be used; for columns packed with beads of average diameter 34 to 90 μm , a 0.45- μm filter may be used. The 0.22- μm filter is appropriate for columns packed with beads of average diameter $< 34 \mu\text{m}$ (e.g., the RESOURCE Q). Alternatively, the sample may be centrifuged 5 min at $20,000 \times g$ to remove particulates.

8. Inject sample into column by opening sample injection valve. Begin fraction collection.

Fractions of 1-ml volume are generally sufficient.

The flow rate during sample injection should be reduced for concentrated samples. It may be increased for dilute samples.

9. After all sample is injected, wash column with 3 to 5 V_c of binding buffer at 5 ml/min to remove unbound or weakly bound materials.

The monitor signal should be allowed to approach the baseline before continuing.

10. Elute with a linear gradient of 0% to 100% elution buffer in 20 V_c (20 ml).
Sample-injection valves should be closed to reduce the system dead volume before beginning gradient.
11. Regenerate column by washing with 5 V_c of elution buffer.
12. Reequilibrate column by washing with 5 to 10 V_c of binding buffer.
13. Assay fractions for target protein. Pool fractions containing target protein for further processing.

TEST TUBE PILOT EXPERIMENT TO DETERMINE STARTING CONDITIONS FOR ION-EXCHANGE CHROMATOGRAPHY

Before beginning an ion-exchange separation (Basic Protocol 1 or 2), the pH and salt concentration required for binding the target protein and the change in pH or salt concentration required for elution must be determined empirically. Once the initial binding conditions have been determined, the available protein capacity (for batch chromatography) is determined to predict the amount of medium that must be used for a given amount of sample. Dynamic capacity (for column chromatography) may be determined as in Support Protocol 2. This protocol is most appropriate when the sample is not strictly limited—e.g., when milligram quantities of a recombinant protein are available. If sample is scarce, a column method should be substituted.

As illustrated in Figure 10.10.3, aliquots of the protein-containing sample to be purified are mixed in test tubes with small quantities of ion-exchange gel that have been equilibrated with a series of buffers of different pH. The optimal binding pH is chosen on the basis of disappearance of target protein in the supernatant at a certain point in the series, then the process is repeated with another series of test tubes containing gel equilibrated with a series of salt solutions of different concentrations. The optimal salt concentrations for binding and elution are chosen, respectively, on the basis of disappearance, then reappearance at another salt concentration, of protein in the supernatant. Finally, aliquots containing increasing protein concentrations are mixed with the gel in a buffer under the optimal binding pH and salt concentrations previously determined. The available capacity of the gel is then determined on the basis of the point where unbound protein appears in the supernatant.

The stability of the target protein at extremes of pH must be considered—i.e., the pH range chosen for the purification should be compatible with retention of structure and activity. In general, this can be evaluated with a crude preparation by incubating aliquots at a series of pH values, then performing the structural or functional assay at the optimal pH value.

NOTE: The method presented here is for anion exchange with increasing salt concentration for elution. Differences for cation exchange are noted where appropriate. Select cation-exchange buffers from Table 10.10.1.

Materials

- 20 mM piperazine, pH 5.0, 5.5, and 6.0 (prepare from 100 mM stock)
- 20 mM 1,3-bis[tris(hydroxymethyl)methylamino]propane (bis-Tris propane), pH 6.5 and 7.0 (prepare from 100 mM stock)
- 20 mM Tris·Cl, pH 7.5, 8.0, and 8.5 (*APPENDIX 2*; prepare from 100 mM stock)
- Q Sepharose Fast Flow (50% slurry in 20% ethanol; Amersham Pharmacia Biotech) or equivalent anion exchange resin in appropriate buffer
- Protein sample to be purified, containing known quantity of target and total protein

4 M NaCl

15-ml test tubes

Centrifuge with rotor accommodating 15-ml test tubes (optional)

Determine optimal binding pH

1. Set up a series of test tubes, numbered 1 to 8, containing different buffers as follows:

- tube 1: 5 ml 20 mM piperazine, pH 5.0
- tube 2: 5 ml 20 mM piperazine, pH 5.5
- tube 3: 5 ml 20 mM piperazine, pH 6.0
- tube 4: 5 ml 20 mM bis-Tris propane, pH, 6.5
- tube 5: 5 ml 20 mM bis-Tris propane, pH 7.0
- tube 6: 5 ml 20 mM Tris·Cl, pH 7.5
- tube 7: 5 ml 20 mM Tris·Cl, pH 8.0
- tube 8: 5 ml 20 mM Tris·Cl, pH 8.5.

2. Shake bottle of Q Sepharose Fast Flow to resuspend gel. Pour 25 ml of gel slurry into a graduated cylinder, then allow gel to settle. Adjust volume of liquid above gel to equal the volume of settled gel (i.e., prepare 50% slurry), then resuspend with a glass stirring rod.

Figure 10.10.3 Results of a typical test tube pilot experiment for selecting initial conditions for anion-exchange chromatography. Series of tubes with protein and ion-exchange medium at **(A)** varying pH (to select binding and elution pH); **(B)** constant pH, varying NaCl concentration (to select binding and elution salt concentrations); **(C)** constant pH and NaCl concentration, varying protein concentration (to determine available capacity). The binding pH here will be ≥ 7.5 ; the elution pH will be ≤ 5.0 ; the binding salt concentration will be ≥ 0.15 M; the elution salt concentration will be > 0.3 M; and the available capacity will be > 50 mg/ml.

3. Add 2 ml of 50% slurry of Q Sepharose Fast Flow to each tube and mix.
SP Sepharose Fast Flow (Amersham Pharmacia Biotech) or equivalent may be used for cation exchange.
4. Allow gel to settle to bottom of tube or centrifuge 1 min at $\sim 5000 \times g$, room temperature.
5. Decant supernatant from each tube and replace with 5 ml of the same buffer added in step 1. Gently shake or vortex to resuspend gel, then let tubes stand 2 min.
6. Repeat steps 4 and 5 three times to equilibrate gels in each tube.
7. Decant supernatants and resuspend each equilibrated gel in 1 ml of the same buffer added in step 1.
8. Set up eight identical aliquots (≥ 1 ml) of the protein to be purified in tubes numbered 1 to 8, each containing 0.1 to 1 mg total protein. Adjust the pH of each to obtain eight different pH values corresponding to those of tubes 1 to 8 in step 1.

Quantity of protein to be used depends on availability of sample and extinction coefficient of target protein. pH may be adjusted by titrating with acid or base using pH paper or by diluting 1:1 with buffer of desired pH.

9. Add the corresponding pH-adjusted protein aliquot to each of the 8 tubes from step 7. Mix gently for 10 min by periodic swirling, then allow gel to settle.

If the salt concentration of the sample is too high, no binding will occur. It is therefore recommended that the sample be desalted into the appropriate buffer as in UNIT 10.9.

10. Assay supernatant from each tube for the target protein.

Measuring the absorbance of the supernatant at 280 nm is usually sufficient. Figure 10.10.3 shows a set of possible results. A decrease or absence of target protein activity (or absorbance) in the supernatant indicates binding. Specific assays for the target protein may also be used.

11. Select the lowest pH at which the highest quantity of target protein is bound to use as the binding pH for further work. Select the highest pH where no binding occurs as the elution pH.

For anion exchange, it is best to select a binding pH no more than 0.5 to 1 pH unit (pH 7.5 to 8.0 in Fig. 10.10.3) above the highest pH at which no binding occurs. If too high a pH is chosen, elution becomes difficult and high salt concentrations may be required.

For cation exchange, select a binding pH 0.5 to 1 unit below the lowest pH where no binding occurs. Select the lowest pH where no binding occurs as the elution pH.

Determine salt concentration for binding and elution

12. Set up a series of test tubes, numbered 1 to 10. Using the binding buffer selected in step 10 in place of the different buffers in step 1, perform steps 1 to 7 to equilibrate the Q Sepharose Fast Flow with buffer in all ten tubes.
13. To each tube, add the same amount of the protein to be purified that was added to the tubes in step 8, equilibrated in the binding buffer selected in step 10.
14. Mix contents of tubes gently for 10 min, then allow gel to settle.
15. Decant supernatants from each tube and discard. Wash gel two times with 5 ml of the binding buffer, allowing the gel to settle and decanting the supernatants after each addition of buffer.

16. Add 2 ml of the binding buffer to each tube, then sequentially add water and 4 M NaCl to each tube as follows:

tube 1: 1.90 ml H₂O and 0.10 ml 4 M NaCl (0.10 M NaCl final)
tube 2: 1.80 ml H₂O and 0.20 ml 4 M NaCl (0.20 M NaCl final)
tube 3: 1.70 ml H₂O and 0.30 ml 4 M NaCl (0.30 M NaCl final)
tube 4: 1.60 ml H₂O and 0.40 ml 4 M NaCl (0.40 M NaCl final)
tube 5: 1.50 ml H₂O and 0.50 ml 4 M NaCl (0.50 M NaCl final)
tube 6: 1.40 ml H₂O and 0.60 ml 4 M NaCl (0.60 M NaCl final)
tube 7: 1.30 ml H₂O and 0.70 ml 4 M NaCl (0.70 M NaCl final)
tube 8: 1.20 ml H₂O and 0.80 ml 4 M NaCl (0.80 M NaCl final)
tube 9: 1.10 ml H₂O and 0.90 ml 4 M NaCl (0.90 M NaCl final)
tube 10: 1.00 ml H₂O and 1.00 ml 4 M NaCl (1.00 M NaCl final).

17. Mix contents of tubes gently for 10 min, then allow gel to settle.
18. Assay supernatant from each tube for the target protein.

Figure 10.10.3 shows a set of possible results. Presence of target protein in the supernatant indicates elution of the target protein.

19. Select the highest salt concentration at which no elution occurs as the maximum salt concentration allowable for binding target protein and for washing away unbound sample components. Select a salt concentration at least 0.05 M above the concentration where no protein binds to the gel as the salt concentration for elution.

Determine available capacity

20. Prepare a buffer/salt solution with the binding pH selected in step 10 and the binding salt concentration selected in step 19.
21. Set up a series of test tubes numbered 1 to 10. Using the buffer/salt solution prepared in step 20 in place of the different buffers in step 1, perform steps 1 to 7 to equilibrate the Q Sepharose Fast Flow with buffer/salt solution in all ten tubes.
22. Add aliquots of sample to each tube to obtain the following amount of target protein:

tube 1: 10 mg
tube 2: 20 mg
tube 3: 30 mg
tube 4: 40 mg
tube 5: 50 mg
tube 6: 60 mg
tube 7: 70 mg
tube 8: 80 mg
tube 9: 90 mg
tube 10: 100 mg.

23. Mix gently for 10 min, then allow gel to settle.
24. Assay supernatant from each tube for the target protein.

Figure 10.10.3 shows a set of possible results. Presence of target protein in supernatant indicates that the available capacity has been exceeded.

25. Select the highest protein concentration at which the target protein does not appear in the supernatant as the available capacity.

Calculate the amount of ion-exchange medium needed for batch purification based on 50% of the available capacity. If a column system is used in pilot experiments, however, it is best to determine the dynamic capacity of the medium (see Support Protocol 2). However, 20% of the available capacity is a safe and reasonable starting point for pilot experiments using column chromatography.

**MEASUREMENT OF DYNAMIC (COLUMN) CAPACITY AND
BREAKTHROUGH CAPACITY OF ION-EXCHANGE COLUMNS**

For chromatographic separations that will be performed on a routine basis as well as separations that will be scaled up, it is necessary first to optimize conditions with respect to resolution and to determine the capacity of the medium with respect to the target protein (see Support Protocol 1). Knowledge of the capacity allows optimal use of the gel medium in terms of cost and yield, and also allows working limits to be set on the sample load to ensure robustness of a particular purification step. After capacity has been determined, the separation can be optimized with respect to time. There are two capacity terms that commonly appear in the literature (in addition to available capacity; also see Support Protocol 1): dynamic capacity and breakthrough capacity.

The dynamic (or column) capacity is the capacity of an ion-exchange column under defined conditions of flow rate, pH, salt concentration and sample concentration. The breakthrough capacity (Q_B) for a system is obtained by calculating the amount of protein that has been absorbed by the column when the sample is first detected in the effluent, or when the recorder signal reaches some arbitrarily defined percent of full-scale deflection. Breakthrough capacity values at 50% full-scale deflection (Q_{B50}) are commonly reported in the literature. However, it is generally recommended to use only 10% to 20% of the published Q_B as the practical capacity of the column to ensure high recovery of the target protein.

Additional Materials (also see Basic Protocol 2)

Ion-exchange gel of unknown capacity, and column
Elution buffer capable of eluting target protein in single step of salt concentration or pH (e.g., 2 M NaCl; see Support Protocol 1)

1. Pack a defined amount of the ion-exchange gel into the column.

See UNIT 10.9 for guidelines on column packing. Normally, a quantity of gel sufficient to give a packed bed volume of ~1 ml is sufficient. In the case of a prepacked column, the amount of gel is predetermined. The packed bed volume (V_c) is calculated according to the equation $V_c = \pi r^2 \times L$, where r is the radius of the column and L is the bed height (i.e., the height of the packed medium in the column).

2. Prepare chromatography system and column (see Basic Protocol 2, steps 1 to 6) using the optimal binding and elution conditions determined in Support Protocol 1.

Do not exceed 75% of the flow rate used for packing. The effect of flow rate on capacity should be determined in a true optimization.

3. Prepare protein solution and inject into column (see Basic Protocol 2, steps 7 and 8). Apply solution continually until the recorder shows >50% full-scale deflection, then stop.

The absorbance of the binding buffer corresponds to 0% and the absorbance of the sample corresponds to 100% full-scale deflection.

4. Wash column with binding buffer until 0% full-scale deflection is approached.

5. Elute proteins with a buffer providing a single-step increase in salt concentration or pH. Continue collecting eluant until recorder shows $\leq 2\%$ full-scale deflection, then pool fractions.

A typical chromatogram for this procedure is presented in Figure 10.10.4.

6. Assay pooled fractions from step 5 for target protein. Calculate maximum amount of protein (A) that can be bound to the column according to the equation $A = C_p \times V$,

Figure 10.10.4 Typical chromatogram for determining the capacity of an ion-exchange column. The volume of eluant (x) at 50% full-scale deflection is used to calculate the breakthrough capacity (Q_{B50}).

where C_p is the protein concentration of the pooled fractions (mg/ml) and V is the volume of the pooled fractions (ml).

7. Calculate the column (dynamic) capacity (mg/ml) using the equation dynamic capacity = A/V_c .
8. Calculate breakthrough capacity (Q_{B50}) using the equation $Q_{B50} = (C_s \times x)/V_c$, where C_s is the concentration of protein in the original sample and x is the volume of sample that has been applied to the column at the point where 50% full-scale deflection has been attained.

If Q_{B50} greatly exceeds the dynamic capacity, then the target material may still be adsorbed on the column, and the elution conditions should be reexamined.

See Figure 10.10.4 for graphical depiction of these variables.

GRADIENT-FORMATION TECHNIQUES

Simple Gradient Mixers

Gradient mixers of the type shown in Figure 10.10.5 can generate linear pH or salt gradients in gravity-based or one-pump chromatography systems. Similarly designed gradient mixers used for casting electrophoresis gels may also be used for chromatography. The reservoir closest to the column is filled with the binding buffer and the second reservoir is filled with an equal volume of the elution buffer. The gradient begins when the valve between the two reservoirs is opened. Continuous mixing is required in the reservoir closest to the column to ensure gradient linearity and reproducibility.

**SUPPORT
PROTOCOL 3**

**Analysis of
Proteins**

10.10.21

Figure 10.10.5 Gradient mixer for forming gradients of pH and salt concentration used during ion-exchange chromatography. The apparatus shown is an Amersham Pharmacia Biotech Gradient Mixer GM-1, which can be used for preparing gradients up to 500 ml. A linear gradient of salt concentration is produced by filling the reservoirs with buffers at the same pH and different salt concentration. The mixing chamber contains the lower-salt-concentration (binding) buffer, and the other chamber contains the higher-salt-concentration (elution) buffer. A continuous linear or nonlinear pH gradient may be produced by filling the reservoirs with buffers at the same salt concentration and different pH. A gradient of increasing pH is used for cation-exchange separations, and a gradient of decreasing pH is used for anion-exchange separations. The buffer chambers are joined by a channel controlled by a valve, and outflow from the mixing chamber is controlled by another valve.

Gradient Mixing with Multichannel Peristaltic Pumps

Peristaltic pumps that can accommodate three or more pumping channels simultaneously (Fig. 10.10.6) can be used to form linear or complex gradients (see Critical Parameters). Linear gradients are easily formed by using the same size tubing for all channels, pumping with one channel from the elution buffer reservoir to the binding buffer reservoir, and pumping with the other two channels from the binding buffer reservoir to the column. Continuous mixing is required in the binding buffer reservoir closest to the column to ensure gradient linearity and reproducibility.

Switch-Valve-Based Gradient Mixing

Switch-valve-based gradient formation is useful for forming step, linear, and complex gradients (see Critical Parameters). Gradients are formed by proportioning variable amounts of binding buffer and elution buffer through a single three-way valve using a system controller. When programmed to deliver 10% elution buffer, the controller will open the valve port for binding buffer 90% of the time and the port for elution buffer 10% of the time. As higher switching rates are required for lower flow rates to ensure gradient accuracy, high-quality system controllers will vary the rate at which the valve switches (i.e., the number of switching events per unit time) as a function of flow rate. A dynamic mixer should be included in the flow path just after the proportioning valve to ensure gradient accuracy. Switch-valve-based gradients are generally not very accurate from 1% to 10% elution buffer (90% to 99% binding buffer) or from 1% to 10% binding buffer (90% to 99% elution buffer). Therefore, the ionic strength of the binding and elution buffers may be adjusted to allow a gradient of the desired composition to be formed by mixing the two buffers in the range of 20% to 80% elution buffer (80% to 20% binding buffer).

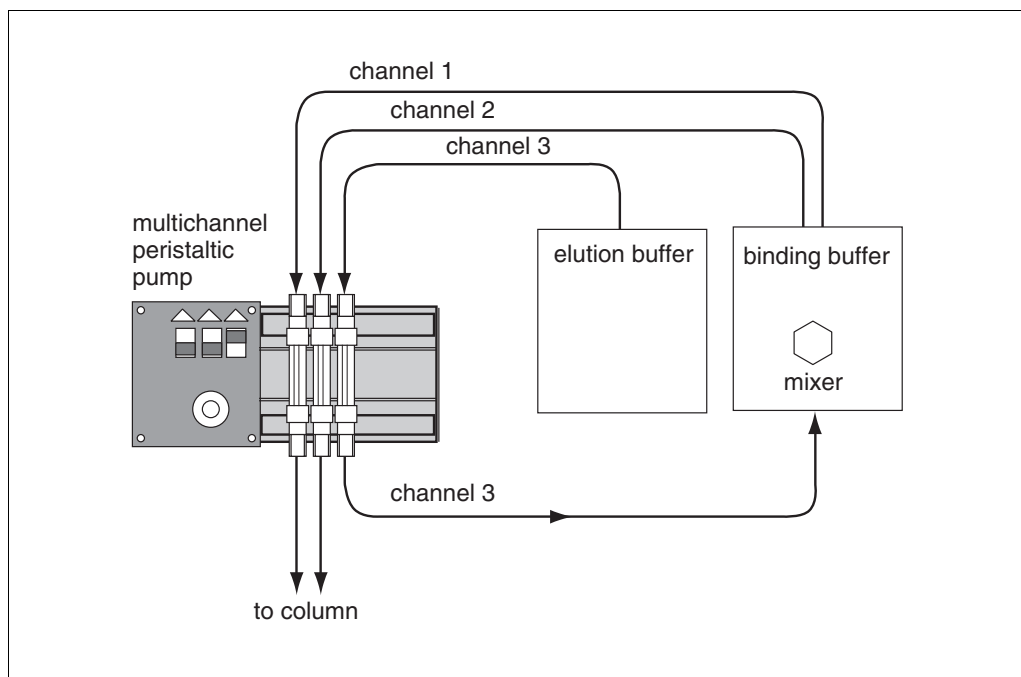

Figure 10.10.6 Peristaltic pump accommodating three pumping channels for continuous gradient formation.

Gradient Formation by Autoblending

Some chromatography systems allow gradient formation over a range of both pH and salt concentration. Four solvents—a high-pH buffer, a low-pH buffer, a concentrated salt solution, and water—are blended via four two-way valves. A system controller proportions the high- and low-pH buffers to achieve the desired pH gradient while simultaneously proportioning the concentrated salt solution and water to achieve the desired salt-concentration gradient. Gradients formed in this way are usually difficult to reproduce but may be useful for scouting initial binding and elution conditions.

Gradient Formation with Twin Pumps

Use of two positive-displacement pumps, as in HPLC and FPLC systems, provides the highest degree of accuracy, precision, and reproducibility in gradient formation. One pump delivers binding buffer while the other delivers elution buffer. A system controller allows gradient formation simply by controlling the flow rate of each pump. A dynamic mixer should be included in the flow path, after the pumps and before the column, to ensure gradient accuracy.

CLEANING AND REGENERATION OF ION-EXCHANGE MEDIA

Proper maintenance of chromatography media is as much an art as protein purification itself. Knowing what kind of contaminating material from the sample is bound to the column helps in selecting a regime for maintaining good column hygiene. It is best to practice preventative maintenance by regenerating the medium after every run, using a high-salt buffer or large change in pH, and periodically cleaning the column and checking the system flow characteristics. If any increase in column back-pressure is noted, the column should be cleaned as soon as possible. Once enough contaminant has bound to a column to reduce or block the flow, it is probably too late to save the medium without investing considerable time and effort.

**SUPPORT
PROTOCOL 4**

**Analysis of
Proteins**

10.10.23

Routine Washing of Columns and Media

Columns or bulk medium should be washed after every run with salt solution until an ionic strength of ≥ 2 M is reached. This should remove any substances bound by ionic forces. This is recommended after every run.

Removal of Contaminants

Alkali-soluble contaminants. Contaminants such as lipids, proteins, and nucleic acids can usually be removed by washing with 2 to 3 column volumes of 0.1 M NaOH, followed by 2 to 3 column volumes of Milli-Q-purified (or equivalent) distilled water and then 2 to 3 column volumes of binding buffer. Many media can tolerate brief exposure to 1 M NaOH, if harsher conditions are required to remove contaminants; however, manufacturer's guidelines should be consulted regarding pH stability of the medium.

Hydrophobic contaminants. Lipids and other hydrophobic materials may be removed by washing with alcohol solutions (e.g., 70% ethanol) or nonionic detergents. When using alcohols or organic solvents to remove hydrophobic materials, it is often effective to wash first with a gradient from 0% to 100% and then with a gradient from 100% to 0%. Repeat washing with the alternating gradients until no contaminants are detected in the eluant.

Metallic contaminants. Contamination with metals may cause blue or gray discoloration at the top of an ion-exchange column. These metals can originate from impurities in buffer salts or water, or they can leach from metallic system components in contact with buffer solutions. Metal contaminants may usually be removed by treating the column with several column volumes of 10 mM HCl (i.e., pH 2) saturated with EDTA. Manufacturer's guidelines should be checked for pH stability of medium and column before exposure to mild or strong acid solutions.

Precipitated materials. Precipitated materials that have accumulated in a column are very difficult to remove. Unless the precipitated material can be physically removed by removing the gel at the top of the column, the material will have to be resolubilized. Detergents, urea, and guanidine-Cl can be introduced to help dissolve contaminants. The viscosity of concentrated solutions used for cleaning may require very low flow rates. The column may be equilibrated and incubated in 6 M urea, then washed with distilled water and buffer. Degradative enzymes (e.g., proteases and lipases) may also be introduced in an attempt to degrade precipitates on the column; however, enzymatic cleaning can be quite expensive. It may be useful to reverse the direction of flow through the column (i.e., from bottom to top) when attempting to remove particulate material from the top of the bed.

SUPPORT PROTOCOL 5

STORAGE OF ION-EXCHANGE MEDIA

Bacterial and microbial growth can seriously interfere with the chromatographic properties of any chromatography medium and endanger the sample as well. Prior to storage, all media should be cleaned and sanitized. During prolonged experiments or storage (i.e., >24 hr at room temperature or 48 hr at 4°C), a bacteriostatic or antimicrobial agent should be added to the ion exchanger. Antimicrobials chosen to be added for storage should not bind to the ion exchanger and should be easily removed when the gel is to be reused. Azide is anionic and will bind to anion-exchange media.

Treatment with 1 M NaOH for 1 hr will sanitize most media by lowering the bacterial count 100-fold, and will help solubilize dead cells (Pharmacia Biotech, 1997). Storage of sanitized media in 0.1 M NaOH will not leave any toxic materials on the column—a significant consideration in pharmaceutical production. Manufacturer's guidelines should

be checked for stability of the medium and column in NaOH. Silica-based media will not tolerate high pH.

Exposure to 70% ethanol for 3 to 4 hr can be used to sanitize most media. Most ion-exchange media and columns can be stored for prolonged periods of time in 20% ethanol. Manufacturer's guidelines should be checked for stability of the medium and column in ethanol.

Effective antimicrobial agents appropriate for use with anion-exchange media include either 0.001% phenyl mercuric salts or 0.002% chlorhexidine, in weakly alkaline solution.

An effective antimicrobial agent for use with cation-exchange media is 0.005% merthiolate in weakly acidic solution. An agent that is effective for use with either anion or cation exchangers is 0.05% trichlorobutanol in weakly acidic solution.

COMMENTARY

Background Information

The first ion exchangers were synthetic resins designed for applications such as demineralization, water treatment, and recovery of ions from waste. Early ion-exchange resins were tightly cross-linked hydrophobic polymers, highly substituted with ionic groups, and had very high capacity for small ions. The high degree of cross-linking provided mechanical strength, but the limited porosity restricted use of these media with large molecules. In addition, the high charge density resulted in very strong binding, and the hydrophobic matrix tended to adsorb and denature labile biological materials. The first ion exchangers designed for use with biomolecules were developed by Peterson and Sober (1956). These cellulose-matrix ion exchangers were very hydrophilic and had little tendency to denature proteins, but had low capacities and poor flow characteristics. Modern ion-exchange media have very high capacity, often >100 mg/ml. Modern particle technology has significantly increased the mechanical strength and flow characteristics of ion-exchange media so that separations that once required hours or days may now be completed in a few minutes.

Ion-exchange can easily be coupled to other methods of protein separation in a multistep purification. Samples purified by ion exchange can typically be applied to a hydrophobic-interaction chromatography (HIC) medium simply by adding NaCl (or other salts) to a concentration sufficient for binding. Samples to be further purified by chromatofocusing or an additional round of ion exchange will require desalting (UNIT 10.9). Samples may usually be applied directly to gel-filtration columns (UNIT 10.9) with no intervening treatment.

Critical Parameters

The most critical aspects of any ion-exchange experiment are selection of the appropriate ion-exchange medium and of the initial conditions for binding and elution of the target protein or contaminants. Once these parameters are selected, conditions can be optimized with respect to the three primary parameters of any chromatographic separation—i.e., resolution, capacity, and speed. These three parameters are mutually exclusive. Resolution will typically decrease when the sample load is increased and when the flow rate is increased (to increase speed). It is generally recommended that resolution be optimized first, then capacity, and finally speed.

Optimization of resolution

This parameter is most easily optimized by controlling the selectivity of the medium through manipulation of binding and elution conditions. Construction of chromatographic titration curves followed by optimization of the shape of the elution gradient is a common approach to achieving maximum resolution.

Chromatographic titration curves can be constructed by performing a series of anion- and cation-exchange experiments at different pH values as in Figure 10.10.7. For each of these experiments, the elution salt concentrations (in mM NaCl) for sample components A, B, and C are plotted on the y axis and the operating pH is plotted on the x axis. It is then simple to observe the pH ranges within which optimal resolution between the various sample components is achieved. The different sample components are usually detected by UV absorption, but may also be viewed by other means (e.g., fluorescence or bioactivity). Data for chromatographic titration curves can often

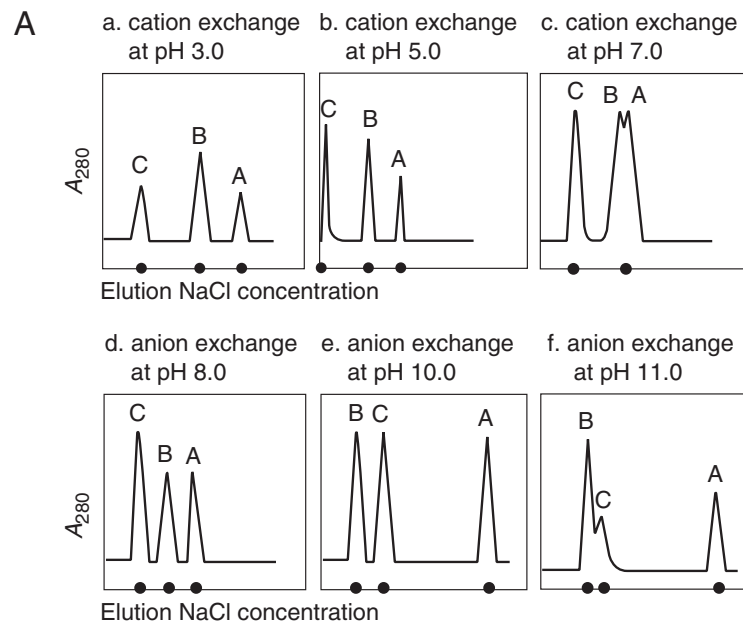

Figure 10.10.7 Construction of a chromatographic titration curve. **(A)** Six chromatographic separations (a to f) of a sample containing proteins A, B, and C are carried out at six different operating pHs using a linear gradient of increasing salt concentration. **(B)** The elution ionic strengths for components A, B, and C (y axis) are plotted against the operating pH (x axis) for experiments a to f. Note that the salt concentration in mM NaCl (y axis) is ascending in both directions. The optimal resolution with respect to component A occurs below pH 5 with cation exchange and above pH 9 with anion exchange.

be generated by fast screening with low-volume gradients (e.g., 5 to 10 V_c) and low sample mass (e.g., <1 mg).

After optimization of resolution with respect to pH, the shape of the elution gradient can be optimized. A gradient can be conceptually divided into segments, and each segment may have a different gradient shape. Gradient shapes include linear, concave, convex, and step. Complex gradients are constructed by using different gradient shapes in consecutive segments. The slope (e.g., mM NaCl per minute) of a linear segment is constant, that of a concave segment continually increases, that of a convex gradient continually decreases, and that of a step gradient approaches infinity. Resolution between sample components in any segment can usually be increased by decreasing the gradient slope in that segment. However, decreasing the gradient slope will increase the peak volume during elution, the gradient volume, and the time of the separation. Step gradients can provide the most concentrated fractions, and are desirable when minimizing sample volume is of primary importance. Use of concave gradients in the initial part of a segment and convex gradients in the later part of a segment can improve resolution. The capabilities of available equipment must be considered in the construction of complex gradients. Use of simple gradients that do not stress the performance limits of the system will result in robust methods that are insensitive to small changes in sample or buffer composition and gradient shape, thereby increasing probability of success.

To construct a complete gradient profile, it is first necessary to identify the gradient range where desorption of the target protein occurs, as well as the gradient slope that provides optimal resolution. A single-step elution is then done at a salt concentration just below the range of where the target protein elutes, to remove weakly bound material. The target protein is then desorbed and eluted. A single-step elution at a high salt concentration will then remove tightly bound sample components and prepare the ion-exchange gel for regeneration. This approach, using step gradients before and after the range of interest, can provide simple, robust methods that are easy to scale up, and will save time and reagents.

Different ion-exchange media offer different selectivities. If adequate resolution for a specific stage in a purification cannot be obtained with a specific ion-exchange medium, it

may be desirable to select an alternate ion exchanger with a different functional group, or to use a different chromatographic technique at this stage in the separation. Salts other than NaCl may be used in elution, but there are no specific effects from different salts on the separation in ion-exchange chromatography, other than differences in concentration. Karlsson et al. (1998) provides a good review of the effects of nonbuffering ionic species in ion exchange.

Optimization of capacity

When optimum resolution has been achieved, the effect of increasing sample load on resolution should be evaluated to determine the optimal balance of resolution and capacity utilization. The procedure for determining the dynamic (column) capacity is described in Support Protocol 3 and can be performed using the conditions for optimal resolution (as determined above) to elute the target protein. Once the capacity is determined under the optimal elution conditions, the effect of changes in sample load on resolution can be investigated to identify optimal conditions. It is generally recommended that only 10% to 20% of the dynamic capacity be used to ensure high recoveries of the target protein.

Optimization of throughput

Once optimal conditions for resolution and capacity have been determined, the flow rate in each gradient segment may be increased and the effect on resolution and capacity monitored to complete the optimization process.

Troubleshooting

Common problems encountered during ion-exchange experiments, their potential causes, and suggested solutions are outlined in Table 10.10.5.

Anticipated Results

A chromatogram illustrating typical results of an ion-exchange column chromatography experiment (i.e., Basic Protocol 1) is shown in Figure 10.10.8.

The goal of any purification step is the pure target protein obtained at the end of the day. The chromatogram is only a record for comparison and is deceptive at best. Great care should be exercised in interpreting a chromatogram—i.e., the results from assays performed on fractions collected must be used in interpreting the chromatogram and inferring the identity of any given chromatographic peak.

Table 10.10.5 Troubleshooting Guide for Ion-Exchange Chromatography

Problem	Possible cause	Solution
Protein does not elute in the salt gradient	Buffer pH is incorrect	Use buffer pH closer to pI of the protein
	Salt concentration is too low	Use more concentrated elution buffer
Protein does not elute in pH gradient	Buffer pH is incorrect	Calibrate pH meter and prepare new solutions
Protein elutes in wash phase	Salt concentration of binding buffer is too high	Decrease salt concentration of binding buffer
	Salt concentration of sample is too high or pH is wrong	Perform buffer exchange on sample
	Column is not properly equilibrated	Repeat or prolong equilibration until conductivity is constant
	Ionic detergents or other additives are absorbed to column	Clean column
Resolution is less than expected	Gradient slope is too steep	Use shallower gradient or include plateau in gradient
	Flow rate is too high	Run separation at lower flow rate
	Proteins or lipids have precipitated on columns	Clean and regenerate column
	Sample has not been filtered properly before application to the column	Regenerate column, filter sample, and repeat chromatography
	Proteins in sample have formed aggregates that bind strongly to gel	Use urea or detergents to clean column
	Column is poorly packed	Check packing by running a colored compound and observing the band. Repack column if necessary.
	Too much sample mass has been loaded onto column	Clean and regenerate column. Decrease sample load and repeat run.
	Detector flow cell volume or mixing spaces in or after column are too large	Change flow cell or reduce all post-column volumes
Leading or very rounded peaks observed in chromatogram	Column is overloaded	Decrease sample load and repeat run
	Column is poorly packed	Check packing by running a colored compound and observing the band. Repack column if necessary.
	Column needs regeneration	Clean and regenerate column. If this does not help, replace with new one.
Tailing of peak is observed in the chromatogram	Sample is too viscous	Reduce amount of protein, or remove nucleic acids from sample.
	Precipitation of protein has occurred in column filter and/or at top of the gel bed	Clean column; exchange or clean filter.
	Column is poorly packed	Check packing by running a colored compound and observing band. Repack column if necessary.
Previous elution profile cannot be reproduced	Buffer pH and/or ionic strength are incorrect	Prepare new solutions
	Sample has deteriorated during storage	Prepare fresh sample
	Proteins or lipids have precipitated on column	Clean and regenerate column

continued

Table 10.10.5 Troubleshooting Guide for Ion-Exchange Chromatography, continued

Problem	Possible cause	Solution
	Sample has not been filtered properly	Regenerate column, filter sample carefully, and repeat step
	Equilibration was incomplete	Repeat or prolong equilibration until conductivity is constant
Recovery of activity is low but recovery of protein is normal	Target protein is not stable in the elution buffer and is therefore inactivated	Change elution conditions
	Enzyme separated from cofactor or other substance needed for activity	Test by pooling all fractions and repeating assay
	Microbial growth has occurred in the column	Clean column and store gel in 20% ethanol or other antimicrobial agent ^a
Amount of protein in the eluted fractions is much less than expected	Protein was degraded by proteinases	Add proteinase inhibitors to buffers
	Protein adsorbed to filter during sample preparation	Use another type of filter or add detergents to buffer
	Microbial growth occurred in the column	Clean column and store gel in 20% ethanol or other antimicrobial agent ^a

^aMicrobial growth rarely occurs in columns during use, but steps should always be taken to prevent infection of packed columns, buffers, and gel suspensions; see Support Protocol 5.

Figure 10.10.8 Chromatogram representing typical results of stages of an ion-exchange column chromatography experiment. A linear gradient of 0% to 100% elution buffer is used as in Basic Protocol 2. The broken line superimposed on the chromatogram represents the composition of the elution gradient (100% binding buffer to equilibrate column and remove unbound sample components, followed by a linear gradient from 100% binding buffer to 100% elution buffer to elute bound proteins and a final wash with 100% elution buffer). V_c represents the packed bed volume of the column.

Time Considerations

If all necessary equipment is available and functioning properly, it should be possible to develop a chromatographic method in a day. With automated systems (e.g., FPLC and HPLC) and modern ion-exchange media, method development may require just a few hours. However, the most time-consuming aspect in developing a purification step is typically the determination of protein purity in the fractions collected, which will always depend on the specific protein of interest. The key to minimizing the time required for such determinations is to strive for high resolution and a minimum number of fractions.

Immunoaffinity Chromatography

UNIT 10.11A

Immunoaffinity purification is a powerful technique for isolating proteins. Purifications of 10,000-fold or more can often be achieved in one step. Immunoaffinity columns most often employ monoclonal antibodies covalently attached to a solid-phase matrix; polyclonal antibodies have been used successfully, but they usually lack the specificity required for a single-step protein purification. The amount of protein that can be purified is solely dependent on the amount and affinity of the antibody employed.

This unit describes the isolation of soluble or membrane-bound protein antigens from cells or homogenized tissue by immunoaffinity chromatography. The technique involves the elution of a single protein from an immunoaffinity column after prior elution of nonspecifically adsorbed proteins. Specifically, antibodies are coupled to Sepharose (an insoluble, large-pore-size chromatographic matrix). High-molecular-weight antigens pass freely into and out of the pores and bind to antibodies covalently bound to the matrix. To elute the bound antigen from the immunoaffinity matrix, the antibody-antigen interaction is destabilized by brief exposure to high-pH (see Basic Protocol) or low-pH (see Alternate Protocol 1) buffer. The use of batch purification of antigens shortens the column loading time (see Alternate Protocol 2). The detergent octyl β -D-glucoside can be used instead of Triton X-100 for elution. Because octyl β -D-glucoside has a high critical micelle concentration (CMC), it can be readily removed by dialysis (see Alternate Protocol 3).

ISOLATION OF SOLUBLE OR MEMBRANE-BOUND ANTIGENS

Two different Sepharose columns in series—a precolumn to remove nonspecifically binding material and a specific column—are used to isolate antigens from a cell or tissue lysate. Column fractions are analyzed by SDS-PAGE and silver staining to detect the antigens.

Materials

- Antibody (Ab)-Sepharose (UNIT 10.16)
- Activated, quenched (control) Sepharose, prepared as for Ab-Sepharose (Support Protocol, UNIT 10.16) but eliminating Ab or substituting irrelevant Ab during coupling
- Cells or homogenized tissue
- Tris/saline/azide (TSA) solution (see recipe), ice cold
- Lysis buffer (see recipe), ice cold
- 5% (w/v) sodium deoxycholate (Na-DOC; filter sterilize and store at room temperature)
- Wash buffer (see recipe)
- Tris/Triton/NaCl buffers, pH 8.0 and 9.0 (see recipe), ice-cold
- Triethanolamine solution (see recipe), ice cold
- 1 M Tris·Cl, pH 6.7 (APPENDIX 2), ice cold
- Column storage solution (see recipe), ice cold
- Chromatography columns
- Ultracentrifuge
- Quick-seal centrifuge tubes (Beckman)
- Additional reagents and equipment for column chromatography (APPENDIX 3A), preparing antibody-Sepharose (UNIT 10.16), SDS-PAGE (UNIT 10.2), and silver staining (UNIT 10.6)

NOTE: Carry out all procedures involving antigen in a 4°C cold room or on ice.

Supplement 36

Prepare the columns

1. Prepare an Ab-Sepharose immunoaffinity column (5 ml; 5 mg/ml antibody per milliliter packed Sepharose) and an activated, quenched (control) Sepharose precolumn (5 ml packed bed volume) linked in series (Fig. 10.11A.1).

Irrelevant antibody can be coupled to the Sepharose in the precolumn.

Column size can vary; adjust amounts of Sepharose and cells proportionally.

Prepare the lysate

2. Suspend 50 g of cells at $1-5 \times 10^8$ cells/ml in ice-cold TSA solution, or add 1 to 5 vol ice-cold TSA per vol packed cells or homogenized tissue. Add an equal volume of ice-cold lysis buffer and stir 1 hr at 4°C.

For glycosylphosphatidylinositol (GPI)-anchored proteins, incubate 10 min at 20°C for efficient solubilization.

3. Centrifuge 10 min at $4000 \times g$, 4°C, to remove nuclei. Decant supernatant and save.

For purification of cytoplasmic (soluble) antigens, it is not necessary to add detergents to the solutions and buffer used in subsequent steps. Detergent is needed only for cell lysis and solubilization of integral membrane proteins.

4. For purification of membrane antigens, add 0.2 vol of 5% Na-DOC to the postnuclear supernatant, and leave 10 min at 4°C or on ice. Transfer to quick-seal centrifuge tubes and centrifuge 1 hr at $100,000 \times g$, 4°C. Carefully remove supernatant and save.

Set up and wash the columns

5. Attach Sepharose precolumn to immunoaffinity column (Fig. 10.11A.1).

6. Wash both columns using the following regimen:

10 column volumes of wash buffer

5 column volumes of Tris/Triton/NaCl buffer, pH 8.0

5 column volumes of Tris/Triton/NaCl buffer, pH 9.0

5 column volumes of triethanolamine solution

5 column volumes of wash buffer.

Isolate the antigen

7. Apply the supernatant from steps 3 or 4 (reserving some for analysis as described in step 15 below) to the precolumn and allow it to flow through the precolumn and specific column linked in series at a flow rate of 5 column volumes/hr. Collect the flowthrough fractions, each $\frac{1}{10}$ to $\frac{1}{100}$ the volume of the applied supernatant.

“Fat” chromatography columns, filled with Sepharose to a height of $\sim 2 \times$ column diameter, are used to maximize flow rates. A 10- to 20-ml syringe is used for 5 ml of Sepharose. The flow rate is adjusted with a hydrostatic head of up to 250 cm (Fig. 10.11A.1). Sample loading can routinely take up to 2 days with no deleterious effect, but longer periods would suggest the column is clogged or the lysate is too viscous. The latter is usually due to the presence of DNA.

8. Wash with 5 column volumes of wash buffer, then close the stopcocks on both columns and disconnect the precolumn from the immunoaffinity column. Open the stopcock of the immunoaffinity column and allow fluid above the top of the column to drain out to bed level.

The Sepharose has some elasticity and draining can continue until there is no buffer above the Sepharose bed. Draining until cracks appear in the Sepharose should be avoided.

Fractions of this wash and washes obtained below should be saved.

Figure 10.11A.1 Immunoaffinity chromatography. During the application of the sample, two Sepharose columns, a Sepharose precolumn (without covalently bound specific antibody or with a covalently bound irrelevant antibody) and an immunoaffinity column (with covalently bound antibody), are attached in series to a buffer reservoir containing the sample. After the sample has been washed through, the precolumn is removed and the tubing of the safety loop is connected to the immunoaffinity column. The hydrostatic pressure head is the distance between the top of the solution in the buffer reservoir and the tip of the tubing at the bottom of the immunoaffinity column. When the elution reservoir is emptied, the hydrostatic head becomes zero when the fluid level reaches the safety loop, preventing columns from running dry. Fluid remaining above the column beds can be removed by raising the safety loop. After rinsing the tubing, the next elution is begun by placing the end of the safety loop in another reservoir containing the next elution buffer.

Inset: Schematic diagram of an immunoaffinity column. (a) 50- μ l disposable capillary micropipet. (b) Tubing: Tygon S-54-HL Microbore, 0.05-in. i.d., or Tygon R-3603, $\frac{1}{16}$ -in. i.d. (softer tubing). (c) Female Luer fitting, white nylon (Value Plastics), $\frac{1}{16}$ in. (d) Kontes Flex-column (Kontes Glass). (e) Barbed nipple connector, polypropylene, $\frac{3}{32}$ -in. top, $\frac{1}{16}$ -in. bottom (Value Plastics, Series AD). (f) Luer-Lok two-way stopcock (Kontes Glass).

9. Wash the immunoaffinity column between each change of buffers (steps 10 to 14) as follows. Close the stopcock and remove the end cap of the column. With a syringe connected to the outlet of the tubing from the buffer reservoir, aspirate all buffer from the tubing. Place tubing into the next buffer contained in another reservoir. Aspirating with a syringe, fill the tubing from the reservoir and remove the syringe. Crimp the tubing to regulate flow and rinse the inside wall of the column with the buffer. Open the column stopcock and drain the buffer to bed level. Put end cap loosely on the column and allow buffer to drain into the column to a level several centimeters above the bed. Secure end cap and commence washes or elution.
10. Wash with 5 column volumes of wash buffer.
11. Wash with 5 column volumes of Tris/Triton/NaCl buffer, pH 8.0.
12. Wash with 5 column volumes of Tris/Triton/NaCl buffer, pH 9.0.

Some nonspecifically bound proteins may be eluted at this step. In addition, some monoclonal antibodies may release some ligand at this pH. This should be checked.
13. Elute the antigen with 5 column volumes of triethanolamine solution. Collect fractions of 1 column volume into tubes containing 0.2 vol of 1 M Tris·Cl, pH 6.7, to neutralize the fractions collected.

In some cases it may be desirable to lower the pH of the triethanolamine solution to preserve the functional activity of the ligand. The ideal pH gives complete release of the ligand, as verified by SDS-PAGE evaluation of a sample (~20 μ l) of the eluted column bed (Ab-Sepharose) and eluate (50 μ l).
14. Wash the column with 5 column volumes of TSA solution.

A column may be reused many times and remain active for several years after storage at 4°C in TSA solution. It is important to prevent drying out of a column during storage. The use of column storage solutions inhibits the growth of microorganisms.
15. Analyze fractions for the presence of antigen—50- μ l aliquots of each eluate fraction should be analyzed by SDS-PAGE and silver staining. Analyze 0.5- to 1-ml aliquots of the sample applied to the column and representative flowthrough and wash fractions by immunoprecipitation with Ab-Sepharose, and detect by silver staining to determine whether the column was saturated.

If antibody leaches off the column during elution, it may be removed from the eluate by passage through protein A-Sepharose (Ey et al., 1978). Even the weakly binding mouse IgG1 subclass can be quantitatively removed at pH 8 (M. Dustin, pers. comm.).

Preliminary analysis of fractions can be done using A_{280} readings when octyl β -D-glucoside or sodium deoxycholate are used as detergents.

**ALTERNATE
PROTOCOL 1**

LOW-pH ELUTION OF ANTIGENS

Some protein antigens may be eluted more completely, with greater retention of native conformation and with fewer contaminants, by employing low-pH buffers.

Additional Materials (also see Basic Protocol)

- Sodium phosphate buffer, pH 6.3 (see recipe)
- Glycine buffer (see recipe)
- 1 M Tris·Cl, pH 9.0 (APPENDIX 2)

1. Prepare the columns and lysate, wash the columns, and isolate the antigen (see Basic Protocol, steps 1 to 11).

It is essential to remove sodium deoxycholate from the column before acid elution, because it precipitates or forms a gel at acid to neutral pH.

TSA and triethanolamine solutions used here may also be modified by substituting 1% octyl β -D-glucoside for 0.1% Triton X-100 (see Alternate Protocol 3).

2. Wash with 5 column volumes of sodium phosphate buffer, pH 6.3.
3. Elute with 5 column volumes of glycine buffer. Collect fractions into tubes containing 0.2 vol of 1 M Tris-Cl, pH 9.0.

Mix each fraction immediately after collection.

4. Analyze fractions for antigen (see Basic Protocol, step 15).

BATCH PURIFICATION OF ANTIGENS

Batch purification of antigens shortens the column loading time. This technique is valuable for viscous lysates that take too long to load on a column and for antigens especially susceptible to proteolysis, because less time is required to complete the steps. A precolumn is not utilized because the supernatant is mixed with Ab-Sepharose and poured into a column. The antigen is then eluted (see Basic Protocol). The drawbacks of this protocol are that more “hands-on” time is required by the investigator and that nonspecifically binding material is not removed by a precolumn.

1. Suspend and centrifuge the cells and purify the membrane antigens (see Basic Protocol, steps 2 to 4) to obtain the postnuclear supernatant.
2. Suspend Ab-Sepharose in the supernatant in a flask. Shake gently on a rotary shaker for 3 hr. Stop shaking and allow the Sepharose to settle.
3. Decant most of the supernatant. Pour the Ab-Sepharose and the remainder of the supernatant into a column and open the stopcock. Continue draining the column until all the Sepharose has been added. Allow the fluid to drain to bed level and close the stopcock.
4. Wash the immunoaffinity column, elute the antigen, and analyze the fractions (see Basic Protocol, steps 9 to 15).

ELUTION IN OCTYL β -D-GLUCOSIDE

The detergent octyl β -D-glucoside has a high critical micelle concentration (CMC) of 0.73% and can therefore be readily removed by dialysis. Also, adsorption of membrane proteins to surfaces for ELISA or adhesion assays is much more efficient when solutions containing membrane proteins are diluted so that the concentration of octyl β -D-glucoside is below the CMC. Because octyl β -D-glucoside is expensive, initial steps requiring large volumes may be done as described in the Basic Protocol; the initial detergent is then replaced by octyl β -D-glucoside in the wash step prior to elution.

Additional Materials (also see Basic Protocol)

TSA solution (see recipe) containing 1% octyl β -D-glucoside

1. Prepare the columns and lysate, wash the columns, and isolate the antigen (see Basic Protocol, steps 1 to 11).
2. Wash with 5 column volumes of TSA solution containing 1% octyl β -D-glucoside.
3. Elute with 5 column volumes of triethanolamine solution with 1% octyl β -D-glucoside substituted for 0.1% Triton X-100.
4. Collect fractions of 1 column volume into tubes containing 0.2 vol of 1 M Tris-Cl, pH 6.7, to neutralize the fractions collected.

**ALTERNATE
PROTOCOL 2**

**ALTERNATE
PROTOCOL 3**

**Analysis of
Proteins**

10.11.5

5. Wash the column and analyze the fractions (see Basic Protocol, steps 14 and 15).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Column storage solution

Prepare in TSA solution (see recipe) either 1 mM EDTA/20 µg/ml gentamicin *or* 0.01% thimerosal (Aldrich).

Detergent stock solutions

Prepare 10% Triton X-100 *or* 5% sodium deoxycholate in water. Sterilize either solution by Millipore filtration. Both solutions remain stable for 5 years at room temperature; Triton X-100 solution should be stored in the dark to prevent photo-oxidation.

NP-40 can be used in place of Triton X-100.

Glycine buffer

50 mM glycine-HCl, pH 2.5
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.15 M NaCl

Lysis buffer

TSA solution (see recipe) containing:
2% Triton X-100 (see recipe for detergent stock solutions)
5 mM iodoacetamide
Aprotinin (0.2 trypsin inhibitor U/ml)
1 mM phenylmethylsulfonyl fluoride (add fresh from 100 mM stock solution prepared in absolute ethanol)

IMPORTANT NOTE: *Iodoacetamide is a protease inhibitor and prevents oxidation of free cysteines to disulfide-bonded cysteines. It should be omitted for enzymes that require cysteines for activity.*

NP-40 can be used in place of Triton X-100.

Sodium phosphate buffer, pH 6.3

50 mM sodium phosphate, pH 6.3
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.5 M NaCl

Triethanolamine solution

50 mM triethanolamine, pH ~11.5
0.1% Triton X-100 (see recipe for detergent stock solutions)
0.15 M NaCl

Other organic solutions, such as diethylamine, may be used in place of triethanolamine. The pH of this solution should be determined for each antibody as elution conditions may vary (see Critical Parameters).

Tris/saline/azide (TSA) solution

0.01 M Tris-Cl, pH 8.0 (at 4°C)
0.14 M NaCl
0.025% NaN₃

CAUTION: *Sodium azide (NaN₃) is poisonous; wear gloves and handle cautiously.*

Tris/Triton/NaCl buffer, pH 8.0 and 9.0

50 mM Tris·Cl, pH 8.0 or pH 9.0

0.1% Triton X-100 (see recipe for detergent stock solutions)

0.5 M NaCl

Wash buffer

0.01 M Tris·Cl, pH 8.0 (at 4°C)

0.14 M NaCl

0.025% NaN₃

0.5% Triton X-100 (see recipe for detergent stock solutions)

0.5% sodium deoxycholate (see recipe for detergent stock solutions)

CAUTION: *Sodium azide (NaN₃) is poisonous; wear gloves and handle cautiously.*

COMMENTARY

Background Information

The review of affinity chromatography by Wilchek et al. (1984) discusses available methods for activation of solid supports, coupling of ligands, adsorption of proteins, and elution of protein from affinity columns. Table III of that review lists numerous examples of proteins that have been purified by immunoaffinity chromatography and the elution conditions for each purification.

Traditionally, purification of membrane proteins started with a membrane purification step, and in some cases this is still desirable. However, it is difficult to achieve more than a 5-fold purification of plasma membranes and yields are usually only 10% to 40%. Omission of membrane purification in this protocol (Williams and Barclay, 1986; Johnson et al., 1985) results in increased yield and decreased experiment time.

Purification to homogeneity or near-homogeneity can usually be achieved for protein antigens present in $\geq 10,000$ molecules per eukaryotic cell. This protocol can be used for both membrane and intracellular antigens. However, for soluble antigens, immunoaffinity chromatography is completed without detergent.

Critical Parameters

Binding capacities of Ab-Sepharose columns (coupled at 5 mg monoclonal antibody/ml Sepharose) have been found to be 2% to 20% of the theoretical binding capacity. The lowest and highest binding capacity values were found for antigens of 150,000 and 18,000 M_r , respectively, suggesting that increased antigen size may constrain access to antibody in the pores of the affinity matrix. Because of its larger pore size, Sepharose CL-4B (a 4% cross-linked agarose) is far preferable to Sepharose 6B (a 6% agarose), which is the usual commer-

cially available preactivated agarose. The cross-links in the CL series yield mechanically more robust beads and do not appreciably decrease activation with cyanogen bromide (CNBr).

A binding capacity of 40% was reported for coupling at 2 to 3 mg antibody/ml Sepharose. Successful purification has been achieved using monoclonal antibodies with affinity constants ranging from 2×10^7 to 4×10^8 M⁻¹. The column should be saturated with antigen by allowing some of the antigen to flow through the column during loading. This will result in the highest antigen purity and a mass yield, and will diminish the relative level of antibody eluted along with the antigen when antibody is leaching off the column.

Sodium deoxycholate is used in the solubilization protocol (Johnson et al., 1985) because it dissociates proteins from the membrane more effectively than Triton X-100. However, because sodium deoxycholate releases DNA from nuclei, it must be added to the lysate after the nuclei are removed. Sodium deoxycholate forms a mixed micelle with Triton X-100. Although sodium deoxycholate can be substituted for Triton X-100 during high-pH elution, it gels at low pH and in high salt. Both sodium deoxycholate and nonionic detergents may dissociate subunits of protein complexes, which interact within the membrane. Addition of phospholipid, low concentrations of Triton X-100, and mild detergents (e.g., digitonin, octylglucoside, and CHAPS) preserves membrane protein complexes (Helenius et al., 1979; Rivnay et al., 1982; Tsuchiya and Saito, 1984).

Glycosylphosphatidylinositol (GPI)-anchored proteins are resistant to detergent solubilization at 4°C (Schroeder et al., 1994). Preparation of the lysate (see Basic Protocol, step 2) should be conducted for 10 min at 20°C

for these antigens. Additional information regarding detection, extraction, and partitioning of GPI-anchored proteins can be found in *Current Protocols in Protein Science* (Doering et al., 1995).

Octyl β -D-glucoside is an expensive detergent that is readily removable by dialysis. Furthermore, adsorption of proteins to substrates is enhanced by dilution below a CMC of 0.73%. In Alternate Protocol 3, the initial detergent is replaced with octyl β -D-glucoside prior to elution of antigen from the affinity column.

Protein antigens eluted by acid or base can frequently be renatured by neutralization. However, some protein antigens are irreversibly denatured. The structure of certain antigens is preserved after acid, but not base, elution (Plunkett and Springer, 1986), whereas the structure of other antigens is preserved after base, but not acid, elution (Johnson et al., 1985). Some antigens are eluted at low pH, but not at high pH; for others the reverse is true. For each antibody-antigen combination, the optimal pH for elution of specific antigens as well as contaminants must be empirically defined. Antibody binding capacity is usually retained after repeated exposure to low- and high-pH elution buffers (see Alternate Protocol 1 and see Basic Protocol, respectively). The use of chaotropic agents (e.g., potassium thiocyanate and urea) for elution is a seldom-employed alternative (Johnson et al., 1985).

Troubleshooting

Immunoaffinity chromatography relies on the elution of a single protein from an immunoaffinity column after prior elution of all other nonspecifically adsorbed proteins. Thus, depending on the elution conditions used, the desired protein antigen may be contaminated with other proteins. It is very important to determine whether a contaminant is present if the protein is to be analyzed for amino acid composition or protein sequence. One-dimensional gel electrophoresis (UNIT 8.4) should be used to verify elution of contaminating proteins during washing of the immunoaffinity column, as well as the purity of the protein in the final eluate. If the protein is not pure, the wash steps must be optimized to ensure that other contaminating proteins are removed.

Anticipated Results

Antigen yield is typically 40% to 70% of starting material (Kürzinger and Springer, 1982; Johnson et al., 1985) and purification factors of 1,000- to 10,000-fold may be achieved (Kürz-

inger and Springer, 1982; Williams and Barclay, 1986; Plunkett and Springer, 1986). Further purification can usually be achieved by a second cycle of immunoaffinity chromatography. Monoclonal antibodies are most convenient, but affinity-purified polyclonal IgG can also be used.

Time Considerations

Pouring the column takes a few minutes and lysate preparation requires ~6 hr. Purification proceeds over 1 to 2 days depending on the flow rate of the immunoaffinity column. The majority of this time involves loading the sample on the column, which may be done from a reservoir and requires little hands-on time. The use of batch purification (see Alternate Protocol 2) reduces the sample application time to 3 hr. Elution of an immunoaffinity column requires 5 to 6 hr.

Metal-Chelate Affinity Chromatography

Recombinant proteins engineered to have six consecutive histidine residues on either the amino or carboxyl terminus can be purified using a resin containing nickel ions (Ni^{2+}) that have been immobilized by covalently attached nitrilotriacetic acid (NTA). This technique, known as metal-chelate affinity chromatography (MCAC), can readily be performed with either native or denatured protein. The Strategic Planning section discusses techniques for creating a fusion protein consisting of the protein of interest with a histidine tail attached (for purification by MCAC). The Basic Protocol describes expression of histidine-tail fusion proteins and their purification in native form by MCAC. Two alternate protocols describe purification of histidine-tail fusion proteins by MCAC under denaturing conditions and their renaturation by either dialysis or solid-phase renaturation. Support protocols are provided for analysis of the purified product and regeneration of the NTA resin. All of these protocols are easily adaptable to any protein expression system.

Prior to large-scale preparation, the cells should be tested for expression of the protein in soluble form (see UNIT 16.2). Even if protein is expressed mostly in insoluble form (i.e., bacterial inclusion bodies), there may be a small fraction that remains soluble and can therefore be purified using the Basic Protocol. If little or no soluble protein is observed, one of the denaturing protocols (see Alternate Protocols 1 and 2) should be used.

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and proper sterile technique should be used accordingly.

STRATEGIC PLANNING

MCAC is designed to purify a specific protein whose complementary DNA (cDNA) sequence is available. A protein-expression system is selected and the cDNA is inserted into the appropriate expression vector (see Chapter 16). The cDNA sequence must encode a minimum of six histidines at either the amino or carboxyl terminus and must include an initiator methionine at the amino terminus and a termination codon at the carboxyl terminus. This can be accomplished by polymerase chain reaction (PCR) using primers containing unique restriction-site sequences at the 5' end (Fig. 10.11B.1). Properly

A	5'-GGGNNNNNNATGCATCATCATCATCAT ... N ₁₅₋₃₀ -3' RE site – MetHisHisHisHisHisHis ...
B	5'-GGGNNNNNNNTTAATGATGATGATGATGATG ... N ₁₅₋₃₀ -3' RE site – ENHisHisHisHisHisHis ...

Figure 10.11B.1 Sequences of primers required to create histidine tails at protein termini. Functions (e.g., protein sequence) are marked below. Three guanines are included at the 5' ends of each primer to facilitate restriction enzyme digestion of the PCR product prior to subcloning. NNNNNN represents a unique restriction enzyme site compatible with the selected vector. N₁₅₋₃₀ represents 15 to 30 additional nucleotides specific to the cDNA beginning with the second codon. Met represents an initiator methionine and END represents a termination codon. **(A)** Sequence of 5' primer used to create a histidine tail at the amino terminus. The 3' primer should include a second unique restriction enzyme site and the final 5 to 10 codons (including a stop codon) of the cDNA sequence. **(B)** Sequence of 3' (antisense) primer used to create a histidine tail at the carboxyl terminus. The 5' primer should contain a second unique restriction site and the first 5 to 10 codons of the cDNA sequence.

designed primers will permit insertion and expression of the cDNA in the correct reading frame (see *UNITS 3.17, 15.1 & 15.7*).

An alternative to PCR is to subclone the cDNA into an existing vector, synthesize complementary oligonucleotides containing the hexahistidine sequence with compatible restriction enzyme site overhangs, and insert them into the subcloned cDNA (*UNIT 3.16*). It is important to insert the oligonucleotide into the cDNA near one of the termini in the correct reading frame.

Several companies (e.g., Qiagen, Novagen, and Invitrogen; see *APPENDIX 4*) sell expression systems that permit direct subcloning of cDNAs into vectors already containing oligohistidine tail sequences along with adjacent protease cleavage sites to allow removal of the tail after purification. Vectors have been developed for expression of histidine fusion proteins by bacteria, yeast, baculovirus, vaccinia, and various eukaryotic promoters. The protocols that follow are designed for use with a Novagen pET vector (Fig. 10.11B.2) but may easily be modified for other vectors.

NATIVE MCAC FOR PURIFICATION OF SOLUBLE HISTIDINE-TAIL FUSION PROTEINS

**BASIC
PROTOCOL**

This protocol describes expression and purification of histidine fusion proteins in *E. coli*. A desired protein is induced in bacteria, which are then harvested and lysed. The lysate is loaded directly onto a column containing Ni²⁺-NTA resin and the protein is eluted in nearly pure form with MCAC buffer containing imidazole.

Materials

- M9ZB medium (see recipe) containing 50 µg/ml ampicillin and 25 µg/ml chloramphenicol
- E. coli* BL21(DE3)pLysS or other suitable strain (Novagen) containing a pET vector (Fig. 10.11B.2) expressing a histidine-tail fusion protein
- 0.1 M IPTG (Table 1.4.2), filter sterilized
- NTA resin slurry: 50% (w/v) suspension in 20% (v/v) ethanol (Qiagen)
- 100 mM NiSO₄·6H₂O
- MCAC-0, MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, MCAC-200, and MCAC-1000 buffers (see recipe)
- 150× protease inhibitor cocktail (see recipe)
- 10% (v/v) Triton X-100
- 1 M MgCl₂
- MCAC-EDTA buffer (see recipe)
- DNase I solution (see recipe)
- Centrifuge with Beckman JA-20 rotor or equivalent
- 1 × 10-cm glass or polypropylene column
- Additional reagents and equipment for growth of bacteria in liquid medium (*UNIT 1.2*) and analysis and processing of purified proteins by SDS-PAGE (see Support Protocol 1)

Express the protein

1. Inoculate 10 ml M9ZB/ampicillin/chloramphenicol with *E. coli* BL21(DE3)pLysS containing a pET vector expressing a desired histidine-tail fusion protein. Grow overnight with shaking at 37°C (*UNIT 1.2*).
2. Inoculate 100 ml M9ZB/ampicillin/chloramphenicol with 1 ml of the overnight culture and grow with shaking at 37°C to OD₆₀₀ = 0.7 to 1.0.

**Analysis of
Proteins**

10.11.11

Figure 10.11B.2 pET-15b, one of a series of pET vectors designed for cloning, expression, and purification of recombinant proteins. Reprinted with the permission of Novagen. **(A)** pET-15b vector; **(B)** sequence of pET-15b cloning/expression region. The target gene is cloned into the pET plasmid such that its expression is under the control of bacteriophage T7 transcription and translation signals (see UNIT 16.2). pET-15b encodes an amino-terminal His-Tag leader that allows purification of the resulting recombinant protein over Ni²⁺-NTA resin. Following purification, the His-Tag can be removed by thrombin cleavage (see UNIT 16.7). The pET series are derivatives of vectors originally described by Studier et al. (1990) and are available from Novagen. Figure reproduced by permission of Novagen, Inc.

3. Add 1 ml of 0.1 M IPTG (to 1 mM final) and continue shaking incubation 1 to 3 hr at 37°C.

Incubation time will depend on the solubility of the expressed protein. A 3-hr incubation will allow maximal expression but may result in mostly insoluble protein. A 1-hr incubation will produce less protein but more of it may be soluble.

4. Centrifuge 10 min at 4400 × g (5000 rpm in a Beckman JA-20 rotor), 4°C. Discard supernatant. Freeze pellet at -70°C.

It is not necessary to wash the cell pellet. The wet weight of the cell pellet will be ~0.5 g. The pellet can be stored indefinitely at -70°C before proceeding. Alternatively, extract preparation (steps 9 to 13) can be carried out immediately and the column prepared during the centrifugation at step 13.

Prepare the affinity column

5. Add 0.2 ml NTA resin slurry to a 1 × 10-cm column and allow liquid to drain.

During this and subsequent column washes, liquid should be allowed to drain to the top of the packed resin bed that forms as resin settles (packed bed volume should be 0.1 ml) and resin should not be allowed to dry.

6. Wash column with 1 ml (5 bed volumes) deionized water.
7. Charge column by washing with 1 ml (5 bed volumes) of 100 mM NiSO₄·6H₂O.
8. Wash column with 2 ml MCAC-0 buffer.

NTA resin is nitrilotriacetic acid covalently coupled to Sepharose CL-6B. When charged with nickel ions, it has a light blue-green color, and when stripped of nickel, it is white. See supplier's instructions for resin preparation.

Charged resin can be stored at 4°C. If column is to be stored >1 day, wash with 10 bed volumes of 20% ethanol and add 1 bed volume of 20% ethanol prior to storage. Keep column sealed to prevent evaporation.

Prepare the extract

IMPORTANT NOTE: Beginning with this step, all procedures should be performed on ice or in a cold room unless otherwise indicated.

9. Thaw cell pellet (from step 4) on ice. Add 5 ml MCAC-0 buffer and 33 µl of 150× protease inhibitor cocktail and resuspend by pipetting, sonication, or homogenization.

All MCAC buffers contain phenylmethylsulfonyl fluoride (PMSF) as a protease inhibitor; to reduce expense, protease inhibitor cocktail is added only to the crude extract.

10. Add 0.05 ml of 10% (v/v) Triton X-100 (0.1% final). Mix thoroughly and subject the sample to 3 cycles of freezing at -70°C and thawing on ice.

Ionic detergents may interfere with binding of the protein to the resin and should not be used.

Cell lysis is evidenced by a visible increase in viscosity. The pLysS plasmid in these cells encodes an endogenous lysozyme that eliminates the need for exogenous lysozyme treatment to disrupt the bacterial cell wall.

11. Add 0.05 ml of 1 M MgCl₂ (final concentration 10 mM) and 0.05 ml of DNase I solution (final concentration 10 µg/ml DNase I). Mix gently and incubate 10 min at room temperature.

The DNase I treatment reduces the viscosity of the lysate.

12. Centrifuge 15 min at $27,000 \times g$ (15,000 rpm in JA-20 rotor), 4°C. Decant the supernatant into a clean container on ice and discard the pellet. Set aside and freeze a 10- μ l aliquot at -70°C for later analysis by SDS-PAGE (see Support Protocol 1).

The supernatant can be frozen at -70°C indefinitely before continuing with the procedure.

Purify protein

13. If extract is frozen, thaw on ice. Load onto Ni^{2+} -NTA column and allow to flow through at a rate of 10 to 15 ml/hr. Collect column flowthrough and save for SDS-PAGE (see Support Protocol 1).

Charged NTA resin has a capacity of 5 to 10 mg histidine-tagged protein per milliliter of packed resin. The amount of extract that can be loaded on the column will depend on the amount of soluble histidine-tagged protein in the extract.

14. Wash column with 5 ml MCAC-0 buffer at a flow rate of 20 to 30 ml/hr. Discard flowthrough.
15. Wash column in stepwise fashion with 5 ml each of MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, MCAC-200, and MCAC-1000 buffers at a flow rate of 10 to 15 ml/hr. Collect 0.5-ml fractions and save on ice for SDS-PAGE (see Support Protocol 1).

Alternatively, the column can be eluted with a 5-ml linear gradient (UNIT 10.10) of 0 to 400 mM imidazole in MCAC buffer.

The second and third fractions of each wash will contain most of the eluted proteins. Most proteins with hexahistidine tails will remain bound in 60 mM imidazole (MCAC-60) and elute with 100 to 200 mM imidazole (MCAC-100 or -200); therefore, the purified protein will elute in MCAC-100 or -200. Proteins with longer histidine tails (e.g., 10 residues) bind to Ni^{2+} -NTA with greater affinity and require higher imidazole concentrations for elution. However, optimum washing and elution conditions must be determined for each protein.

Once optimum washing and elution conditions are established, it is possible to prepare the crude extract in a buffer that contains the highest imidazole concentration in which the histidine tail remains bound to the Ni^{2+} -NTA (e.g., MCAC-40 or -60 buffer). This decreases nonspecific binding of proteins to resin and permits use of a single buffer for extract preparation, column loading, and column washing.

16. Elute column with 1 ml MCAC-EDTA buffer at a flow rate of 10 to 15 ml/hr, collecting 0.5-ml fractions.

The blue-green color of the column will disappear as nickel is removed by EDTA. More tightly bound proteins may be found in these fractions. The resin can now be recharged (repeat steps 6 to 8) and the column reused.

If protein is eluted adequately with imidazole (as determined by overall yield for subsequent preparations), EDTA washing can be omitted. The column can be reequilibrated with MCAC-0 buffer and the purification repeated. The same column can be used three to five times before EDTA stripping and nickel recharging are necessary. Only one protein should be purified on any given column.

17. Analyze fractions for the presence of eluted protein.

An ultraviolet (280-nm) absorbance flow monitor is helpful for following column elution but is not necessary. An alternative is to measure the OD_{280} of individual fractions to identify protein-containing fractions. However, imidazole will also absorb at 280 nm.

A quick and easy method to determine which fractions contain eluted protein is to place 2 μ l undiluted Protein Assay Dye Reagent Concentrate (Bio-Rad) on a piece of

Parafilm, add 8 μ l from fraction to be tested, and mix by pipetting up and down. Immediate appearance of blue color indicates that the fraction contains protein. This does not work in the presence of Triton X-100 because the detergent itself produces an intense blue color; for this reason, Triton X-100 is excluded from the washing and elution buffers.

18. Combine the fractions containing eluted protein and remove a 10- μ l aliquot for SDS-PAGE (see Support Protocol 1). Freeze the remainder in smaller aliquots at -70°C or in liquid nitrogen.

If a different buffer for the protein is desired (e.g., for proteolytic removal of the histidine tail), the protein should be dialyzed against the buffer of choice to remove the MCAC buffer prior to storage at -70°C or in liquid nitrogen.

19. If time permits, proceed immediately to analysis of fractions by SDS-PAGE and processing of protein (see Support Protocol 1). Otherwise, freeze all samples at -70°C until ready for analysis and processing.

DENATURING MCAC FOR PURIFICATION OF INSOLUBLE HISTIDINE-TAIL FUSION PROTEINS

**ALTERNATE
PROTOCOL 1**

High-level expression of foreign proteins in bacteria and other cells frequently results in poor solubility of the expressed protein (see *UNIT 16.4*). These insoluble proteins form inclusion bodies in bacteria, and strong chaotropic agents such as guanidine, urea, or SDS are usually required to solubilize them. These agents denature the protein and destroy the secondary structure that is essential to other affinity purification methods (e.g., maltose-binding protein or glutathione-S-transferase fusion proteins; *UNITS 16.6 & 16.7*). A significant advantage of metal-chelate affinity chromatography is that the oligohistidine tail will bind to the Ni^{2+} -NTA resin even when the protein is denatured. In denaturing MCAC, the protein extract is solubilized with 6 M guanidine and the entire affinity purification procedure is carried out in guanidine. The purified, denatured protein is renatured during dialysis.

Additional Materials (also see *Basic Protocol*)

GuMCAC-0, GuMCAC-20, GuMCAC-40, GuMCAC-60, GuMCAC-100, and GuMCAC-500 buffers (see recipe)
GuMCAC-EDTA buffer (see recipe)
Appropriate final buffer for protein (e.g., for proteolytic cleavage or long-term storage)
Guanidine-HCl

Additional reagents and equipment for analysis and processing of purified proteins (see Support Protocol 1) and dialysis (*APPENDIX 3C*)

Express the protein

1. Prepare the pellet of *E. coli* expressing a histidine-tail fusion protein (see Basic Protocol, steps 1 to 4).

The pellet can be stored indefinitely at -70°C before proceeding. Alternatively, extract preparation (steps 5 and 6) can be carried out immediately and the column prepared during the centrifugation at step 6.

Prepare the affinity column

2. Prepare column (see Basic Protocol, steps 5 to 7).
3. Wash column with 2 ml GuMCAC-0 buffer.

During this and subsequent column washes, liquid should be allowed to drain to top of packed resin bed and resin should not be allowed to dry.

**Analysis of
Proteins**

10.11.15

Prepare cell extract

4. Thaw cell pellet (from step 1) on ice. Resuspend in 5 ml GuMCAC-0 buffer by pipetting, sonication, or homogenization.
5. Freeze 10 min at -70°C and thaw at room temperature.

Protease inhibitors are omitted because proteases are inactivated by guanidine. Triton X-100 is not needed at this step. Freezing is not necessary but is included because it ensures complete lysis of cells.

Subsequent steps can be performed at room temperature. However, if solid-phase renaturation is used (see Alternate Protocol 2), it is better to maintain lower temperatures throughout the process.

6. Gently mix samples for 30 min using a rocker, rotating mixer, or magnetic stirrer. Centrifuge 15 min at $27,000 \times g$ (15,000 rpm in Beckman JA-20 rotor), 4°C . Decant supernatant into a clean container and discard pellet. Set aside a 10- μl aliquot for analysis by SDS-PAGE (see Support Protocol 1).

The supernatant can be frozen at -70°C indefinitely before continuing with the procedure.

Purify protein

7. If extract from step 5 is frozen, thaw at room temperature. Load onto Ni^{2+} -NTA column and allow to flow through at a rate of 10 to 15 ml/hr. Collect flowthrough and save a 10- μl aliquot for SDS-PAGE (see Support Protocol 1).
8. Wash column with 5 ml GuMCAC-0 buffer at a rate of 20 to 30 ml/hr. Discard the flowthrough.
9. Wash column in stepwise fashion with 5 ml GuMCAC-20, -40, -60, -100, and -500 buffers at a rate of 10 to 15 ml/hr. Collect 0.5-ml fractions and save for SDS-PAGE (see Support Protocol 1).

The second and third fractions from each wash will contain most of the unbound protein. The histidine tail binds slightly less avidly under denaturing conditions. Lower imidazole concentrations are therefore required for washing and elution than in the Basic Protocol.

10. Elute with 1 ml GuMCAC-EDTA buffer at a rate of 10 to 15 ml/hr, collecting 0.5-ml fractions.
11. Identify fractions containing the protein, pool together, transfer to dialysis tubing, and seal.

Alternatively, fractions can be frozen at -70°C indefinitely before continuing with the procedure.

Guanidine precipitates in the presence of SDS and must be removed by dialysis before SDS-PAGE. An alternative technique employs buffers that switch from 6 M guanidine to 8 M urea during affinity column washing (Stüber et al., 1990). This permits samples to be taken directly from urea fractions without dialysis and analyzed by SDS-PAGE or injected into animals for antibody production.

Renature purified protein by dialysis

12. Prepare appropriate final buffer for protein (e.g., for proteolytic cleavage or long-term storage) and add sufficient guanidine to bring final concentration to 4 M.
13. Dialyze purified protein from step 11 for ≥ 2 hr at 4°C against 500 ml buffer/4 M guanidine (see APPENDIX 3C).

The MWCO of the dialysis membrane should be chosen to be smaller than the MW of the purified protein. In most cases an MWCO of 12 to 14 kDa is sufficient.

14. Remove 250 ml buffer/guanidine and add 250 ml buffer without guanidine. Continue dialysis ≥ 2 hr. Repeat.

With some proteins, renaturation by dialysis may require longer dialysis periods and more gradual decrements in the guanidine concentration of the buffer. Conditions for each protein must be determined empirically.

15. Remove dialysis bag to a container containing 500 ml of fresh buffer without guanidine at 4°C. Continue dialysis 2 hr to overnight.

16. Remove sample from dialysis bag, divide into aliquots, and freeze at -70°C or in liquid nitrogen.

If protein precipitates during dialysis, solid-phase renaturation (see Alternate Protocol 2), in which protein bound to the column is renatured before elution, should be employed.

17. Analyze fractions and process protein (see Support Protocol 1).

SOLID-PHASE RENATURATION OF MCAC-PURIFIED PROTEINS

ALTERNATE PROTOCOL 2

In Alternate Protocol 1, removal of denaturants by dialysis will occasionally lead to precipitation of protein, possibly due in part to entanglement or aggregation of separate protein molecules as they refold. To avoid this problem, solid-phase renaturation may be attempted. In this procedure, protein extract is prepared and bound to the column under denaturing conditions. A series of washes removes the denaturing agent before the target protein is eluted and the resulting renatured protein is eluted from the column under native conditions.

Additional Materials (also see *Basic Protocol*)

- 1:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)
- 3:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)
- 7:1 (v/v) MCAC-20/GuMCAC-20 buffer (see recipes)

1. Prepare protein extract, bind to column, and wash with GuMCAC buffers (see Alternate Protocol 1, steps 1 to 9).

2. Wash column with 5 ml of 1:1 (v/v) MCAC-20/GuMCAC-20 buffer.

During this and subsequent washes, liquid should be allowed to drain just to top of packed resin bed and resin should not be allowed to dry.

3. Wash column with 5 ml of 3:1 (v/v) MCAC-20/GuMCAC-20 buffer.

4. Wash column with 5 ml of 7:1 (v/v) MCAC-20/GuMCAC-20 buffer.

5. Wash column with MCAC buffers, elute proteins, and analyze (see Basic Protocol, steps 15 to 19).

Slow elution (between 1 and 2 hr) with a 5-ml linear gradient from 100% GuMCAC-20 buffer to 100% MCAC-20 buffer may also yield efficient renaturation.

ANALYSIS AND PROCESSING OF PURIFIED PROTEINS

The success of the purification scheme (particularly during a small pilot study) should be monitored at each stage by SDS-PAGE. If the fusion protein contains a specific protease cleavage site, the histidine tail can be removed using an appropriate proteolytic procedure, if desired.

Materials

Fractions from MCAC column purification (crude extract, flowthroughs, and purified protein; see Basic Protocol or Alternate Protocols 1 or 2)

2× SDS sample buffer (UNIT 10.2)

MCAC-0 buffer (see recipe)

Additional reagents and equipment for one-dimensional SDS-PAGE (UNIT 10.2), cleavage of proteins with factor Xa or thrombin (UNIT 16.4B; optional), and dialysis (APPENDIX 3C)

1. Thaw aliquots of fractions to be analyzed on ice. Mix 5 µl from crude extract and crude flowthrough fractions and 10 µl from the second and third fractions from each washing step with an equal volume of 2× SDS sample buffer.
2. Load samples onto a standard SDS-PAGE gel. Run gel and visualize to identify the fractions containing purified protein (UNIT 10.2).

Guanidine must be removed by dialysis prior to addition of SDS sample buffer.

3. Thaw the remaining aliquots of fractions containing purified protein, dialyze against the appropriate proteolysis buffer, and carry out cleavage procedure if desired. If necessary, after cleavage dialyze the protein against an appropriate storage buffer and freeze in aliquots.

The size of the cleaved histidine tail will generally be <3 kDa, depending on the design of the fusion protein. This fragment will usually be removed by the dialysis. It may also be removed by ultrafiltration (which will also concentrate the protein), size-exclusion chromatography, or a second MCAC (see Basic Protocol, steps 13 to 19). The advantage of a second MCAC is that the histidine tail and any uncleaved protein will bind to the column and only the cleaved protein will be found in the flowthrough from step 12. Aliquots of each fraction should be analyzed by SDS-PAGE to verify recovery of pure protein.

If an expression vector other than pET has been used, and the fusion protein does not contain an appropriate cleavage site for factor Xa or thrombin, or if the histidine tail will not interfere with subsequent studies, omit the cleavage procedure. Presence of the histidine tail will not generally affect the protein's biological functions (see Background Information).

NTA RESIN REGENERATION

NTA resin can be repeatedly charged with Ni²⁺ and stripped. Over time, however, some protein residue will accumulate and decrease the efficiency of the resin, resulting in slow flow rates or lack of blue-green color after charging with Ni²⁺. Periodic regeneration (e.g., after 5 to 10 cycles of charging and stripping) permits recycling of resin for long-term use.

Materials

2.5 ml used NTA resin (packed volume)

Stripping solution: 0.2 M acetic acid/6 M guanidine-HCl

2% (w/v) SDS

20%, 25%, 50%, 75%, and 100% (v/v) ethanol

0.1 M EDTA, pH 8.0

1. Wash resin with 5 ml stripping solution.
In this and all subsequent washes, liquid added to the column should be allowed to drain to top of packed resin bed and resin should not be allowed to dry.
2. Wash with 5 ml water.
3. Wash with 7.5 ml of 2% (w/v) SDS.
4. Wash with 2.5 ml of 25% (v/v) ethanol.
5. Wash with 2.5 ml of 50% (v/v) ethanol.
6. Wash with 2.5 ml of 75% (v/v) ethanol.
7. Wash with 12.5 ml of 100% (v/v) ethanol.
8. Wash with 2.5 ml of 75% (v/v) ethanol.
9. Wash with 2.5 ml of 50% (v/v) ethanol.
10. Wash with 2.5 ml of 25% (v/v) ethanol.
11. Wash with 2.5 ml water.
12. Wash with 12.5 ml of 0.1 M EDTA, pH 8.0.
13. Wash with 7.5 ml water. Proceed either to nickel charging (see Basic Protocol, step 7) or to step 14 below for long-term storage of the resin.
14. Add 2.5 ml of 20% (v/v) ethanol to resin and store at 4°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

DNase I solution

Dissolve lyophilized DNase I (U.S. Biochemical) at a final concentration of 1 mg/ml in 50% glycerol/1 mM CaCl₂. Store ≤1 year at -20°C.

GuMCAC buffers (store ≤6 months at 4°C)

GuMCAC-0 buffer:

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl

GuMCAC-500 buffer:

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl
0.5 M imidazole

GuMCAC-20, GuMCAC-40, GuMCAC-60, and GuMCAC-100 buffers:

These buffers (containing different concentrations of imidazole) are made by mixing GuMCAC-0 buffer and GuMCAC-500 buffer in the appropriate ratios: e.g., for GuMCAC-20 buffer, use 96:4 (v/v) GuMCAC-0/GuMCAC-500.

GuMCAC-EDTA buffer

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
6 M guanidine·HCl
0.1 M EDTA, pH 8.0
Store ≤6 months at 4°C

M9ZB medium

Dissolve 10 g N-Z-Amine A (Sigma) and 5 g NaCl in 889 ml water. Autoclave, cool, and add 100 ml of 10× M9 medium (see UNIT 1.1), 1 ml of 1 M sterile MgSO₄, and 10 ml of 40% (w/v) glucose (filter sterilized). Store ≤1 year at room temperature.

MCAC buffers (store ≤6 months at 4°C)*MCAC-0 buffer:*

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
1 mM PMSF (phenylmethylsulfonyl fluoride)

MCAC-1000 buffer:

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
1 M imidazole
1 mM PMSF

Add PMSF immediately before use from a 0.2 M stock in 100% ethanol stored at room temperature. All buffers used with Ni²⁺-NTA resin contain high salt concentrations to reduce nonspecific electrostatic interactions between proteins and resin. Lower salt concentrations can be used but may lead to nonspecific binding of unwanted proteins to the resin.

*MCAC-20, MCAC-40, MCAC-60, MCAC-80, MCAC-100, and**MCAC-200 buffers:*

These buffers (containing different concentrations of imidazole) are made by mixing MCAC-0 buffer and MCAC-1000 buffer in the appropriate ratios: e.g., for MCAC-60 buffer, 94:6 (v/v) MCAC-0/MCAC-1000.

MCAC-EDTA buffer

20 mM Tris·Cl, pH 7.9
0.5 M NaCl
10% glycerol
0.1 M EDTA, pH 8.0
1 mM PMSF
Store ≤6 months at 4°C

Protease inhibitor cocktail, 150×*Stock solutions:*

2 mg/ml aprotinin in H₂O
1 mg/ml leupeptin in H₂O
1 mg/ml pepstatin A in methanol

Cocktail: Combine 1.5 vol of each stock solution with 5.5 vol sterile water.

Protease inhibitors can be obtained from Sigma or U.S. Biochemical. The stock solutions and cocktail are stable ≥6 months at -20°C.

COMMENTARY

Background Information

Metal-chelate affinity chromatography (also called immobilized metal affinity chromatography or IMAC) for protein purification was first described in 1975 (Porath et al., 1975). It is based on the ability of certain amino acids acting as electron donors on the surface of proteins (histidine, tryptophan, tyrosine, or phenylalanine) to bind reversibly to transition-metal ions that have been immobilized by a chelating group covalently bound to a solid support. Of these amino acids, histidine is quantitatively the most important in mediating the binding of most proteins to immobilized metal ions. Histidine binds selectively to immobilized metal ions even in the presence of excess free metal ions in solution (Hutchens and Yip, 1990b). Copper and nickel ions have the greatest affinity for histidine (Yip et al., 1989).

Proteins and peptides containing phospho-amino acids (phosphoserine, phosphotyrosine, or phosphothreonine) have also been purified by MCAC via selective interaction of the terminal phosphate group with Fe^{3+} (Muszynska et al., 1992). Phosphoproteins also bind to less common metals such as lutetium, scandium, and thorium (Andersson and Porath, 1986).

The chelating group that has been used most extensively for MCAC is iminodiacetic acid (IDA). The tridentate IDA group binds to three sites within the coordination sphere of divalent metal ions such as copper, nickel, zinc, and cobalt. When copper ions (coordination number of 4) are bound to IDA, only one site remains available for interaction with proteins (Hochuli et al., 1987). For nickel ions (coordination number of 6) bound to IDA, three sites are available for binding to proteins. Thus Cu^{2+} -IDA complexes are stable on the column but have lower capacity for protein binding. Conversely, Ni^{2+} -IDA complexes bind proteins more avidly, but the Ni^{2+} -protein complexes are more likely to dissociate from the solid support.

A pentadentate chelating group—*N,N,N'*-tris(carboxymethyl)ethylenediamine (TED)—has also been used for MCAC. This chelator binds five coordination sites of the metal ions, providing highly stable metal ion–TED groups. However, for metal ions with a coordination number of 6, this leaves only one site available for protein interaction.

The development of a new metal-chelating adsorbent, nitrilotriacetic acid (NTA), has pro-

vided a convenient and inexpensive tool for purification of proteins containing histidine residues (Hochuli et al., 1987). The quadridentate NTA moiety covalently coupled via a spacer arm to Sepharose CL-6B forms an extremely stable complex with metal ions possessing a coordination number of 6 (e.g., Ni^{2+}). After binding to the NTA, the Ni^{2+} ion has two sites within its octahedral coordination sphere available for binding to electron donor groups (i.e., histidine) on the surface of proteins. Thus the advantage of NTA over IDA is that the Ni^{2+} ion is bound by four rather than three of its coordination sites. This minimizes leaching of the metal from the solid support and allows for more stringent purification conditions. The NTA also binds Cu^{2+} ions with high affinity, but this occupies all of the coordination sites, rendering the resulting complex ineffective for MCAC.

The affinity of histidine residues for immobilized Ni^{2+} ions allows selective purification of proteins containing a high proportion of histidine residues on the surface. Immobilized copper or nickel ions bind native proteins with a K_d of $1\text{--}17 \times 10^{-5}$ M (Hutchens and Yip, 1990a). This affinity is enhanced significantly by designing proteins to contain short stretches (6 to 10 residues) of histidines in regions likely to be surface exposed (amino or carboxyl termini) using recombinant DNA technology. Addition of a histidine tail results in a protein that binds to the Ni^{2+} -NTA complex with a K_d of 10^{-13} M at pH 8.0 even in the presence of detergent, ethanol, 2 M KCl (Hoffmann and Roeder, 1991), 6 M guanidine (Hochuli et al., 1988), or 8 M urea (Stüber et al., 1990).

The histidine tail binds to the Ni^{2+} -NTA resin via the imidazole side chains of the histidine residues. At $\text{pH} \geq 7.0$, the imidazole side chain is deprotonated, with a net negative charge; at $\text{pH} 5.97$ (the pK of the imidazole side chain of histidine), 50% of the histidines are protonated; and at $\text{pH} \leq 4.5$, almost all of the histidines are protonated and do not interact with Ni^{2+} -NTA. Thus, there are two methods of dissociating histidine tails from the Ni^{2+} -NTA resin. The first method, presented in this unit, uses increasing concentrations of imidazole at constant pH to displace the histidine tail from the Ni^{2+} -NTA. This technique provides great versatility because it can be used for both native and denaturing MCAC and buffer preparation is simplified. The second method uses buffers

of decreasing pH to elute the histidine tail and is quite efficient for producing pure protein (Hochuli et al., 1988). Disadvantages are that the pH must be maintained accurately at all temperatures and that some proteins may not be able to withstand the extreme pH change.

Creation of a small histidine tail has advantages over other fusion protein systems. Addition of six histidines to the protein adds only 0.84 kDa to the mass of the protein, whereas other fusion protein systems utilize much larger affinity groups that often must be removed to allow normal protein function (e.g., glutathione-*S*-transferase, protein A, maltose-binding protein, and lacZ have masses of 26, 30, 40, and 116 kDa, respectively). The small histidine tail is not immunogenic and therefore need not be removed before the purified protein is injected into animals for antibody production. Histidine tail fusion proteins often retain their normal biologic functions—e.g., dihydrofolate reductase and adenylylcyclase retain their enzymatic activities (Hochuli, 1990; Tausig et al., 1993) and the TATA box binding protein retains its transcriptional regulatory function (Parvin et al., 1992). The aforementioned studies also demonstrate the technique's suitability for purification of membrane, cytoplasmic, and nuclear proteins. However, although it often is not necessary to remove the histidine tail, it is possible to include this step and still generate sufficient quantities of protein pure enough for detailed X-ray crystallographic studies (Nikolov et al., 1992).

The histidine tail can also be used to detect the recombinant protein. Ni²⁺-NTA covalently coupled to alkaline phosphate (available from Qiagen; see *SUPPLIERS APPENDIX*) can bind directly to histidine tailed proteins, and the bound alkaline phosphatase can be quantitated by standard techniques (*UNIT 10.8*). This allows for direct quantitation of histidine-tailed proteins blotted to membranes without the need for primary and secondary antibodies (Botting and Randall, 1995).

The protocols presented in this unit utilize protein produced in bacteria; an example protocol for the purification of HIV-1 integrase expressed in *E. coli* is presented in *UNIT 6.5*. Histidine-tail fusion proteins have also been expressed and purified from HeLa cells using transient transfection techniques (Janknecht and Nordheim, 1992; Papavassiliou et al., 1992) or a vaccinia expression system (Janknecht et al., 1991) and from baculovirus-infected insect cells (Gearing et al., 1993; Tausig

et al., 1993). Therefore, MCAC can be used with any protein expression system currently available.

This technique can also be used to prepare immunoaffinity columns (*UNIT 10.11A*). Histidine tails have been covalently linked to oligosaccharide moieties of monoclonal antibodies and then subsequently bound to Ni²⁺-NTA columns (Loetscher et al., 1992). The advantage of this method over more conventional techniques of antibody immobilization is that the immobilized antibody will retain a much greater ability to bind antigen and is recoverable from the column.

Critical Parameters

NTA can be synthesized according to the protocol provided by Hochuli (1990); more commonly, it is purchased from Qiagen, which provides detailed protocols for its use.

Binding and elution of proteins from the Ni²⁺-NTA resin depend upon the histidine content of the protein. Each protein will have a slightly different histidine content and optimal elution profile on the Ni²⁺-NTA resin. Therefore, it is important to establish the buffer imidazole concentrations that will give the best purification of a particular protein. As outlined in the Basic Protocol, gradient or stepwise elution of small-scale preparations should be done before large-scale preparations are attempted. It is also possible to perform batch purification by adding charged resin to a tube containing the extract, mixing for 1 hr, loading into a column, washing, and eluting.

Troubleshooting

The most common problem is low yield of purified protein in the expected fraction. This can be caused by insufficient protein loaded on the column, protein not binding to the column, or protein not eluting from the column.

Insufficient protein

It is important to verify that the desired protein is adequately expressed in the chosen system. Check the crude extract for the presence of the expressed protein by SDS-PAGE or other methods before proceeding to the affinity purification steps.

Protein in the crude lysate may undergo significant proteolytic degradation in some cell types. Always use PMSF, minimize freezing and thawing, maintain low temperatures during purification, and use additional protease inhibitors whenever practical.

Lack of binding

If the protein does not bind to the column, either the protein lacks a histidine tail, the column is inadequately charged with nickel, or the histidine tail is buried in the protein and is inaccessible to the resin. Before expression and purification are attempted, verify that the DNA sequence of the histidine tail and adjacent protein-coding sequence are in frame with each other and that initiation and termination codons are present. If the histidine tail is at the amino terminus, it may be helpful to delete the endogenous codon for initiator methionine; if this is present, translation may initiate downstream of it, producing a full-length protein without a tail. Placing the histidine tail at the carboxyl terminus ensures that only the full-length protein will bind to the Ni²⁺-NTA resin (if protease activity is controlled). However, a histidine tail at the carboxyl terminus is more likely to be inaccessible to the resin.

Chelating agents (e.g., EDTA and EGTA) must be excluded from all solutions because they will strip the Ni²⁺ ions from the affinity column. Strong reducing agents such as dithiothreitol should also be avoided because they reduce the Ni²⁺ ions to metallic nickel, forming a brown precipitate. Some proteins will require the presence of reducing agents to maintain structure. It is possible to use up to 10 mM 2-mercaptoethanol with the Ni²⁺-NTA resin, although the lowest possible concentration should be used.

The Ni²⁺-NTA should retain a distinct blue-green color throughout the purification process until EDTA is applied. If the resin is white or if the blue-green color is faint after charging the column with Ni²⁺, check all buffers and make sure no chelating and reducing agents are present. Recharge the column with Ni²⁺ and if the color is still faint or absent, regenerate the NTA resin (see Support Protocol 2) and repeat Ni²⁺ charging (see Basic Protocol, steps 6 to 8). If the resin is still white, discard it and start over with a new batch.

If the protein has or should have a histidine tail but is not binding to the resin, perform the purification under denaturing conditions (see Alternate Protocol 1 or 2) to unmask the inaccessible histidine tail. Placing the histidine tail at the opposite terminus of the protein may also be helpful.

Failure to elute

If the protein appears to be binding to the column but not eluting, make a final elution with EDTA-containing buffer. Any protein

bound to the Ni²⁺-NTA will be removed with the EDTA. Occasionally the protein bound to the resin will precipitate and not elute; if this problem is suspected, purify the protein under denaturing conditions and analyze all eluted fractions by SDS-PAGE for the presence of the expressed protein.

Anticipated Results

The maximum binding capacity of Ni²⁺-NTA resin is 5 to 10 mg of protein per milliliter of packed resin. Under ideal conditions, as much as 80% of the bound protein can be recovered. The limiting factor in most instances will probably be the amount of protein loaded on the resin, which depends on the protein expression system.

Time Considerations

Expression of protein and preparation of crude extract require 1 day for the system described here. Column preparation requires 30 to 60 min. Loading, washing, and eluting the column require 4 to 6 hr.

PURIFICATION OF PROTEINS BY HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

HPLC of Peptides and Proteins: Preparation and System Set-Up

High-performance liquid chromatography (HPLC) is an essential tool for the purification and characterization of biomacromolecules. The choice of the chromatographic method and the type of high-performance equipment are determined by the molecular nature of the investigated molecules and the aim of the research. There are eight basic modes of HPLC currently in use for peptide and protein analysis and purification, namely size-exclusion chromatography (HP-SEC), ion exchange chromatography (HP-IEX), normal phase chromatography (HP-NPC), hydrophobic interaction chromatography (HP-HIC), reversed-phase chromatography (RP-HPLC), hydrophilic interaction chromatography (HP-HILIC), immobilized metal ion affinity chromatography (HP-IMAC), and biospecific/biomimetic affinity chromatography (HP-BAC), and a number of subsets of these chromatographic modes, e.g., mixed mode chromatography (HP-MMC), charge transfer chromatography (HP-CTC), or ligand-exchange chromatography (HP-LEC).

In terms of usage, versatility, and flexibility, RP-HPLC techniques dominate the application world with peptides and proteins at the analytical- and laboratory-scale preparative levels (see *UNITS 10.13 & 10.14*). All of these various chromatographic modes can be operated under isocratic or gradient elution conditions, and in analytical or preparative situations. They all have common start-up procedures, which are outlined in this unit, and specific standard conditions that are detailed for the major modes and which represent starting points for further method development, as presented in *UNIT 10.13*.

THE PROPERTIES OF PEPTIDES AND PROTEINS AND THEIR IMPLICATIONS FOR HPLC METHOD DEVELOPMENT

Peptides and proteins are a class of molecules containing amino acids as the fundamental units. The chemical organization (i.e., the primary structure or amino acid sequence) and

the folded structure (i.e., the secondary, tertiary and quaternary structure) are the essential features of a polypeptide or protein, around which a chromatographic separation can be designed. Two sets of factors must be considered. The first relates to the structural properties of the amino acid entities themselves; the second relates to the chemical and physical attributes of the separation system per se.

Biophysical Properties of Peptides and Proteins

The 20 naturally occurring L- α -amino acids found in peptides and proteins vary dramatically in terms of the properties of the side chain or R-groups. Table 10.12.1 lists some of the fundamental properties of the common L- α -amino acids found in peptides and proteins. This chemical diversity becomes even greater in circumstances where some of these side chains have been post-translationally modified with carbohydrates or lipid moieties. The side-chains are generally classified according to their polarity (e.g., non-polar or hydrophobic versus polar or hydrophilic). The polar side chains are divided into three groups: uncharged polar, positively charged or basic, and negatively charged or acidic side chains. Peptides and proteins generally contain several ionizable basic and acidic functionalities. They therefore typically exhibit characteristic isoelectric points with the overall net charge and polarity in aqueous solution varying with pH, solvent composition and temperature. Cyclic peptides without ionizable side chains will have zero net charge, and they represent an exceptional subgroup.

The number and distribution of charged groups will influence the polarizability and ionization status of a peptide or protein, as well as the microscopic and global hydrophobicity. These important factors ultimately determine the selection of the optimal separation conditions for the resolution of peptide and protein mixtures. Table 10.12.1 can be used to evaluate

the impact of amino acid composition on retention behavior. For example, this information can be used to direct the choice of eluent composition or the gradient range in RP-HPLC; to assess the impact on retention of amino acid substitution or deletion with small peptides; or alternatively to guide the identification of peptide fragments derived from tryptic digestion of proteins for further sequence analysis.

Parameters of the Mobile Phase/Stationary Phase

These parameters directly impact on the molecular properties of the polypeptide or protein during liquid chromatographic separations, and are listed in Table 10.12.2. In solution, a polypeptide or protein can, in principle, explore a relatively large array of conforma-

tional space. For small peptides (up to ~15 amino acid residues) a defined secondary structure (α -helical, β -sheet or β -turn motif) is generally absent. With increasing polypeptide chain length, depending on the nature of the amino acid sequence, specific regions/domains of a polypeptide or protein can adopt preferred secondary, tertiary or quaternary structures. In aqueous solutions this folding, which internalizes the hydrophobic residues and thus stabilizes the polypeptide structure, becomes a significant feature of peptides and proteins for chromatographic separations. A critical factor in the selection of an HPLC procedure is that the choice of experimental conditions will inevitably cause perturbations of the conformational status of these biomacromolecules. Although polypeptide and protein conformational

Table 10.12.2 Chemical and Physical Factors of the Chromatographic System that Contribute to the Variation in the Resolution and Recovery of Polypeptides, Proteins and Other Biomacromolecules in HPLC Systems (Hearn, 2000)

Mobile phase contributions	Stationary phase contributions

stability can be manipulated in a number of ways (e.g., mobile and stationary phase composition, temperature) in HPLC, in most cases an integrated biophysical experimental strategy—including ^1H 2-dimensional NMR, Fourier transformed infrared (FTIR), ESI-MS (UNIT 10.21), or circular dichroism–optical rotatory dispersion (CD-ORD) spectroscopy—is required in order to determine the secondary and higher-order structure of a polypeptide or protein in solution or in the presence of specific ligands. Availability of such instrumentation is not mandatory, but the quality of the interpretation of the experimental results will become more substantial when additional results are independently obtained with such spectrometric procedures to confirm the participation of conformational or self-self aggregation effects with peptides or proteins under HPLC conditions.

DETECTION OF PEPTIDES AND PROTEINS IN HPLC

The peptide bond absorbs strongly in the far-ultraviolet (UV) region of the spectrum ($\sim\lambda = 205$ to 215 nm). Hence UV detection is the most widely used method for detection of peptides and proteins in HPLC (Table 10.12.3). Besides absorbing in the far-UV range, the aromatic amino acid residues (and to some extent cysteine) also absorb light above 250 nm. Knowledge of the UV spectra, in particular the extinction coefficients of the non-overlapping absorption minima of these amino acids, allows, in conjunction with UV-diode array detection (DAD) and second derivative or difference UV-spectroscopy, verification of peak purity and determination of the aromatic amino acid content of peptides and proteins. Moreover, the knowledge of the relative UV/VIS absorbency of a peptide or protein is therefore crucial, since the choice of detection wavelength of peptides and proteins in RP-HPLC (and in the other HPLC modes) depends on the

Table 10.12.4 UV Cutoff Values of Different Organic Solvents in RP-HPLC

Eluent	UV cutoff (nm) ^a
Methanol	205

Isopropanol	205

^aWavelength at which the absorbance of a 1-cm-long cell filled with the solvent was 1.0, measured against water as reference.

different UV cutoffs of the eluents used (Table 10.12.4). The common use of $\lambda = 215$ nm as the preferred detection wavelength for most analytical reversed-phase applications (and for those of other HPLC modes) with peptides and proteins is a good compromise between detection sensitivity and potential detection interference due to buffer absorption. However, wavelengths between 230 and 280 nm are frequently employed in preparative applications, where the use of more sensitive detection wavelengths could result in overloading of the detector response (usually above an absorbance value of 2.0 to 2.5 AU).

START-UP PROCEDURES

Correct selection of these first important steps may take more time than the ultimate experimental procedure if a high-performance separation of high resolution, robustness, and reproducibility is to be achieved. They require good planning and thorough work. The following details are representative of the types of equipment, materials, chemicals, and experimental protocols that can be routinely required for isocratic or gradient elution HPLC.

Sample

Peptide or protein sample (kept at 4°C if not used)

Apparatus

Pump module
Mixing chamber
Spectrophotometer with analytical or preparative flow cell
Injection valve
Analytical (10 to 100 μ l) or preparative (500 to 1000 μ l) sample loop
Column oven or thermostated column coolant-jacket coupled to recirculating cooler
Autosampler (optional)

Computer, printer, and software, e.g., Beckman, System Gold; Hewlett-Packard HP-1090A liquid chromatograph, or Waters 600/486 HPLC system with attendant data management systems and system automation controllers

Chemicals

Acetonitrile (HPLC grade)
Methanol (HPLC grade)
Acetone (HPLC grade)
Thiourea or sodium nitrate
Milli-Q water

Glassware

Two 1-liter eluent bottles
Two 1-liter measuring cylinders
10-ml measuring cylinder
Waste bottle
All glassware coming into contact with sample before and during analysis should be rinsed three times with Milli-Q water

Mobile phase filtration facility

Vacuum pump
1-liter reservoir
Support base with glass frit and integral vacuum connection
Funnel
Clamp
47-mm membrane filter (0.2 μ m PTFE)

Gases

Helium
Nitrogen (for autosampler)

Columns

See respective sections below and in *UNIT 10.13*

HPLC peptide standards

See respective sections below and in *UNIT 10.13*

Tools

Screwdrivers:

1/8-in. and 1/4-in. flat-head screwdrivers
Phillips screwdriver no. 2

Wrenches:

12-in. adjustable wrench (for compressed gas tank regulator)
Three open-end wrenches (two 1/4-in. × 1/16-in.; one 1/2-in. × 1/16-in.) for fittings columns and valves
Two long-jaw needle-nose pliers
Two bastard files
Two hex key (Allen) wrench sets (metric and nonmetric)
Tweezers
Pump seal insertion tool (if required)
Inner reamer
Teflon tape
Flashlight
Magnetic pick-up tool

Logbook

All steps must be documented to facilitate troubleshooting and reproduction

Spare parts

Zero dead volume union
Ferrules (steel, rheodyne) 1/16-in. short and long (for rheodyne valves)
Bushing nuts
One-piece PEEK fitting
Tubing (steel, PEEK)
Column frits
In-line filter
Inlet filter
Fuses

Miscellaneous

Graduated 25- μ l Hamilton glass syringe
1-ml syringe with truncated needle
Conical vials for autosampler
Laboratory coat
Gloves
Safety glasses
Stopwatch

PREPARATION OF THE SAMPLE

The following considerations are relevant to the preparation of samples containing peptides and proteins.

1. Dissolve the sample with half the target volume of eluent A (weak mobile phase). If the sample is not soluble, a small amount of eluent B (strong mobile phase) may be added (typically <25% of total volume). Small amounts of strong mobile phase may cause pre-elution of the sample depending on the sample loop size,

column dimensions, and starting mobile phase composition of the gradient.

2. Inspect the sample for clearness and filter through a 0.2 μ m PTFE filter if insoluble, opalescent, or solid particles are present. Alternatively centrifuge the sample using the supernatant for injection. Samples that are not fully dissolved should not be injected, since they can block injector and column.

3. Store sample if not in use at 4°C or -20°C depending on the planned storage time and usage. Peptides and protein samples can degrade at room temperature. Avoid repeated freeze-thawing of the sample. Rather, prepare small aliquots of the peptide or protein sample, which are kept at -20°C and are used for one task.

PREPARATION OF THE MOBILE PHASE

The following considerations are relevant to the preparation of mobile phases to be used with samples containing peptides and proteins.

1. Prepare 1 liter each of eluent A (weak mobile phase) and B (strong mobile phase).
2. Mix each eluent either by stirring with a magnetic “flea” or by shaking a stoppered cylinder (time depends on volume).
3. Filter the eluents, first A, then B, through a 0.2 μ m PTFE filter. Filtering of eluents increases the column lifetime and contributes to degassing.
4. Close unused eluent bottles with a stopper to avoid evaporation of the organic solvent.

SETTING UP THE HPLC INSTRUMENT

The following steps can be done either with or without a column connected to the HPLC instrumentation.

1. Switch on gas supply, nitrogen for the operation of the autosampler (if available), and helium for the degassing of the eluents.
2. Degas the eluents for 10 min at a rate of 100 ml/min, then reduce to a rate of 20 ml/min, which may be maintained throughout the experiments. Avoid excessive sparging since this will change the eluent composition.
3. Switch the detector lamp on in order to warm it up.

PRIMING OF THE PUMPS AND LOW PRESSURE LINES WITH ELUENTS

The following steps can be done either with or without a column connected to the HPLC instrumentation.

1. Open purge valve.
2. Set the pump at 100% buffer A and a flow rate of 1 ml/min. Under these settings, the eluent will bypass the column and travel directly to the waste fluid container (all wastes are collected for appropriate disposal).
3. Prime all tubing lines by switching the selector to the "prime line" position or by opening an additional valve which has an outlet to attach a syringe (see manufacturers' handbook for specific details).
4. Draw (via the opened valve) 20 ml out of the eluent bottle with the syringe. Close the valve and discharge eluent from syringe in waste.
5. Prime all tubing lines again by drawing 10 ml in syringe, but keep the eluent in the syringe.
6. Switch selector to the "prime pump" position and push eluent gently through the pump.
7. Repeat the last four steps with 100% buffer B.
8. Put the selector in the "operate" position, close the valve, and remove the syringe from instrument.
9. Close the purge valve (now the eluent will travel through the column). This procedure should expel air bubbles from the pump heads and replace the previous eluent (~20 ml) in the solvent lines.

PREPARATION OF THE HPLC SYSTEM

The considerations below are relevant to the preparation of the HPLC system for use with samples containing peptides and proteins (see *UNIT 10.13*). The following steps can be done either with or without a column connected to the HPLC instrumentation.

1. Test the pump delivery system with eluents comprising 100% A and 100% B each for 5 min at a flow rate of 1 ml/min, collecting the eluent into a 10 ml cylinder. Some HPLC systems allow on-line pump diagnostics (e.g., Beckman System Gold). This procedure tests the reliability of the inlet and outlet valve, which may be blocked or not closing properly, e.g., due to salt from previous eluents. Some instrument systems allow the removal of the valve, which then can be sonicated in methanol for 15 min (care must be taken not to mix up the inlet and outlet valves, which often cannot be visually distinguished).
2. Flush the HPLC system with the eluent (e.g., 50% A and 50% B) and monitor the detector baseline. If spikes occur after 15 min of flushing in the absence of the column, the

pressure in the detector cell is too low, leading to an outgassing of air and cycling bubble formation. Use the back-pressure restrictor (alternatively a restriction capillary) on the detector outlet to slightly, and very carefully, enhance the back-pressure. Every piece of capillary must be checked for blockage beforehand by connecting to a pump, thus bypassing the column and detector, since the detector cell is very sensitive to high pressure (consult manufacturer's handbook for details).

3. Flush the needle port with the eluent B using a truncated 1-ml syringe in systems with manual injector. This procedure removes sample residues from previous injections.
4. Flush the Hamilton glass syringe (for manual injection) with methanol, then water to rinse it.
5. Flush the sample loop (in the load position) with three times the sample loop volume with eluent B using a Hamilton glass syringe.

THE GRADIENT DELAY (DWELL VOLUME) OF THE HPLC SYSTEM

The following steps must be done without a column connected to the HPLC instrumentation.

1. Connect the injector directly to the detector with union piece (zero length column).
2. Prepare a special eluent A and B, 200 ml each:

Eluent A: acetonitrile

Eluent B: acetonitrile/0.2% acetone.

3. Run a gradient of 10% to 90% B in 10 min at a flow rate of 2.0 ml/min. Detection is carried out at 254 nm. The measured value of the dwell volume can be influenced by the injection technique. If after the injection the valve remains in the inject position, the dwell volume will include the volume of the sample loop; if the valve is put back in load position, the dwell volume will not. This effect can produce errors with sample loops >100 μ l. The same consideration is valid if the sample loop is exchanged from an analytical separation (e.g., a sample loop of 50 μ l) to a semipreparative separation (e.g., a sample loop of \geq 500 μ l) on the same column.

4. Determine the gradient delay and present the results graphically in a format similar to that shown as Figure 10.12.1.

The dwell volume, V_D , is the volume of eluent from the pump heads to the column inlet (including the mixing chamber volume). The dwell volume values range from 2 to 7 ml; autosamplers in particular make a large contribution to the delay volume. It should be deter-

Figure 10.12.1 Graphical illustration of the approach employed to determine the gradient delay volume, D_V . In this figure the gradient profile is illustrated for a defined flow rate (2 ml/min), with the gradient profile recorded from 10% to 90% buffer B at a specified wavelength such as 254 nm, as described in the text with acetonitrile-water-acetone mixtures.

mined with an accuracy of ± 0.5 ml. The profile can be used for diagnostic purposes, since the volume accuracy of the pump delivery is also monitored.

Knowledge of the gradient delay is essential for method development, since it allows the accurate calculation of the S and k_0 values (Ghrst and Snyder, 1988; Hearn, 1991). Its determination is particularly important when establishing segmented gradients (since various errors can accumulate here), and when an established HPLC method is transferred from one instrument to another instrument.

CONNECTING THE COLUMN

The following considerations are relevant to the preparation of the HPLC column for use with samples containing peptides and proteins.

1. Flush the column with eluent B with the inlet connected to the injector and the outlet facing the waste collector (5 min at 1 ml/min for analytical columns). This procedure removes air that may have been trapped and replaces the storage buffer.

2. Connect the column outlet to the detector. Start the flow with 0.5 ml/min and slowly increase the flow rate to 1 ml/min.

3. Equilibrate the column first with eluent B until a stable baseline is reached or alterna-

tively with 10 column volumes (~ 15 min for analytical column at 1 ml/min) and then with eluent A again with 10 column volumes. The pressure should be monitored and documented for each eluent since it can be used for diagnostic purposes.

PROGRAMMING THE HPLC INSTRUMENT

The following considerations are relevant to the programming of the HPLC instrument for use with samples containing peptides and proteins.

1. Program, according to the manufacturer's handbook, the pump, the detector, the integration module, and the autosampler. Test the method with a test run before leaving the instrument alone.

2. Program a shutdown method for overnight runs, which will switch off the lamp and pump. This approach prolongs lamp life and saves eluents.

INJECTING THE SAMPLE

The following considerations are relevant to the injection of the samples containing peptides and proteins onto the HPLC column.

1. Switch the sample loop to the load position and rinse with eluent A. This procedure

removes eluent B (which may be present from rinsing the loop or previous runs). Failure to do so can cause pre-elution of the peptide or protein sample, particularly in conjunction with partially filled sample loops.

2. Load the sample slowly into the loop avoiding air bubbles. Do not squirt the sample into the loop too fast as it will end up in the waste.

3. Inject the sample by switching the valve swiftly into the inject position. If the switching is done too slowly, the pumps might shut down because the pressure limit is exceeded, as the valve is blocked in the intermediate switching position.

TESTING THE FUNCTIONAL HPLC SYSTEM

The following considerations are relevant to the testing of the HPLC system for use with samples containing peptides and proteins.

1. Produce a blank run (inject eluent A) and run a gradient from 100% eluent A to 100% eluent B under the same conditions as intended for the peptide or protein sample. Repeat if peaks occur. This procedure cleans the column of peptides and proteins from previous separations, which have not been removed by the flushing process.

2. Measure the dead volume of the column with thiourea or sodium nitrate (or any other noninteractive solute).

3. Test the column performance with a gradient run and an appropriate test mixture (see specific sections in *UNIT 10.13* for details). First, this test allows the evaluation of the column bed integrity (low integrity will be associated with split, fronting or tailing peaks) and column performance (in terms of plate numbers). Second, this test allows, if repeated at regular intervals, the monitoring of the performance during the lifetime of a column, and the assessment of batch-to-batch differences of column fillings.

LOGBOOKS

Record keeping is essential for liquid chromatography system maintenance and confirmation/substantiation of the experimental results. Three types of logbooks are recommended, the system logbook, the column logbook, and the experiment/assay logbook (Dolan and Snyder, 1989).

System Logbook

This logbook should contain information on:

1. The module identification (brand, model, serial number, purchase data, warranty information) for the entire liquid chromatography (LC) system: injector, autosampler, pump(s), detector, software, column.

2. Module replacements, maintenance records and upgrades.

3. Reference chromatograms and operating parameters.

4. Maintenance: activity, time, operator, and name/reliability of service engineer.

5. Column replacement (cross-reference to column logbook).

Column Logbook

This logbook should contain information including a summary of use, column life in months and number and type of samples, cause of failure, and suggestions for extending life. For each column this would be tabulated as follows.

1. Date column first used.
2. Specification: mobile phase flow rate, plate number, peak shape, dead volume over the lifetime of the column.
3. Performance of new column (validated with a test mixture).
4. Record of use (instrument, operator, number and type of samples).
5. Storage information.
6. Maintenance performed (type of back-flush protocols, frit replacement, etc.).
7. Reevaluation of column performance.
8. Cause of failure.

Experiment/Assay Logbook

This logbook should contain information on:

1. Equipment configuration.
2. Operating condition(s).
3. Mobile phase recipe(s) (literature references if available).
4. Sample pre-treatment method(s) (literature references if available).
5. Assay procedure(s) (literature references if available).
6. Data analysis procedure(s).

UNIT 10.13 presents illustrative examples of standard operating protocols for the major modes of HPLC, based on the instrumental system validation procedures described above.

HPLC of Peptides and Proteins: Standard Operating Conditions

This unit builds upon the general discussion of HPLC preparation and system setup in UNIT 10.12 by presenting standard operating conditions for HP-SEC, HP-NPC, HP-HIC, HP-IEX, HP-HILIC, HP-IMAC, HP-BAC, and RP-HPLC. As an example for appropriate method development, the RP-HPLC mode is described in greater detail and discussed according to four possible intended purposes, i.e.: (1) the purification of one component out of a natural or synthesized sample; (2) the simultaneous purification of several components; (3) the desalting of proteins or polypeptides obtained from other purification procedures; and (4) the characterization of the physicochemical properties of peptides or proteins. They all require a good understanding of the underlying common principles of polypeptide-ligand interaction. The basics of these principles are touched upon with references to further reading. Finally, a short section of this unit is dedicated to troubleshooting; however, many of the “check-back” confirmatory procedures implicit to sound operational practices and the identification of suitable alternatives for the separation strategy are included in the section on method development.

STANDARD OPERATING CONDITIONS FOR HP-SEC

The separation of peptides and proteins by high-performance size-exclusion chromatography (HP-SEC) is based on the concept that molecules of different sizes (hydrodynamic volume, Stoke's radius) permeate to different extents into porous SEC separation media and thus exhibit different permeation coefficients according to differences in their molecular weights (Regnier, 1983). However, many SEC materials are slightly hydrophobic or can weakly act as ion exchangers. These properties lead to nonideal behavior (specifically electrostatic or hydrophobic interactions between the peptide or protein and the matrix). This feature is not necessarily a disadvantage, since mixed-mode selectivities can be achieved, but can be suppressed by the addition of a salt at a reasonably high ionic strength, i.e., ≥ 100 mM, to the mobile phase (Mant et al., 1987).

Chromatographic Conditions

Column: e.g., TSK-250 (10 μ m, 300 Å, 300-mm length \times 7.5-mm i.d.)

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μ l

Isocratic elution

Eluent A: 50 mM KH_2PO_4 , pH 6.5, 0.1 M KCl

Flow rate: 0.5 ml/min

Detection: 214 nm

Temperature: room temperature

Peptide standards for column testing as described, e.g., in Mant and Hodges (1991a)

Method development in the HP-SEC of peptides and proteins can be performed via the following steps:

1. Select sorbent of the most appropriate average pore size, packed into a column of suitable length.
2. Check for “ideal” and “non-ideal” retention effects.
3. Optimize plate number (adjust the flow rate or change to a column of different length).

An example of HP-SEC for the separation of peptides and proteins is illustrated in Figure 10.13.1. In this example, the resolution of the 50S ribosomal proteins from *Thermus aquaticus* was achieved on a tandem TSK-250 column (75-mm length \times 7.5-mm i.d. and 300-mm length \times 7.5-mm i.d.) at a flow rate of 0.5 ml/min with a 50 mM $(\text{NH}_4)_2\text{SO}_4$ /20 mM NaH_2PO_4 buffer system, pH 5.0.

STANDARD OPERATING CONDITIONS FOR HP-NPC

Chromatographic systems in which the stationary phase is more polar than the mobile phase were developed at the beginning of the modern era of liquid chromatography and were known under the acronym NPC (“normal phase” liquid chromatography). In contrast to RPC with immobilized *n*-alkyl ligands, where the interaction of solute and stationary phase is based on solvophobic phenomena, the interaction in NP-LC is based on adsorption. The retention behavior of peptides and proteins in NP-LC is often described in terms of the classical concepts of multisite displacement and site occupancy theory (Snyder, 1970). Today, NP-HPLC is mainly used for the separation of polyaromatic hydrocarbons (PAHs), heteroaromatic compounds, nucleotides, nucleosides, etc., and much less frequently for protected

synthetic peptides, deprotected small peptides in the “flash chromatographic mode,” and protected amino acid derivatives used in peptide synthesis (Ballschmiter and Wossner, 1998). Originally, normal phase chromatography was limited to unmodified silica columns. Recent work has, however, utilized polar bonded phases such as amino (-NH₂), cyano (-CN), or diol (-COHCOH-) coated sorbents. Chromatography on such modified normal phase packing materials is also known as polar bonded phase chromatography (PBPC), which is used for the separation of peptides (Yoshida, 1998) and proteins (Buchholz et al., 1982). Today, one of the main applications of modified normal phase silica materials is in HPLC-integrated solid phase extraction procedures (SPE; Papadoyannis et al., 1995). These types of sorbents, particularly when used as precolumn packing materials in LC-LC column switching settings in conjunction with restricted access sorbents materials (RAM), allow multiple injections of untreated complex biological samples such as hemolyzed blood, plasma serum, fermentation broth, cell tissue homogenates, etc., for the isolation of bioactive peptides. Typically, with RAM materials, hydrophilic, electroneutral diol groups are immobilized onto the outer surface of spherical particles.

This layer prevents nonspecific interactions between the support matrix and protein(s) or other high-molecular-weight biomolecules, which are thus excluded from the interior regions of the particle and elute as nonretained components. The inner surfaces of the porous RAM particles are, however, chemically modified with *n*-alkyl ligands, which are only freely accessible for low molecular analytes, such as peptides. As a consequence, significant enrichment or partial resolution of peptide analytes can be achieved.

Chromatographic Conditions

Column: e.g., diol-phase, aminopropyl-phase, cyano-phase column, 250-mm length × 4.6-mm i.d.

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μl

Linear A→B gradient

Eluent A: 0.1% TFA in water

Eluent B: 0.1% TFA in 20% acetonitrile/80% water (v/v)

Gradient range and time: 0% to 100% eluent B in 60 min

Flow rate: 1 ml/min

Detection: 214 nm

Temperature: room temperature

Figure 10.13.1 Illustrative example of the use of HP-SEC in peptide and protein separation and analysis. In this example the resolution of 50S ribosomal proteins from *Thermus aquaticus* in 2% acetic acid (Molnar et al., 1989b) was achieved with a tandem TSK-250 column (75-mm length × 7.5-mm i.d. and 300-mm length × 7.5-mm i.d.) using a flow rate of 0.5 ml/min and a 50 mM (NH₄)₂SO₄, 20 mM NaH₂PO₄, pH 5.0, with detection at 205 nm.

An example of the use of HP-NPC for the separation of peptides and proteins is illustrated in Figure 10.13.2. In this example, the resolution of ferritin, bovine serum albumin, chymotrypsinogen, cytochrome *c*, and alanine was achieved on a LiChrosorb Diol column (250-mm length \times 16-mm i.d.) at flow rate of 2.5 ml/min and a 0.1 M phosphate buffer system, pH 5.0 (Buchholz et al., 1982).

STANDARD OPERATING CONDITIONS FOR HP-HIC

As in reversed-phase chromatography, the hydrophobic interaction between the peptide or protein and the nonpolar ligands immobilized onto the surface of the sorbent represents the dominant effect in hydrophobic interaction chromatography (Fausnaugh et al., 1984; Fausnaugh and Regnier, 1986; Gooding et al., 1986; Wu et al., 1986a,b; Melander et al., 1989; Antia et al., 1995; Hearn, 2001a). In both techniques, peptides and proteins are eluted by lowering the surface tension of the mobile phase. However, in HP-HIC, this is achieved with a decreasing

salt concentration, i.e., by increasing the water content of the eluent, in contrast to RP-HPLC where the decrease in surface tension of the eluent is achieved through an increase in the organic solvent content of the mobile phase. As such, the minimum surface tension reached in the HP-HIC of polypeptides or proteins with binary water-salt systems corresponds to the surface tension of pure water, i.e., 78 dynes/cm. These differences between RP-HPLC and HP-HIC have fundamental effects on the recovery of proteins in bioactive state, as well as on the selectivity of the system. Typically, kosmotropic (anti-chaotropic) salts, i.e., ammonium sulfate, sodium sulfate, or magnesium chloride of high molal surface tension increment, are to be preferred for HP-HIC applications with polypeptides and proteins. In HP-HIC, non-polar ligands with lower hydrophobicity and lower ligand density ($\sim 1/10$ th that of RP-HPLC sorbents) are employed. HP-HIC sorbents should be selected on the basis of the critical hydrophobicity concept (Hearn, 2000, 2001a). In combination with nondenaturing mobile

Figure 10.13.2 Illustrative example of the use of HP-NPC in peptide and protein separation and analysis. In this example the resolution of ferritin (M_r , 364,600), bovine serum albumin (M_r , 67,000), chymotrypsinogen (M_r , 25,000), cytochrome *c* (M_r , 12,500), and alanine (M_r , 121; Buchholz et al., 1982) was achieved on a LiChrospher Diol column (250-mm length \times 16-mm i.d.) at a flow rate of 2.5 ml/min and a 0.1 M phosphate buffer system, pH 5.0. In this specific case, size exclusion effects dominated the global resolution, with polar phase effects contributing to the individual selectivities of these proteins, as assessed from the “nonideality” of the log M_r versus V_e plots.

Figure 10.13.3 Illustrative example of the use of HP-HIC in peptide and protein separation and analysis. In this example the resolution of: 1, cytochrome *c*; 2, ribonuclease; 3, lysozyme; 4, bovine serum albumin; 5, ovalbumin; 6, α -chymotrypsin; 7, α -chymotrypsinogen; and 8, myoglobin was achieved (Kato et al., 1983) on a Butyl-G3000 SW column (150-mm length \times 6-mm i.d., 10 μ m) with a 60-min linear gradient from 0% to 100% eluent B (eluent A: 1.5 M ammonium sulfate, 0.1 M phosphate buffer, pH 6.0; eluent B: 0.1 M phosphate buffer, pH 6.0).

phases, proteins, in particular, can potentially be eluted in their native conformation from HP-HIC sorbents.

Chromatographic Conditions

Column: e.g., TSK Phenyl column, 75-mm length \times 7.5-mm i.d., 10 μ m

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μ l

Linear A \rightarrow B gradient is the preferred method with “hold” options

Eluent A: 0.1 M NaH₂PO₄, 2.0 M (NH₄)₂SO₄, pH 7.0

Eluent B: 0.1 M NaH₂PO₄, pH 7.0

Gradient rate: 5% eluent B/min

Gradient range and time: 0 to 100% B in 20 min

Flow rate: 1 ml/min

Detection: 214 nm

Temperature: room temperature

The method development in HP-HIC can be performed in the following steps:

1. Select type of salt (antichaotropic) and concentration range, taking into account the concentration of the salt that is required to reach

saturation, and then keep the maximum concentration below this value by \sim 20%.

2. Optimize the gradient conditions (gradient run time, starting and final mobile phase composition).

3. Optimize the band spacing (pH, organic solvent).

4. Optimize the column conditions (flow, column length).

Examples of the use of HP-HIC with proteins are described in Fausnaugh et al. (1984); Fausnaugh and Regnier (1986); Gooding et al. (1986); Melander et al. (1989); Wu et al. (1986a,b); Antia et al. (1995); and Hearn (2000, 2001a). Figure 10.13.3 illustrates the resolution of cytochrome *c* (1), ribonuclease (2), lysozyme (3), bovine serum albumin (4), ovalbumin (5), α -chymotrypsin (7), and myoglobin (8) on a Butyl-G3000 SW column (150-mm length \times 6-mm i.d., 10 μ m) with a 60-min linear gradient from 0% to 100% B using eluent A (1.5 M ammonium sulfate, 0.1 M phosphate buffer, pH 6.0) and eluent B (0.1 M phosphate buffer, pH 6.0).

STANDARD OPERATING CONDITIONS FOR HP-IEX

Peptides and proteins can be eluted in ion exchange chromatography by either isocratic or gradient elution (Chang et al., 1976; Kopaciewicz and Regnier, 1983a, 1986; Regnier, 1984; Kopaciewicz et al., 1985; Hearn et al., 1988; Heinitz et al., 1988; Hodder et al., 1990). Gradient elution is usually performed with a linear A→B gradient of a salt such as sodium or potassium chloride in phosphate buffer. The retention of peptides and proteins on ion-exchange sorbents arises from electrostatic interactions between the ionized surface of the solute and the charged surface of the sorbent. For peptide and protein separations, the use of a strong cation exchanger has a considerable advantage over other varieties of ion-exchanger (Mant and Hodges, 1985), since the column can retain its negatively charged character over the whole range from acidic to neutral pH. Both weak and strong cation exchangers, e.g., based on carboxymethyl or sulfonopropyl ligands, as well as weak and strong anion exchangers, e.g., dimethylamino or quaternary ammonium ligands, are available and can be applied to the HP-IEX of peptides and proteins.

With peptides and proteins, at neutral pH, the side-chain carboxyl groups of the acidic amino acid residues—glutamic acid and aspartic acid—are completely ionized. Below pH 3.0 they are almost completely protonated. A change of pH therefore allows the retention of peptides and proteins to be varied according to the net charge of these biosolute(s). Even when the most dominant effect in IEX is electrostatic, in many cases the participation of a mixed mode separation, whereby hydrophobic interaction contributes, cannot be excluded (Burke et al., 1989). This is not necessarily a disadvantage, since it permits selectivity modulation with complex mixtures of peptides and proteins. Hydrophobic interactions can be suppressed by adding a nonpolar solvent, such as acetonitrile, or a nonionic detergent, such as Brij-25, to the mobile phase.

Chromatographic Conditions

Column: e.g., strong cation exchanger with sulfonate functionality (5 μm , 300 \AA , 75-mm length \times 7.5-mm i.d.)

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μl

Linear A→B gradient

Eluent A: 5 mM KH_2PO_4 , pH between 3.0 and 7.0

Eluent B: 5 mM KH_2PO_4 /0.5 M KCl, pH between 3.0 and 7.0

Gradient rate: 3.3% eluent B/min

Gradient range and time: 0% to 100% eluent B in 30 min

Flow rate: 1 ml/min

Detection: 214 nm

Temperature: room temperature

Peptide standards for column testing as described, e.g., in Mant and Hodges (1991a)

The method development in HP-IEX can be performed in the following steps:

1. Select type of anion or cation exchanger.
2. Optimize gradient conditions (gradient run time, starting and final mobile phase composition).
3. Optimize band spacing (pH, salt type).
4. Optimize column conditions (flow, column length).

Examples of the use of HP-IEX with proteins are described in Chang et al. (1976); Regnier (1984); Kopaciewicz et al. (1985); Kopaciewicz and Regnier (1986); Hearn et al. (1988); Heinitz et al. (1988); Burke et al. (1989); Hodder et al. (1990); Mant and Hodges (1985, 1991b); and Hearn (2000). Figure 10.13.4 illustrates the use of HP-IEC for the resolution under gradient elution conditions from 0% to 100% B (eluent A: 0.1 M Tris-Cl, pH 7.5; Eluent B: 0.1 M Tris-Cl/0.2 M NaCl, pH 7.5) of ovalbumin isoforms on a TSK-GEL IEX-545 DEAE SIL column (150-mm length \times 6-mm i.d.) using a 90-min linear gradient at a flow rate of 1.0 ml/min.

STANDARD OPERATING CONDITIONS FOR HP-HILIC

Peptides can be separated on strong hydrophilic materials, i.e., poly(2-hydroxyethyl-aspartamide) silica (Alpert, 1990), whereby their selectivity changes with the concentration of the organic modifier. At high organic modifier concentrations (i.e., >55% *n*-propanol), the solute is retained on the column. The solute is subsequently eluted with a decreasing gradient of organic modifier, whereby with low organic modifier concentrations the separation of the solutes is governed by molecular sieving effects. HP-HILIC allows specifically the evaluation of highly polar compounds, which cannot be retained on traditional reversed-phase stationary phases. To date a variety of HP-HILIC sorbent packings, including amide-, poly(2-hydroxyethyl)-aspartamide-, cyclodextrin-, or teicoplanin-derivatized stationary phases are available (Strege, 1998; Risley and Strege, 2000). HP-HILIC can be applied in a variety of

challenging separation tasks, e.g., the separation of glycopeptides (Zhang and Wang, 1998) or the desalting of electroeluted proteins from SDS-PAGE systems (Jeno et al., 1993). In this mixed-mode hydrophilic interaction/cation exchange chromatographic mode (Mant et al., 1998a,b; Litowski et al., 1999), peptides are usually subjected to linear, decreasing salt gradients in the presence of high levels of organic modifier. The following example is representative of the conditions that can be employed in the HP-HILIC of peptides and small proteins.

Chromatographic Conditions

Column: e.g., HILIC PolySulfoethyl A sorbent with a poly(2-sulfonethylaspartimide) functionality (5 μm , 300 \AA , 200-mm length \times 4.6-mm i.d.)

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μl

Linear A \rightarrow B gradient

Eluent A: 20 mM triethylammonium phosphate/80% acetonitrile, pH 3.0

Eluent B: eluent A with 400 mM NaClO_4 , pH 3.0.

Gradient rate: 2.5% B/min

Gradient range and time: 0% to 100% B in 90 min

Flow rate: 1 ml/min

Detection: 214 nm

Temperature: 30°C

Method development in the HP-HILIC of peptides and proteins can be performed via the following steps:

1. Select sorbent of the most appropriate average pore size, packed into a column of suitable length.

2. Check for “ideal” and “non-ideal” retention effects.

3. Optimize selectivity through the changes in the composition or concentration of the organic solvent and kosmotropic/chaotropic salt additives.

4. Optimize plate number (by adjusting the flow rate, or changing to a column of different length).

Examples of the use of HP-HILIC with peptide standards for column testing are described in Mant and Hodges (1991b). In Figure 10.13.5 is shown the separation of the tryptic glycopeptides of Asn^{97} for recombinant human interferon γ (Zhang and Wang, 1998) on a polyhydroxyethylaspartamide column (150-mm length \times 1-mm i.d.) using a flow rate of 50 $\mu\text{l}/\text{min}$. In this example, a 60-min gradient from 100% A (85% acetonitrile, 15% water, 10 mM triethylamine) to 100% B (20% acetonitrile, 15% water, 10 mM triethylamine, 25 mM sodium perchlorate), pH 6.0 was employed.

Figure 10.13.4 Illustrative example of the use of HP-IEX in peptide and protein separation and analysis. In this example the resolution of ovalbumin isoforms (Kato et al., 1982), Frla and FrIb, was achieved on a TSK-GEL IEX-545 DEAE SIL column (150-mm length \times 6-mm i.d.) using a 90 min linear gradient at a flow rate of 1.0 ml/min from 0-100% B (eluent A: 0.1 M Tris-Cl, pH 7.5; eluent B: to 0.1 M Tris-Cl, 0.2 M NaCl, pH 7.5).

STANDARD OPERATING CONDITIONS FOR HP-IMAC

Immobilized metal-chelate affinity chromatography (IMAC) exploits the affinities of the side chain moieties of specific surface accessible amino acids in peptides and proteins for the coordination sites of immobilized transition metal ions (Porath et al., 1975; Zachariou et al., 1993). The majority of investigations employed tri- or tetradentate ligands, such as iminodiacetic acid (IDA), nitrilotriacetic acid (NTA), tris-(carboxymethyl)ethylenediamine (TED), *O*-phosphoserine (OPS) or carboxymethylaspartic acid (CMA) (Zachariou et al., 1993). Novel immobilized chelate systems, such as 2,6-diaminomethylpyridine or *cis* and *trans* carboxymethylproline, have shown binding properties different from the IMAC behavior of other chelating ligands (Hearn et al., 1997; Chaouk and Hearn, 1999). These techniques, in conjunction with soft gel matrices, have been predominantly applied for the preparative purification of globular proteins. Procedures to immobilize the IMAC ligand at the surface of silica supports, based on classical ligand exchange principles, have permitted useful guidelines to be developed for the design

of HP-IMAC applications for peptides and proteins at the analytical level (Wirth and Hearn, 1993). However, for the majority of the possible HP-IMAC applications with peptides or proteins no standard chromatographic conditions exist. Rather, different elution regimes have tended to be employed with HP-IMAC systems, based on the selection of either empirical step- or gradient-elution protocols involving changes in pH, buffer composition, or the concentration of salts or another competitive binding reagent such as imidazole or malonic acid. Various applications of different IMAC systems for the separation of peptides and proteins have recently been reviewed elsewhere (Porath et al., 1975; Jenó et al., 1993; Mant et al., 1998a,b; Litowski et al., 1999; Hearn, 2000). The following example is representative of the conditions that can be employed in the HP-IMAC of peptides and small globular proteins.

Chromatographic Conditions

Column: e.g., HP-IMAC sorbent with a Cu^{2+} ion chelated to immobilized iminodiacetic acid functionality, i.e., IDA-Cu(II) TSK gel chelate-5PW column (5 μm , 300 \AA , 100-mm length \times 4.6-mm i.d. or 75-mm length \times 8-mm i.d.)

Figure 10.13.5 Illustrative example of the use of HP-HILIC in peptide and protein separation and analysis. In this example the resolution of the tryptic Asn⁹⁷ glycopeptides (1-8) of recombinant human interferon γ (Zhang and Wang, 1998) was achieved on a polyhydroxyethyl aspartamide column (150-mm length \times 1-mm i.d.) using a flow rate of 50 $\mu\text{l}/\text{min}$ and a 60-min gradient from 100% A (85% acetonitrile, 15% water, 10 mM triethylamine) to 100% B (20% acetonitrile, 15% water, 10 mM triethylamine, 25 mM sodium perchlorate), pH 6.

Sample size: <1 mg peptide/protein
Sample loop size: 20 to 200 μ l
Linear A \rightarrow B gradient
Eluent A: 50 mM acetic acid/50 mM MES/50 mM HEPES/80 mM Na₂SO₄/2 \times 10⁻⁶ M Cu²⁺, pH 8.0; or 1 mM imidazole/20 mM sodium phosphate buffer containing 0.5 M NaCl, pH 7.0
Eluent B: 50 mM acetic acid/50 mM MES/50 mM HEPES/50 mM ammonium acetate/2 \times 10⁻⁶ M Cu²⁺, pH 5.5; or 20 mM sodium phosphate buffer containing 0.5 M NaCl, pH 7.0 with 20 mM imidazole gradient
Gradient rate: 5% B/min
Gradient range and time: 0% to 100% eluent B in 20 min
Flow rate: 1 ml/min
Detection: 280 nm
Temperature: 25°C

Method development in the HP-IMAC of peptides and proteins can be performed via the following steps:

1. Select sorbent of the most appropriate average pore-size, packed into a column of suitable length.
2. Check for "ideal" and "non-ideal" retention effects.
3. Optimize selectivity through the changes in the type of chelating ligand and metal ion, i.e., whether borderline, hard or soft metal ion, the pH, the type and concentration of the buffer used at the loading and washing stages, and finally at the elution stage.
4. Optimize plate number (by adjusting the flow rate or changing to a column of different length).

Examples of the use of HP-IMAC with proteins are described in Porath et al. (1975); Wirth and Hearn (1993); Zachariou et al. (1993); Jiang et al. (1998); Porath (1988); and Hearn (2000). Figure 10.13.6 illustrates the use of HP-IMAC for the resolution of human gastrin (24), human GIP (29), Trp(for)- human GIP (30), human big gastrin (35), porcine GIP (38), and bovine GIP on an IDA-Cu(II) TSK gel chelate-5PW column (75-mm length \times 8-mm i.d.) at a flow rate of 1 ml/min equilibrated with a 1 mM imidazole/20 mM sodium phosphate buffer containing 0.5 M NaCl, pH 7.0 and eluted with a 1 to 20 mM imidazole gradient (dotted line).

STANDARD OPERATING CONDITIONS FOR HP-BAC

During the last 25 years, biospecific affinity chromatography (BAC) had evolved as a well established method for analytical separation

(Porath, 1988), as well as the preparative scale purification of biopolymers of complex biological origin. Additionally, HP-BAC is a useful technique to investigate peptide-protein and protein-protein interactions. In HP-BAC, the separation is based on the propensity for biorecognition between the protein or peptide and its naturally occurring ligand (or suitable mimetic), in particular, on its relative binding affinity for a specific ligand. The ligand should have a high specificity for the protein or peptide, should bind to the protein or peptide reversibly with rapid on-and-off kinetics, and should be chemically stable under elution conditions. The introduction of HP-BAC dramatically increased the speed of affinity chromatographic separation of proteins, including sample loading and column regeneration (Ohlsson et al., 1978). However, since the specificity and the selectivity of the HP-BAC both are very high, the range of applications is, paradoxically, much more limited than the other modes of HPLC. Every separation ideally demands its own ligand type, ligand density, column configuration, and particle type in order to enable the optimal purification of a particular component. Consequently, there are no "standard" HP-BAC conditions due to the broad range of ligand types. Some ligands are specific for a particular class of protein; however, other ligands can be multifunctional and bind to a number of related molecules. Currently, commercially available HP-BAC columns are supplied as activated supports (epoxy-, N-hydroxysuccinimido-, tresyl-, hydroxylpropyl-) ready for coupling appropriate ligands (via accessible SH, OH, or NH₂ groups) or alternatively as preformed matrices with commonly used ligands already attached (e.g., protein A). The following example is representative of the conditions that can be employed in the HP-BAC with peptides and small globular proteins.

Chromatographic Conditions

Column: custom designed, i.e., glycidopropyl-activated silica such as epoxy-activated LiChrosorb containing a suitable immobilized ligand functionality (10 μ m, 10000 Å , 100-mm length \times 4.6-mm i.d.)

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μ l

Linear gradient or step elution

Eluent for equilibration: nondenaturing conditions with adequate buffer capacity

Eluent for desorption: non-denaturing conditions of different pH to the equilibration conditions, with adequate buffer capacity and ap-

Figure 10.13.6 Illustrative example of the use of HP-IMAC in peptide and protein separation and analysis. In this example the resolution of human gastrin-I (24), human GIP(21-42) (29), Trp(for)-human GIP(21-42) (30), human big gastrin (35), human GIP (37), porcine GIP (38), and bovine GIP(39) (Yip et al., 1989) was achieved on an IDA-Cu(II) TSK gel chelate-5PW column (75-mm length \times 8-mm i.d.) with a flow rate of 1 ml/min equilibrated with a 1 mM imidazole, 20 mM sodium phosphate buffer containing 0.5 M NaCl, pH 7.0, and eluted with an 1-20 mM imidazole gradient (dotted line).

appropriate competitive species to affect efficient dissociation of the affinant-affinate cognate interaction

Gradient rate: according to affinity of interaction, HP-BAC sorbent characteristics, and flow rate

Flow rate: 0.5 to 1 ml/min

Detection: 214 to 280 nm

Temperature: 4°C

In Figure 10.13.7 an example is shown of the use of HP-BAC for the resolution of rabbit muscle lactate dehydrogenase (LDH) on a Procion Red MX5B dye immobilized onto nonporous silica column (40-mm length \times 6-mm i.d.) using a flow rate of 1 ml/min and step elution with eluent A: 10 mM phosphate buffer, pH 8.0, and eluent B: 0.5 M sodium chloride in 10 mM phosphate buffer, pH 8.0.

STANDARD OPERATING CONDITIONS FOR RP-HPLC

As noted above, RP-HPLC procedures currently represent the majority of applications for peptide analysis and purification, and over 80% of all analytical studies with proteins. The dominant effect in reversed-phase chromatography is a hydrophobic interaction between the nonpolar amino acid residues of peptides or proteins and the nonpolar ligands, typically immobilized onto the surface of a spherical, porous silica particle (Hearn, 2001b), although nonpolar polymeric sorbents derived, e.g., from cross-linked polystyrene-divinylbenzene, can also be employed. In this technique, isocratic elution, step elution, or gradient elution modes can be utilized to purify peptides and proteins. Besides the requirement for an organic solvent to be used as a surface tension modifier, ion-pair reagents (Mant and Hodges, 1991c) are utilized at low pH (e.g., pH 2.1) to

suppress silanophilic interactions between free silanol groups on the silica surface and basic amino acid residues. Silica-based packing materials of 3 to 10 μm average particle diameter and ≥ 300 Å pore size, with *n*-butyl, *n*-octyl, or *n*-octadecyl ligands, are widely used.

Chromatographic Conditions

Chemicals

HPLC-grade acetonitrile, 2-propanol, methanol, or other suitable organic solvents with UV transparency down to 210 nm

Trifluoroacetic acid (TFA)

NaH_2PO_4 or other suitable salts

H_3PO_4

Milli-Q water or equivalent

TFA employed for protein sequencing may not be suitable because it can contain antioxidants.

Preparing the mobile phase

1. Prepare eluent A and B, e.g.: eluent A: 0.1% TFA in water and eluent B: 0.09% TFA in 60% acetonitrile/40% water (v/v).

The volumes of organic solvent and water are measured in two different cylinders and then combined, because of the volume contraction upon mixing, which may be up to 30 ml per liter of prepared solvent (depending on the nature of the solvent). Failure to do so can lead to substantial errors in mobile phase composition.

To compensate for the baseline shift in gradient elution (because organic components absorb more light at low wavelengths) when working with water/organic eluents, the amount of ion pair reagent (TFA, H_3PO_4) in eluent B is usually decreased by 10% to 15% in comparison with eluent A, yielding a flat baseline (Dolan and Snyder, 1989; Dolan, 1991).

It is imperative that eluents be prepared in the fume hood. TFA is extremely corrosive; laboratory coat, gloves, and protective glasses must be worn.

2. Mix the solvent either by stirring with a Teflon-coated magnetic flea or by shaking a stoppered cylinder.

Parafilm should not be used, under any circumstances, to cover the eluents, since the or-

Figure 10.13.7 Illustrative example of the use of HP-BAC in peptide and protein separation and analysis. In this example, the enzyme activity is shown for rabbit muscle lactate dehydrogenase (LDH) (Anspach et al., 1988) separated on a Procion Red MX5B immobilized non-porous silica column (40-mm length \times 6-mm i.d.) using a flow rate of 1 ml/min and step elution (eluent A: 10 mM phosphate buffer, pH 8.0; eluent B: 0.5 M sodium chloride in 10 mM phosphate buffer, pH 8.0).

ganic solvents in combination with acidic ion-pair reagent components in the eluents will dissolve components in the Parafilm, yielding extra peaks in the chromatogram.

Testing the RP-HPLC stationary phase

The following considerations are relevant to the evaluation of HPLC stationary phases for use with samples containing peptides and proteins.

1. Test the column performance with a gradient run and a test mixture: RP-HPLC test mixture example: 0.15% (w/v) dimethylphthalate, 0.15% (w/v) diethylphthalate, 0.01% (w/v) diphenyl, 0.03% (w/v) *O*-terphenyl, 0.32% (w/v) dioctylphthalate in methanol.

2. Peptide standards for column testing are described, for example, in Mant and Hodges (1991b).

Peptide purification by RP-HPLC

In addition to the reagents and procedures described in the preceding section the following additional materials are required:

Chemicals: acetonitrile, trifluoroacetic acid (TFA)

Columns: analytical C-18 or other appropriate *n*-alkylsilica sorbent material (5 μ m, 300 \AA , 150-mm length \times 4.6-mm i.d.)

Preparative C-18 or other appropriate *n*-alkylsilica sorbent material (10 μ m, 300 \AA , 300-mm length \times 21.5-mm i.d.)

Apparatus: in addition to an analytical HPLC instrument with autosampler: preparative HPLC pump(s), manual injector, detector with preparative flow cell, and fraction collector are required

Purification of peptides derived from Solid-Phase Peptide Synthesis (SPPS) can be performed in the following steps.

1. Separation of the crude peptide (~100 μ g) with an analytical RP-HPLC procedure allows the assessment of the sample in terms of purity, peak profile and elution conditions. Appropriate equipment/conditions are as follows: Column: e.g., C-4, C-8, C-18, etc. (5 μ m, 300 \AA , 150-mm length \times 4.6-mm i.d.)

Sample size: <2 mg peptide/protein

Sample loop size: 20 to 200 μ l

Linear A \rightarrow B gradient

Eluent A: 0.9% aqueous TFA

Eluent B: 0.1% TFA in acetonitrile/water

Gradient rate: 1% B/min

For example, for 60% ACN/water: gradient range and time: 0% to 100% eluent B in 60 min

Flow rate: 1.0 ml/min

Detection: 214 nm

Temperature: room temperature

An example of the analytical use of RP-HPLC in peptide analysis is shown in Figure 10.13.8. In this case, resolution of the crude *N*-acetyl lipocortin-1[2-26] product from solid phase peptide synthesis (panel A), and the purified product (panel B) was achieved with a TSK-ODS-120 T column (150-mm length \times 4.6-mm i.d., 120 \AA , 5 μ m, end-capped) at a flow rate of 1 ml/min and a 60 min gradient from 100% A (0.1% TFA in water) to 100% B (90% acetonitrile 0.09% TFA), pH 2.1.

2. Separation of the crude peptide (~25 to 100 mg) with preparative RP-HPLC procedure. Appropriate equipment/conditions are as follows:

Column: e.g., C-4, C-8, C-18, etc. (10 μ m, 300 \AA , 300-mm length \times 21.5-mm i.d.)

Sample size: <150 mg peptide/protein

Sample loop size: 1 ml, multiple injection

Linear A \rightarrow B gradient

Eluent A: 0.9% aqueous TFA

Eluent B: 0.1% TFA in acetonitrile/water

Gradient rate: 0.66% eluent B/min

For example for 60% ACN/water: gradient range and time: 0% to 100% eluent B in 90 min

Flow rate: 7.5 ml/min

Detection: 254 nm

Temperature: room temperature

The preparative use of RP-HPLC in peptide purification is shown in Figure 10.13.9. In this example, the isolation of the synthetic *N*-acetyl lipocortin-1[2-26] peptide product obtained from solid-phase peptide synthesis was achieved on a TSK-ODS-120 T column (300-mm length \times 21.5-mm i.d., 120 \AA , 10 μ m, end-capped) using a flow rate of 7.5 ml/min and a 135 min gradient from 25% B to 100% B (A: 0.1% TFA in water, B: 60% acetonitrile 0.09% TFA), pH 2.1.

In order to avoid detector response overload effects, usually wavelengths from 230 to 280 nm are chosen. However, small amounts of chemical scavengers (used during the SPPS procedures) present in the crude peptide solution can absorb very strongly in this wavelength range. It may be worthwhile to sacrifice up to 1 mg of sample and to perform a preparative separation with detection at 214 nm in order to unambiguously determine the retention time of the main peptide product.

3. Collection of HPLC-fractions (3 to 7.5 ml).

4. Analysis of aliquots (30 to 50 μ l) of the collected fraction with an analytical RP-HPLC. A blank, the crude peptide solution, the fraction

Figure 10.13.8 Illustrative example of the use of RP-HPLC in peptide separation and analysis. Resolution of *N*-acetyl lipocortin-1 [2-26] peptide product [Ac-AMVSEFLKQAW-FIENEEQEYVQTVK-CONH₂] obtained by solid phase peptide synthesis on a TSK-ODS-120 T column (150-mm length \times 4.6-mm i.d., 120 Å, 5 μ m, end-capped) using a flow rate of 1 ml/min and a 60 min gradient from 100% A (0.1% TFA in water) to 100% B (90% acetonitrile 0.09% TFA), pH 2.1. (A) Crude peptide; (B) purified peptide.

of interest and the 2 fractions before and 2 fractions after are typically analyzed.

5. Freeze drying of selected fraction.
6. Carry out off-line or on-line the ES-MS of purest fraction.

DESALTING OF PEPTIDE AND PROTEIN MIXTURES BY RP-HPLC TECHNIQUES

RP-HPLC can be utilized to desalt peptide or protein samples derived from extraction procedures or from previous HP-HIC, HP-IEC, HP-IMAC, HP-HILIC, or HP-BAC separations. Peptide or protein solutions are injected onto a small RP-HPLC column. An aqueous buffer is used to elute the salts, while the peptides or proteins are concentrated on the top of the column. After elution of the salts, monitored by UV detection, the peptides or proteins are eluted with water-acetonitrile or water 2-propanol mobile phases. The loading capacity of an analytical column (100- to 300-mm length \times 4-mm i.d.) is typically \sim 8 mg, while the

loading capacity for a semi-preparative column (30-mm length \times 16-mm i.d.) is \sim 34 mg (Pohl and Kamp, 1987).

In addition to the reagents and procedures described in the preceding sections the following materials, reagents and conditions are required:

Chromatographic Conditions

Chemicals: acetonitrile, 2-propanol, trifluoroacetic acid (TFA)

Column: e.g., C-4, C-8, C-18, etc. (10 μ m, 300 Å, 300-mm length \times 21.5-mm i.d.)

Sample size: 8 mg peptide or protein sample

Sample loop size: 1 ml

Step elution

Eluent A: 0.1% aqueous TFA

Eluent B: 0.1% TFA in acetonitrile or 2-propanol

Elution conditions: 100% eluent A for 3 min, then 100% eluent B for 3 min

Flow rate: 2.5 ml/min

Detection: 230 nm

Figure 10.13.9 Illustrative example of the use of RP-HPLC in the preparative isolation of synthetic polypeptides. Here, the isolation of the peptide, *N*-acetyl lipocortin-1[2-26]—Ac-AMVSEFLKQAW-FIENEEQEYVQTVK-CONH₂—(70 mg) from the crude mixture obtained from solid phase peptide synthesis using a TSK-ODS-120 T column (300-mm length × 21.5-mm i.d., 120 Å, 10 μm, end-capped) using a flow rate of 7.5 ml/min and a 135-min gradient from 25% B to 100% B (A: 0.1% TFA in water, B: 60% acetonitrile 0.09% TFA), pH 2.1.

Temperature: room temperature

Illustrative of the use of RP-HPLC in the desalting of peptide and protein samples isolated by other techniques is the example shown in Figure 10.13.10 for the step elution of a 50S ribosomal protein sample derived from *Thermus aquaticus* preparation on a C-4 column (40-mm length × 4-mm i.d., 300 Å, 5 μm) using a flow rate of 2.5 ml/min.

MULTIMODAL HPLC: COLUMN SWITCHING

Electronically controlled multimodal HPLC is a valuable technique (Kopaciewicz and Regnier, 1983b; Hulpke and Werthmann, 1986), which allows automated fractionation and sample cleanup. In addition to the reagents and procedures described in the preceding sections, the following materials, reagents, and conditions are required for such experiments: (1) an autosampler with two rheodyne 7010-080 valves, third pump (optional), and (2) columns (e.g., for HP-SEC and RP-HPLC).

Automated fractionation, for example, with a HP-SEC-RP-HPLC coupling, can be performed with the setup shown in Figure 10.13.11. The valves V₂ and V₃ allow the on-line or off-line position of the HP-SEC and RP-HPLC column to be independently controlled. To establish an electronically controlled automated fractionation method, the following steps are needed:

1. Establish a suitable method for HP-SEC-RP-HPLC, whereby the HP-SEC is performed in the isocratic mode and the RP-HPLC is performed in the gradient elution mode, and the HP-SEC eluent and the eluent A of the RP-HPLC are identical.
2. Perform a HP-SEC run (the RP-HPLC column is off-line).
3. Perform a RP-HPLC run (the HP-SEC column is off-line).
4. Determine the valve switching times.
5. Equilibrate both columns with eluent A (with pump P₁), with both columns connected.
6. Switch the RP-HPLC column off-line.

Figure 10.13.10 Illustrative example of the use of RP-HPLC in the desalting of peptide and protein samples isolated by other techniques. In this example, the 50S ribosomal protein from *Thermus aquaticus* on a C-4 column (40-mm length \times 4-mm i.d., 300 Å, 5 μ m) were desalted at a flow rate of 2.5 ml/min using a step elution protocol with 3 min elution with eluent A (0.1% TFA in water) and 3 min elution with eluent B (0.1% TFA in 2-propanol), pH 2.1. Abbreviations: S, salt; P, protein; A, time of injection.

7. Perform a HP-SEC run according to step 1 (see Table 10.13.1).

8. Switch to LC-LC coupling according to step 2 (see Table 10.13.1). The fraction is collected at the inlet of the RP-HPLC column.

9. Switch back to the HP-SEC only mode according to step 3 (see Table 10.13.1). The fraction collection on the RP-HPLC column is stopped. The sample stays on the column (no flow) until the HP-SEC column run is completed.

10. After completion of the HP-SEC run, the HP-SEC column is switched off-line, but flushed with buffer by pump 3, while a RP-HPLC gradient elution run is performed according to step 4 (see Table 10.13.1).

Illustrative of the use of multimodal HPLC techniques for the separation and analysis of peptide and protein samples is the example shown in Figure 10.13.12, panels A to C, for the separation of closely related 50S ribosomal proteins from *Thermus aquaticus* under RP-HPLC, HP-SEC, and again RP-HPLC protocols under different elution conditions to achieve optimal resolution of specific proteins in high purity for further investigations.

METHOD DEVELOPMENT IN RP-HPLC

For the separation of the diverse components of a sample containing peptides or proteins of unknown composition, usually a model is first developed which aims to create separation conditions that result in different retention times of the various components. Currently no algorithm can predict with absolute fidelity, on the basis of the amino acid sequence, the separation behavior of peptides or proteins. In many cases, the nature of the components is not known anyway. Moreover, changes in retention and peak shape will always occur when sample overload or volume overload conditions prevail. There are, however, empirical concepts that describe the retention behavior of peptides and proteins with a ligand in the presence of different solvent combinations. The most commonly adapted concepts are based on the solvophobic theory (Horvath et al., 1976, 1977) and the linear solvent strength theory (Snyder, 1980). These concepts allow the development of fast, robust, and cost-effective separation methods (Boysen et al., 1998).

Various aspects of these theoretical approaches can be used to reach different aims

with a specific separation (Table 10.13.2). These aims may be:

- a. the purification of one component, or alternatively several components simultaneously;
- b. the desalting of a peptide or protein sample;
- c. the characterization of physico-chemical properties of peptides and proteins in hydrophobic environments;
- d. examination of the unfolding behavior of proteins under different sorbent or mobile phase conditions;
- e. determination of linear free energy dependencies between different members of a peptide analog family; selection and optimization of different elution protocols;
- f. examination of the effects of different hydrogen bonding solvents on the retention behavior of peptides or proteins;
- g. the generation of a large variety of empirical data that permits different sorbent types to be validated or batch-to-batch variations characterized. The requirements, in terms of preliminary measurements, for these optimization procedures and data analyses are outlined in Table 10.13.2.

SYSTEMATIC APPROACH TO METHOD DEVELOPMENT

The quality of a separation is determined by the resolution of individual peak zones (Hearn, 1991a). Hence, method development is always an optimization of the resolution, with the trade-off either being the speed or the capacity (sample size) of the separation. The resolution of adjacent peak zones can be defined as:

$$R_s = \frac{(t_1 - t_2)}{(1/2)(\omega_1 + \omega_2)}$$

Equation 10.13.1

Here, t_1 and t_2 are the retention times, while ω_1 and ω_2 are the peak widths of two adjacent peaks. The baseline separation (an overlap of the peaks less than 1%) is given by definition as $R_s = 1.5$. The resolution of two peak zones depends on a large number of factors, including effects that influence the peak symmetry but also on the ratio of the peak areas. R_s values are easily estimated using tables and graphs (Snyder et al., 1988). In a chromatogram, every peak pair has a different R_s value. In developing a very high-resolution analytical separation of a complex mixture of peptide or protein components, method development always focuses on

the least well resolved peak pair. If conditions can be developed to ensure that this “critical peak pair” is well resolved, then all other peaks are also well resolved. However, the peaks that constitute this critical pair can change as a consequence of changes in the experimental conditions. For preparative separations, method development always focuses on the peak of interest and the two adjacent contaminant peaks. In this case, all other peaks can be viewed as superfluous, and directed to the waste. Optimization of the resolution of the peak of interest from the adjacent peaks has to take into account the sample size and the relative abundances of the three components that form the basis of the separation task.

In gradient elution, the resolution also depends on the plate number N , the selectivity α , and the capacity factor \bar{k} , all of which can be experimentally influenced through systematic changes in individual chromatographic parameters. In this case, resolution is determined from:

$$R_s = (1/4)N^{1/2}(\alpha - 1) \left[\frac{\bar{k}}{1 + \bar{k}} \right]$$

Equation 10.13.2

The plate number, N , is the band broadening of the peak zone caused by the column and is a measure of the column performance. The selectivity α describes the selectivity of a chromatographic system for a defined peak pair and is the ratio between the \bar{k} value of the second peak zone and the \bar{k} value of the first peak zone. The capacity factor \bar{k} is a dimensionless parameter of the retention in gradient elution. Its calculation from gradient elution data will be described further below.

In contrast to the isocratic elution, in a gradient elution system N , α , and \bar{k} are the median values for these variables (Hearn, 1991b), since they change during the separation as the shape or duration of the gradient changes. The plate number N has no influence on the selectivity or the retention (except for conditions of temperature change). The selectivity α and the capacity factor \bar{k} have only a minor influence on N . While N and α change only slightly during the solute migration through the column, the \bar{k} value can change by a factor of 10 or more. The best chromatographic separation is achieved within a \bar{k} value range between 1 and 20. Although the resolution is mainly influenced by the mobile phase variables α and \bar{k} , and nearly independent of N for a given column, an optimization strategy should start, from a logistical

Figure 10.13.11 Diagram of column switching unit employed in multi-dimensional HPLC. Abbreviations: D, detector; P_{1,2}, two-pump module for gradient elution mode; P₃, pump equilibrates offline SEC column, while RPC gradient is performed; V₁, injection valve; V₂ and V₃, switching valves. The black field in the switching valve position symbolizes the joined valve positions. In the depicted position, the SEC and the RPC column are connected.

Table 10.13.1 Valve Positions and Pump Activities During the Four Steps in LC-LC Coupling

Step	1	2	3	4
Event	HP-SEC	Start LC-LC	End LC-LC	RP-HPLC
Valve 2: HP-SEC	On	On	On	Off
Valve 3: RP-HPLC	Off	On	Off	On
Mode	Isocratic	Isocratic	Isocratic	Gradient
Pump 1	On	On	On	On
Pump 2	Off	Off	Off	On
Mode	—	—	—	Isocratic
Pump 3	Off	Off	Off	On

Figure 10.13.12 (At right) Illustrative example of the use of multimodal HPLC techniques for the separation and analysis of peptide and protein samples. **(A)** RP-HPLC resolution of the 50S ribosomal proteins from *Thermus aquaticus* in 2% acetic acid (Molnar et al., 1989b) on a C8 column (250-mm length × 4.6-mm i.d.) using a flow rate of 1.5 ml/min and a 30 min gradient from 10% to 100% eluent B [eluent A: 125 mM NaH₂PO₄, 125 mM H₃PO₄; eluent B: acetonitrile: 250 mM NaH₂PO₄, 250 mM H₃PO₄ (50:50), buffer system, pH 2.1]. **(B)** HP-SEC separation of the 50S ribosomal proteins from *Thermus aquaticus* in 2% acetic acid on a tandem TSK-250 column (75-mm length × 7.5-mm i.d. and 300-mm length × 7.5-mm i.d.) using a flow rate of 1.5 ml/min with a isocratic separation with 10% B (eluent as described above) with a fraction cut out and directed on to the reversed-phase column. **(C)** RP-HPLC separation of the fraction of the 50S ribosomal proteins from *Thermus aquaticus* in 2% acetic acid obtained on-line from the size-exclusion chromatography on a C8 column (250-mm length × 4.6-mm i.d.) using a flow rate of 1.5 ml/min and a 30 min gradient from 10% to 100% B (eluent as described above). Proteins 6, 9, and 10, which were coeluted with other proteins in chromatogram A, could now be obtained in relatively pure form for further investigations.

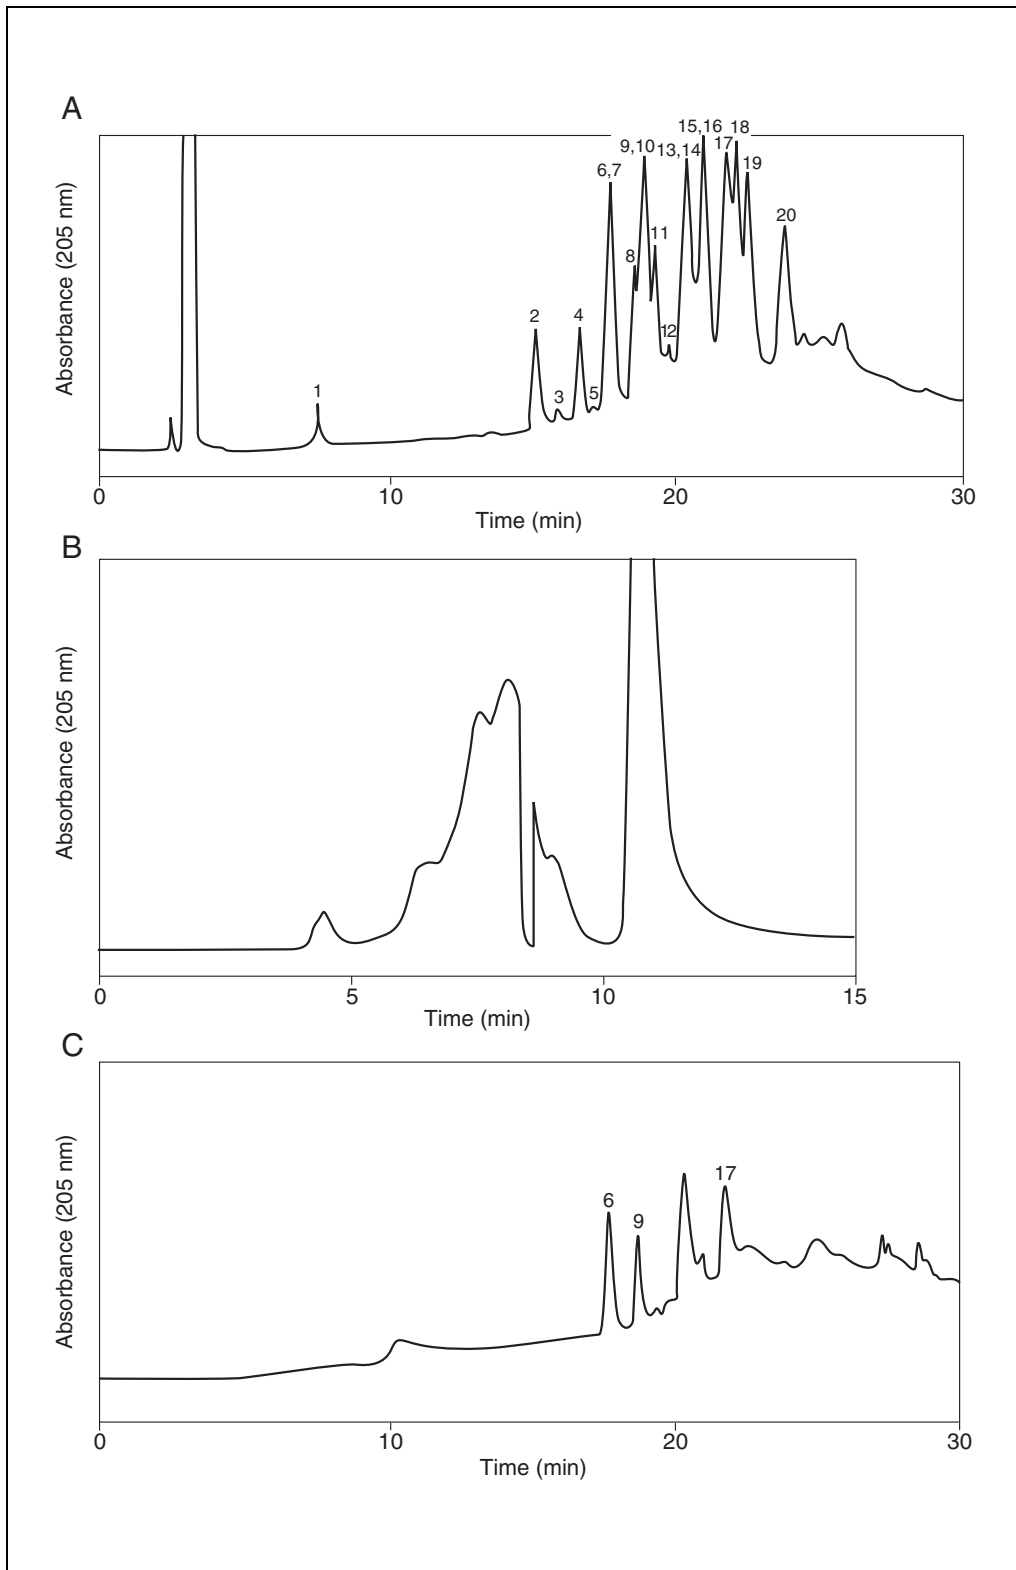

Figure 10.13.12 (See legend on facing page.)

Table 10.13.2 Methodological Requirements of the Different Tasks in RP-HPLC

Task	Purification of one component	Purification of several components simultaneously	Desalting of peptide or protein sample	Characterization of physico-chemical properties
Example	Peptides from solid phase peptide synthesis, enzymatic digestion of a protein	Peptide from tryptic digests, ribosomal proteins, proteins from biological extracts	Fractions from IEX or HIC	Thermodynamic parameters of solute/ligand interaction
Mode	Gradient elution	Gradient elution	Step elution	Isocratic elution
Analytical scale	Yes	Yes	Yes	Yes
Preparative scale	Yes	Yes	Yes	Yes
Measuring of t_0	Yes	Yes	Yes	Yes
Measuring of t_D	Yes	Yes	Yes	—
Column testing	Yes	Yes	Yes	Yes
A value	Yes	Yes	—	Yes
X value	—	Yes	—	—
Y value	—	Yes	—	—
Extra-column band broadening (σ)	—	Yes	—	Yes
Regression analysis	Yes	Yes	—	Yes
Optimization procedures	Yes	Yes	Yes	Yes
Computer simulation	—	Yes	Yes	Yes

point of view, with the optimization of the stationary phase, because many ab initio choices (like column dimensions, choice of ligand, etc.) are determined by the overall strategy (e.g., analytical versus preparative separations). It should be noted, from a theoretical point of view, that optimization of the stationary phase is often performed last (as in some computer simulation programs) when an established analytical method is up-scaled to a preparative method. Typically, a particular RP-HPLC sorbent will be selected empirically as the starting point for the separation. Rarely do most investigators go to the trouble of optimizing the surface chemistries of their own sorbents, although a number of notable exceptions exist. Based on these considerations and in view of the implication of Equation 10.13.2, the optimization can be performed in three modules in the following order: (1) the optimization of the plate number N , then (2) optimization of the selectivity α , and finally, (3) optimization of the \bar{k} values.

Optimization Module 1: The Stationary Phase

The optimization of the peak efficiency, expressed as the theoretical plate number, N , requires an independent optimization of each of the contributing factors that influence the band broadening of the peak zones due to column and the extra-column effects. With a particular sorbent (ligand type, particle size, and pore size) and column configuration, this can be achieved through optimization of the linear velocity (flow rate), the temperature, the detector time constant, and the column packing characteristics, as well as by minimizing extra-column effects, e.g., by using zero-dead volume tubing and connectors. The temperature of the column and the eluents should be constant ($\pm 0.1^\circ\text{C}$) using a thermostatically controlled system in order to facilitate the reproducible determination of the various column parameters and to ensure reproducibility in the resolution.

The theoretical plate numbers measured on the same column are smaller for proteins than for small peptides. This difference in peak width behavior between peptides and proteins can be explained directly from the Knox equation (Knox and Scott, 1983; Freebairn and Knox, 1984), if the N values are expressed as reduced plate heights, i.e., $h = L/Nd_p$, where L is the column length, and d_p is the average particle diameter of the sorbent. According to the Knox equation, h is related to the reduced mobile phase velocity, v , through the relationship $h = Av^{0.33} + Bv^{-1} + Cv$, where $v = ud_p/D_m$, u is the linear velocity, and A , B , and C are constants that describe the packing and solute transport characteristics of a particular sorbent in a column. Observations of reduced plate heights (h values) in the range $3 < h < 15$ for small peptides with reversed-phase sorbents of average particle size of 3 to 10 μm , and for proteins and other high molecular weight macromolecules where h values are >50 , have frequently been made, confirming that the Knox equation can be approximated (Snyder et al., 1983) for small peptides as $h = Av^{0.33}$ and for proteins as $h = Cv$, because, in the latter case, only the intraparticle pore transport and surface interaction (term C), contributes significantly to the band broadening.

The following parameters can be used to assess column and extra column effects:

The A value of the column (a term that reflects the quality of the packing of the sorbent in the column) can be determined according to the procedures described in Stadalius et al. (1987). The A values for well packed columns fall within the limits of $0.5 \leq A \leq 1$. An A value equal to one corresponds to a column containing a theoretically ideal bed of particles in a dodecahedral close-packed arrangement (Stout et al., 1983).

The X value (the column volume of mobile phase outside the pores of the particles) can be calculated according to the procedures described in Stadalius et al. (1987).

The average Y value (an estimate of the diffusional restriction of proteins within the pores of the sorbent) can be calculated according to the procedures described in Stadalius et al. (1987). When no restricted diffusion occurs, the value of Y , which corresponds to the ratio (D_p/D_m) is equal to one. Here D_p is the diffusion constant of the protein within the pores of the particle and D_m is the diffusion coefficient of the peptide or protein in the bulk mobile phase. For proteins with molecular weights within the range 10,000 to 80,000, separated using RP-

HPLC sorbents of large pore diameters (e.g., ≥ 30 nm or larger), the Y values typically fall within the narrow range of 0.8 ± 0.1 , indicating that limited restricted diffusion can occur but that the D_p/D_m ratio is largely independent of the molecular size and weight of the examined proteins. However, with particles of smaller pore size, such as ≤ 10 nm, a larger range of Y values (e.g., $0.05 \leq Y \leq 0.80$) will occur with a significant dependency of the Y value on the molecular characteristics of the test proteins.

The measurement of the extra-column band broadening σ (which describes the decrease in column performance due to instrumental design) can be determined with a "zero-length column" that connects the injector with a sample loop of 1 μl directly to the detector (Freebairn and Knox, 1984; Hupe et al., 1984). Its value can be calculated based on the calculated peak asymmetry values according to the procedures described in Stadalius et al. (1987).

The extra-column band broadening or volume dispersion effects caused by the injector, tubing, and detector influence the performance of the column and should be less than 10% of the plate number of the column. The extra-column band broadening expressed as peak standard deviation should therefore be less than a third of the band broadening due to the characteristics of the packed column, e.g., as given by:

$$\sigma_{\text{COL}} = \frac{V_0}{\sqrt{N}} \text{ with } \sigma_{\text{DI}} \leq (1/3)\sigma_{\text{COL}}$$

Equation 10.13.3

Hence, the LC system should be designed so as to have minimal extra-column band broadening. Care should be taken to attach fittings in such a way as to avoid unnecessary void volumes and to choose tubing with the smallest possible inner diameter, as well as to keep the volume of the detector cell low.

For a standard analytical column, the maximum extra-column band broadening can be therefore be calculated as:

$$\sigma_{\text{COL}} = \frac{1900\mu\text{l}}{\sqrt{10000}} = 19\mu\text{l} \text{ with } \sigma_{\text{DI}} \leq 6.3\mu\text{l}$$

Equation 10.13.4

In order to obtain this value, the detector cell volume must be 5 μl or less.

The flow rate to achieve the minimum plate height, H , for a column can be taken from the literature or experimentally determined accord-

ing to procedures described in Stadalius et al. (1987).

Optimization Module 2: The Mobile Phase Composition

Change in selectivity of the separation with peptides and proteins is the most effective way to influence resolution. This is mainly achieved by changing the chemical nature or concentration of the organic solvent modifier (acetonitrile, methanol, isopropanol, etc.) or the choice of an ion pair reagent (Hancock et al., 1978).

Choice of the organic solvent modifier

A good starting point is the solvent selectivity triangle approach. Here, solvents are classified according to their relative dipole moment, basicity, or acidity in a triangle. Blends of three different solvents, plus water to provide an appropriate \bar{k} range, are selected to differ as much as possible in their polar interactions. This selection permits the solvent combinations to mimic the selectivity that is possible for any given solvent, and confines the boundaries of the triangle (Snyder, 1974, 1978). At the same time, these solvents must be totally miscible with each other and with water. Three solvents that best meet these requirements are methanol, acetonitrile, and tetrahydrofuran. Four-solvent mobile phase optimization using three organic solvents and water provides a significant control over α values in reversed-phase HPLC. If different organic solvents are used, the different eluotropic strengths (Schoenmakers et al., 1979; Patel and Jefferies, 1987) must be considered in order to elute the sample in the appropriate \bar{k} range.

Choice of ion pair reagent

The retention of peptides can be influenced by the presence of ion pair reagents (Horvath et al., 1977; Hearn et al., 1979; Goldberg et al., 1984; Mant and Hodges, 1991c). The ion pair reagents interact with the ionized groups of the peptides: anionic counterions (e.g., hexanesulfonic acid, orthophosphoric acid, TFA, HFBA) interact with basic residues (arginine, lysine, histidine) of a peptide as well as with the protonated *N* terminus; cationic counterions (e.g., triethylammonium, tetrabutyl-ammonium) interact with ionized acidic residues (glutamic and aspartic acid, tyrosine and cysteic acid) as well as ionized free C-terminal carboxylic groups. The actual effect on retention depends strongly on the hydrophobicity of the ion-pair reagent and the number of oppositely charged groups on the peptide. Typically, the retention

of peptides and proteins in the presence of ion pairing reagents follow asymptotic dependencies on the concentration of the different ion pairing reagent.

Once the selectivity parameter is fixed due to the *initial* choices of the mobile and stationary phase, the further optimization should concentrate on resolution optimization via achieving the most appropriate \bar{k} value for the different peptides or proteins in the mixture.

Optimization Module 3: The Gradient Conditions

For resolution optimization, the strategy takes advantage of the relationship between the gradient retention time of a protein (expressed as the median capacity factor, \bar{k}) and the median volume fraction of the organic solvent modifier $\bar{\phi}$, in regular RP-HPLC systems based on the concepts of the linear-solvent-strength theory (Horvath et al., 1976; Snyder, 1980; Hearn and Grego, 1983), such that:

$$\ln \bar{k} = \ln k_0 - S\bar{\phi}$$

Equation 10.13.5

where k_0 is the capacity factor of the solute in the absence of the organic solvent modifier, and S is the slope of the plot of $\ln \bar{k}$ versus $\bar{\phi}$. The values of $\ln k_0$ and S can be calculated by linear regression analysis. The underlying principles of an intuitively performed optimization and manually achieved optimization (using Excel spreadsheets, for example, to calculate the $\ln k_0$ and S values), or, alternatively, optimization via computer simulation software (e.g., Simplex methods, multivariate factor analysis programs, DryLab *G/plus*, etc.) are essentially the same. However, the outcomes result in different levels of precision. Two representative approaches are collectively outlined below.

Resolution R_S of peak zones is optimized through adjustment of \bar{k} by successive change of the parameters t_G and $\Delta\phi$ in the gradient elution mode according to the following steps:

- Initial experiments;
- Peak tracking and assignment of the peaks;
- Calculation of $\ln \bar{k}$ and S values from initial chromatograms;
- Optimization of gradient run time t_G over the whole gradient range;
- Determination of new gradient range;
- Calculation of new gradient retention times t_g ;
- Change of gradient shape (optional);
- Verification of results.

Initial experiments

In initial experiments, the peptide or protein sample is separated under two linear gradient conditions differing by a factor of 3 in their gradient run times t_G (all other chromatographic parameters being held unchanged; Dolan et al., 1989) to obtain the RP-HPLC retention times of each peptide or protein. Irrespective of what optimization strategy will be then used, it is advisable to separate any sample with at least two different gradient run times, in order to identify overlapping peaks. For optimization of the gradient shape and to achieve maximum resolution between adjacent peak zones, the ability to determine the retention times of the peptides or proteins and to classify the parameters that reflect contributions from the mobile phase composition and column dimensions (Table 10.13.3) is essential (Ghrist and Snyder, 1988a,b; Ghrist et al., 1988). The determination of the volume, V_{mix} , is useful (Stadalius et al., 1984); determination of dead volume and gradient delay are essential (Snyder, 1980). With these compiled input parameters, various algorithms including DryLab *G/plus* can generate the relative resolution map (RRM), based on calculation of the corresponding S values and k_0 values for each component. If no DryLab *G/plus* is available, the resolution information can be extracted directly from the vertical distances of the individual R_S versus t_G plots, whereby a cross-over of lines reflects a peak overlap as shown in Figure 10.13.13A,B,C. Over a small range of $\bar{\phi}$ values, the S values and k_0 values for an individual peptide or protein will remain essentially constant. It is assumed that no significant conformational change of the individual peptides or proteins occurs as a consequence of the differences in column residency time and gradient time (Purcell et al., 1993). The typical retention behavior of the peptides and proteins is depicted in Figure 10.13.13 as plots of $\ln \bar{k}$ versus $\bar{\phi}$. These plots become nonparallel, and are frequently intersecting, as the mobile phase composition is varied.

Choice of starting conditions

The S values of peptides and proteins can be empirically correlated with their molecular weights (Snyder et al., 1983), based on a correlation of $S = 0.48(MW)^{0.44}$. Thus S values, estimated with this equation or, alternatively, values of similar peptides or proteins taken from the literature, can be used to calculate a reasonable starting point for the initial experiments according to the following equation:

$$t_G = \frac{V_m \times \Delta\phi \times S \times \bar{k}}{0.87 \times F}$$

Equation 10.13.6

The required gradient run time, t_G , for a separation of peptides and proteins with expected S values of around 20 can be calculated for a gradient of 0% to 100% (60% ACN) at a flow rate of 1 ml/min and the ideal \bar{k} value of 5 as follows:

$$t_G = \frac{1.9 \text{ ml} \times 0.6 \times 20 \times 5}{0.87 \times 1 \text{ ml/min}} = 131 \text{ min}$$

Equation 10.13.7

Based on this calculation, the initial gradients from 0% to 100% eluent B for gradient times of 1 and 3 hr duration can be selected.

On the other hand, availability of the S values, derived from two gradient elution RP-HPLC experiments, can be used as an analytical criterion early in the separation of the target peptide or protein from other components in soluble extracts of biological sources, to distinguish low- from high-molecular-weight molecules and, e.g., to exclude peptide fragments participating in the optimization process, without having to resort to SDS-PAGE experiments. The RP-HPLC behavior of small peptides with molecular weights from 300 to 1000 are approximately correlated (Hearn and Grego, 1981; Snyder, 1990; Wilce et al., 1995) to S values between 3 and 10. For medium-molecular-weight globular proteins, S values above 20 are expected (Aguilar et al., 1985). As an example, cytochrome *c*, with a molecular weight of ~12,000, has an S value of 28.8 on a Nucleosil C-18 column (Stadalius et al., 1984).

Calculation of $\ln k_0$ and S values

The retention times t_{g1} and t_{g2} for a peptide or protein solute separated under conditions of two different gradient run times (t_{G1} and t_{G2} , whereby $t_{G1} < t_{G2}$) can be given by the following equations (Quarry et al., 1986; Ghrist et al., 1988):

$$t_{g1} = \left(\frac{t_0}{b_1} \right) \log(2.3k_0b_1) + t_0 + t_D$$

Equation 10.13.8

$$t_{g2} = \left(\frac{t_0}{b_2} \right) \log(2.3k_0b_2) + t_0 + t_D$$

Equation 10.13.9

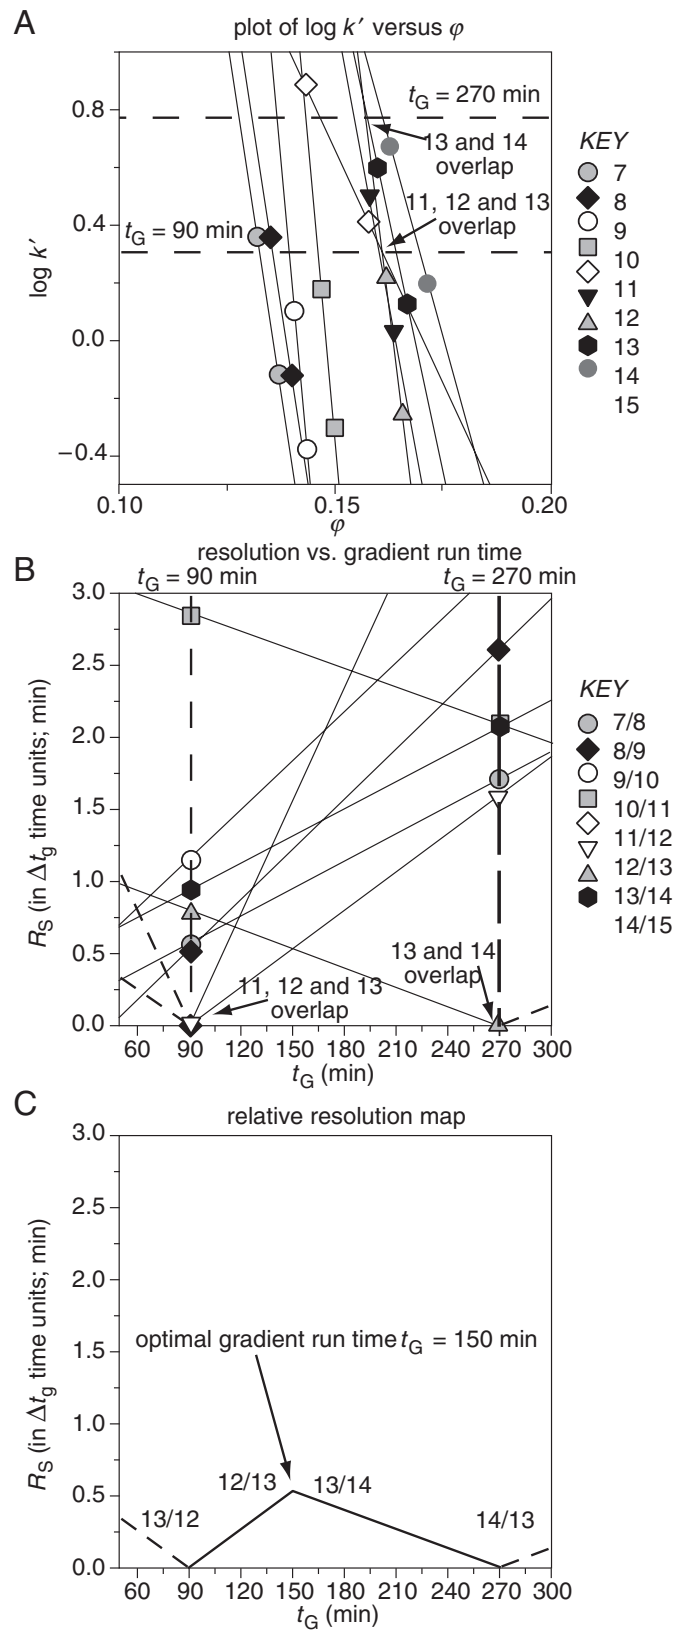

Figure 10.13.13 (A) Plots of logarithmic capacity factor $\ln k'$ versus the volume fraction of organic solvent, ϕ , for 9 different proteins, denoted 7 to 15, obtained from *Thermus aquaticus* on a C18 RP-HPLC column. As evident from this plot, the intersection of two plots represents complete overlap of the peak zones at the specific gradient run times t_G 90 and 270 min. (Legend continues on next page.)

where:

$$\frac{b_1}{b_2} = \frac{t_{G2}}{t_{G1}} = \beta$$

Equation 10.13.10

Here, t_{G1} , t_{G2} are the gradient run time values of t_G for two different gradient runs, resulting in different values of b (b_1 , b_2) and t_g (t_{g1} , t_{g1}) for a single solute; t_{g1} , t_{g1} are the gradient retention times for a single solute in two different gradient runs; b_1 , b_2 are the gradient steepness parameters for a single solute and two gradient runs differing only in their gradient times. Steep gradients correspond to large b values and small \bar{k} values; k_0 is the solute capacity factor at the initial mobile phase composition; β is the ratio of t_{G2} and t_{G1} which is equivalent to the ratio of b_1 and b_2 ; t_0 is the column dead time; and t_D is the gradient delay time.

For peptides and proteins there is an explicit solution (Stadalius et al., 1984; Quarry et al., 1986) for b and k_0 , namely:

$$b_1 = \frac{t_0 \log \beta}{\left[t_{g1} - \left(\frac{t_{g2}}{\beta} \right) + (t_0 + t_D) \left(\frac{1 - \beta}{\beta} \right) \right]}$$

Equation 10.13.11

$$\log k_0 = \left(\frac{b_1}{t_0} \right) (t_{g1} - t_0 - t_D) - \log(2.3b_1)$$

Equation 10.13.12

From the knowledge of b and k_0 the values of \bar{k} and $\bar{\varphi}$ can be calculated (Snyder, 1980; Hearn, 1991b):

$$\bar{k} = \frac{1}{1.15b_1}$$

Equation 10.13.13

$$\bar{\varphi} = \frac{\left[t_{g1} - t_0 - t_D - \left(\frac{t_0}{b_1} \right) \log 2 \right]}{t_{G1}^0}$$

Equation 10.13.14

Table 10.13.3 Parameters Required for the Calculation of $\ln k_0$ and S Values and for the Manual Optimization and Optimization with DryLabG/plus

Parameter	S and $\log k$	RRM
	Manual	DryLab
Gradient delay volume V_D (ml)	Yes	Yes
Dead volume t_0 (ml)	Yes	—
Gradient range (%B)	Yes	Yes
Gradient run time t_{G1} , t_{G2} (min)	Yes	Yes
Column length L (mm)	—	Yes
Column diameter d_C (mm)	—	Yes
Flow rate F (ml/min)	—	Yes
Column plate number N	—	Yes
Retention times t_{g1} for all peaks	Yes	Yes
Retention times t_{g2} for all peaks	Yes	Yes

Figure 10.13.13 (Continued) **(B)** Plots of the resolution R_S (resolution taken as the difference in retention times, Δt_g , for two adjacent peaks) versus the gradient run time t_G of these 9 different proteins from *Thermus aquaticus*. These data represent the blueprint for generation of the relative resolution map (RRM). Since the plotted values of the resolution are absolute values, negative resolution values of peaks that change their elution order are depicted as broken lines. **(C)** RRM is shown for the nine different proteins from *Thermus aquaticus*, depicting only the critical peak pairs including their change in retention order. The resolution optimum for this specific set of chromatographic conditions occurs at $t_G = 150$ min.

Here, \bar{k} is the value of k' (capacity factor) for a solute when it reaches the column midpoint during elution; ϕ is the volume fraction of solvent in the mobile phase; $\Delta\phi$ is the change in ϕ for the mobile phase during the gradient elution ($\Delta\phi = 1$ for a 0% to 100% gradient); $\bar{\phi}$ is the effective value of ϕ during gradient elution and the value of ϕ at band center when the band is at the midpoint of column, and t_G^0 is the normalized gradient time with $t_{G1}^0 = t_{G1}/\Delta\phi$.

By linear regression analysis, using \bar{k} and $\bar{\phi}$, the S value (empirically related to the hydrophobic contact area between solute and ligand) can be derived from the slope of the $\log\bar{k}$ versus $\bar{\phi}$ plots, and $\ln k_0$ (empirically related to the affinity of the solute towards the ligand) as the y-intercept (Horvath et al., 1976):

$$S = \frac{(\ln k_0 - \ln \bar{k})}{\bar{\phi}}$$

Equation 10.13.15

Peak tracking and assignment of the peaks

Complex chromatograms that result from reversed-phase gradient elution can often exhibit changes in peak order when the gradient steepness is changed. Before $\ln k_0$ and S values are calculated, or computer simulation is used, the peaks from the two initial runs need to be correctly assigned. Several approaches to peak tracking have been described, using algorithms based on relative retention and peak areas (Glajch et al., 1986; Lankmayr et al., 1989; Molnar et al., 1989a), or alternatively, based on diode-array detection (Berridge, 1986; Strasters et al., 1989; Round et al., 1994).

The assignment of peaks can be done in the following steps:

1. Integrate the chromatograms (using the integration software of the HPLC system or alternatively an integrator) of the initial runs and correct integration due to baseline drift or other instrumental causes where necessary.
2. Print out both chromatograms including the peak area percent reports.
3. Number all relevant peaks in the chromatogram with the better resolution. Relevant peaks have, e.g., an area >0.5% of the overall peak area.
4. Assign the peaks according to their peak areas allowing a reasonable elution window.

The total peak areas, A_{T1} and A_{T2} for the initial runs 1 and 2 (whereby $t_{G1} < t_{G2}$) are determined, as:

$$A_T = \sum_{i=1}^n A_i$$

Equation 10.13.16

and their ratio is calculated:

$$R_T = \frac{A_{T2}}{A_{T1}}$$

Equation 10.13.17

Consequently the ratio of the peak areas, A_{i1} and A_{i2} of a baseline separated single component in the initial runs 1 and 2, respectively, is:

$$R_i = \frac{A_{i2}}{A_{i1}}$$

Equation 10.13.18

If the peaks are correctly assigned, $R_T = R_i$. Difficulties arise when peaks partially or completely overlap. If $R_T \ll R_i$ and the peak in run 2 is composed of a single component, the peaks are wrongly matched. If $R_T \gg R_i$ then the peaks might be correctly matched, but the peak area in run 1 could be enlarged by a hidden additional peak. In order to resolve these difficulties, the deviation ($\%R_T$) of R_i from R_T can be calculated and taken as a measure of the likelihood that a peak assignment hypothesis is correct:

$$\%R_T = \frac{100R_i}{R_T} - 100$$

Equation 10.13.19

Optimization of the gradient time, t_G , over the whole gradient range

The capacity factor \bar{k} is a linear function of the gradient run time t_G if $\Delta\phi$ is kept constant. Hence:

$$\frac{\bar{k}}{t_G} = \frac{0.87F}{V_m \times \Delta\phi \times S} = \text{constant} = C$$

Equation 10.13.20

The optimized gradient run time t_{GRRM} can be obtained from the RRM or alternatively, from the plot of R_S versus t_G (see Fig. 10.13.13, panels A to C), and yields for each peptide or protein the new values of \bar{k}_{new} by t_{GRRM} being multiplied by C :

$$C t_{GRRM} = \bar{k}_{new}$$

Equation 10.13.21

Determination of the new gradient range

If the gradient run time t_{GRRM} is changed in relation to $\Delta\phi$ with $t_{\text{G1}}^0 = \text{constant}$, the \bar{k} values do not change, as can be seen from the following equation:

$$t_{\text{G1}}^0 = \frac{t_{\text{GRRM}}}{\Delta\phi} = \frac{V_m \times S \times \bar{k}}{0.87 \times F}$$

Equation 10.13.22

where:

$$\Delta\phi_{\text{opt}} = \frac{t_{\text{Gopt}}}{t_{\text{G1}}^0}$$

Equation 10.13.23

and the retention time t_g of the first peak is $>(t_0 + t_D)$ and the retention time t_g of the last peak is $<\Delta t_{\text{Gopt}}$.

Calculation of the new gradient retention times t_g

Based on the knowledge of the S and the $\ln k_0$ values, new gradient retention times can then be calculated.

Change of gradient shape (optional). A multisegmented gradient should only be performed when the gradient delay has been measured. With multisegmented gradients, an error in the gradient delay will reoccur at the beginning and at the end of each gradient step. In addition, the effect of V_{mix} (which can be determined according to the procedures described in Ghrist et al., 1988), which modifies the composition of the gradient at the start and end (rounding of the gradient shape), can lead to deviation of the experimentally determined from the predicted “ideal” retention times in DryLab *G/plus* simulations.

Verification of the results. After completion of the optimization process, the simulated chromatographic separation can now be verified experimentally using the predicted chromatographic conditions.

DETERMINATION OF THERMODYNAMIC PARAMETERS ASSOCIATED WITH PEPTIDE OR PROTEIN INTERACTIONS WITH IMMOBILIZED LIGANDS

Isocratic elution can be utilized to determine thermodynamic parameters associated with the interaction of a peptide or protein with an immobilized ligand in all of the various HPLC modes. Thus, the enthalpy, $\Delta H^0_{\text{assoc}}$, the entropy, $\Delta S^0_{\text{assoc}}$, and the heat capacity, ΔC^0_p , of

the association of a peptide or protein interacting with immobilized nonpolar ligand in RP-HPLC can be evaluated from the dependency of $\ln k'$ on T , i.e., from the van't Hoff plots (Melander et al., 1984; Haidacher et al., 1996; Vailaya and Horvath, 1996; Boysen et al., 1999; Hearn and Zhao, 1999; Hearn, 2001b), and from the Boltzmann-Helmholtz expression:

$$\ln k' = \frac{-\Delta H^0_{\text{assoc}}}{RT} + \frac{\Delta S^0_{\text{assoc}}}{R} + \ln \Phi$$

Equation 10.13.24

In order to derive this fundamental information, in addition to the procedures and reagents described in the sections above, the following materials and conditions are required:

Two 5-liter flasks

Peptide or protein (purity >95%) sample at a concentration of 1 mg/ml in a suitable buffer

1. Measure the dead volume t_0 of the system as described above.

2. Determine the isocratic conditions at which the peptides or proteins elute in a k' range of 2 to 10. Typically, these mobile phase conditions will encompass only a narrow range of values, e.g., 22% to 27% acetonitrile/water (v/v)/0.1% TFA for a RP-HPLC separation, and must be determined by running the sample under different eluent conditions.

3. Prepare stock solutions: e.g., 5 liters each of eluents of appropriate compositions that are ~2% above and 2% below the determined elution range (per the example above 20% and 30% v/v acetonitrile/water/0.1% TFA).

4. Manually mix final buffer in 1% steps from the two stock solutions, according to mixing tables (e.g., Tables for the Laboratory, Merck). Anticipate different eluent consumption for different mobile phase compositions.

5. Inject the sample in order to determine the retention times of the peptide or protein in the temperature range of 5° to 65°C (or higher depending on column specifications) at different isocratic eluent compositions in 5°C increments, allowing no more than 0.5°C column temperature fluctuation, measuring each data point at least twice.

6. Establish the van't Hoff plots and fit the data to a polynomial equation using linear regression analysis as described in Boysen et al. (1999).

7. Use the derived coefficients to calculate the thermodynamic parameters, the enthalpy $\Delta H^0_{\text{assoc}}$ of the association, the entropy $\Delta S^0_{\text{assoc}}$ of the association, and the heat capacity ΔC^0_p exemplified for a second-order approximation

of the solute-ligand interaction by the following equations (Boysen et al., 1999):

$$\ln k' = b_{(0)} + \frac{b_{(1)}}{T} + \frac{b_{(2)}}{T^2} + \ln \Phi$$

Equation 10.13.25

$$\Delta H_{\text{assoc}}^{\circ} = -R \left[b_{(1)} + \frac{2b_{(2)}}{T} \right]$$

Equation 10.13.26

$$\Delta S_{\text{assoc}}^{\circ} = R \left[b_{(0)} - \frac{b_{(2)}}{T^2} \right]$$

Equation 10.13.27

$$\Delta C_p^{\circ} = R \left[\frac{2b_{(2)}}{T^2} \right]$$

Equation 10.13.28

The physical basis and applications of this approach to characterize peptide- or protein-ligand interactions have been extensively described in a variety of papers and reviews (Hearn, 2000, 2001a,b).

TROUBLESHOOTING

There are three approaches to troubleshooting, which are usually practiced in combination: (1) preventive maintenance; (2) anticipation of problems during use by small signs of malfunction; and (3) complacency until complete breakdown.

The choice of the troubleshooting approach ultimately affects the spare part strategy and general instrument management and maintenance approach (see Table 10.13.4). As a consequence, the concept of preventative maintenance

addresses both the hardware and software, as well as the selection of sorbent characteristics, mobile phase composition, and sample preparation.

Preventive Maintenance

By practicing preventive maintenance, the downtime of HPLC instrumentation used in peptide and protein separation can be substantially minimized.

As a general principle, use clean buffer and reagents, use proper sample preparation techniques, keep air out of the LC system, check the system for leaks, remove all unwanted substances (sample, buffer components) from the system at the end of each day's work, and be aware of how the system works under normal conditions.

Mobile phase

Filter all mobile phases except pure HPLC-grade solvents through 0.2- μm filters. During filtration, avoid contamination that might result from the use, e.g., of dirty glassware or rubber stoppers. Degas all solvents thoroughly. Ensure that all fittings on the low-pressure side of the HPLC pump are tight, so that air is not drawn in. Add sodium azide (10,000 ppm) to the mobile phase in order to stop microbial growth, particularly in phosphate and acetate buffers, if they are stored at room temperature for longer than one day.

Use a solvent inlet line filter (usually 10 μm porosity) in order to prevent particulate matter entering the pump and to act as a weight to keep the inlet line at the bottom of the solvent reservoir. Cap reservoir loosely to prevent dust from entering the mobile phase and to allow air influx. Avoid cross-contamination of buffer, discard stale mobile phases, and clean the eluent reservoir regularly.

Table 10.13.4 Troubleshooting Strategy and Resulting Spare Part Policy

Troubleshooting strategy	Spare part strategy	Parts replaced
Preventive maintenance	Have always available and change frequently	Precolumn Guard column Column frits In-line filter Inlet filter
Anticipation of problems	Have available as backup parts	Column Fitting and tubing valves
Wait until complete breakdown	Purchase as needed	Lamps Circuit boards Pump heads Fuses

Stationary phase

Ensure compatibility of the sample solvent with the mobile phase. Incompatibility of the sample buffer with the mobile phase can cause a precipitation of sample in the pores of the column packing.

Ensure compatibility of the mobile phase components with each other. Mobile-phase strength effects can cause precipitation of eluent components, such as salts, inside the column, resulting in column blockage or a packing void.

Ensure compatibility of the column with the mobile phase. The set of guidelines supplied with the column reveal the pressure and temperature limit at which pH range the column can be used (the wrong pH can cause loss of bonded phase with many silica-based sorbents) and which solvents are compatible with the stationary phase (an incompatible solvent can shrink or swell column particles with the polymeric-type of sorbents).

Use in-line filter or guard columns. For SEC and other chromatographic modes with impure samples, the use of an 0.5- μm in-line filter is recommended in order to prevent blockage of the column inlet frit. A guard column, preferably packed with the same material as the separation sorbent, prevents a blockage of the column inlet frit and deterioration of the column performance. The integrity of the guard column must be checked regularly, and it must be exchanged when necessary, since a poor guard column can adversely affect column performance.

Avoid pressure shocks. Pressure shocks can be minimized by using a pulse damper and by avoiding drastic flow rate changes.

Avoid exceeding the pressure limit by using the upper limit switches of the pump in the method program. Do not use default values. Select the upper limit of pressure according to the back-pressure of a new column with an associated method (depending on the viscosity of the mobile phase, it could be the mid-gradient pressure when using water-organic solvents, e.g., 1500 psi) and add a margin of 1000 psi in order to avoid stopping of overnight runs, etc. (yielding a pressure limit of, e.g., 2500 psi).

Wash the column after use. All columns should be flushed with 10 column volumes of either an organic solvent/water mixture or water with 10,000 ppm sodium azide to suppress microbial growth.

Store the column, when not in use, in the appropriate solvent (see manufacturers' instructions)—either in >10% organic solvent or

with sodium azide when organic solvents have to be avoided. The mobile phase in which the column is stored should not contain any salts, acids, or bases.

Fittings and tubing

Assemble the fittings so that the tubing contacts the bottom of the fitting body. Tighten the fitting sufficiently to prevent leaks, but not so much as to distort the ferrule. In order to minimize the extra column band broadening, all tubing on the high-pressure side from the injector to the detector (excluding detector outlet) should be 0.01-in. and as short as convenient. Larger i.d. tubing (e.g., 0.020-in.) is suitable for connecting the pump with the injector. The extra column band broadening can be measured with a zero length column.

Manual injector

Filter all samples. Avoid pressure values above 5000 psi. Do not use syringes with sharp needles (e.g., from gas chromatography). Maintain adequate gas pressure for air- or nitrogen-operated valves. Flush injector at the end of each day's work. If a leaking valve requires the replacement of a damaged seal, rebuild the valve using the kit and instructions supplied by valve vendor. Finally, store the injector in a nonbuffered mobile phase when not in use.

Pump(s)

Avoid air bubbles entering pump. If an air bubble arises in the pump see discussion of Priming the Pumps and Low-Pressure Lines with Eluents in *UNIT 10.12*.

Always flush the HPLC after use to prevent salt deposits at the pump valves. If blocked, see discussion on Preparing the HPLC System in *UNIT 10.12*.

Flush behind the pump seal at the end of each day's LC operation, first with 5 to 10 ml water, then with 5 to 10 ml methanol or isopropanol in order to remove the water. Many LC systems have a flushing port. By design, the pump seal does not seal completely around the piston. Crystalline buffer residues may act as an abrasive on the pump seal when restarted, damaging the seal with possible scratching of the piston. Store pumps in nonbuffered mobile phase or pure organic solvent.

Detector(s)

Keep the detector cell clean by washing it at the end of each day's work with the strong mobile phase. Do not perform acid washing on

a routine basis. Switch the detector lamp off when not in use for the next 2 hr or longer. Avoid frequent "on and off" switching.

Recorder, printer and data systems

Replace ink when recorder ink begins to fade. Lift the pen from the paper and cap it, when recorder is not in use. Check paper supply before HPLC instrument is started and before leaving the HPLC instrument unattended. Ensure that adequate disk storage space exists within the computer for unattended runs.

Anticipation of Problems

With this strategy parts are replaced when minor signs of malfunction occur.

Troubleshooting after HPLC Breakdown

The first aim of troubleshooting is the reduction of HPLC instrument down time. Equally important is the prevention of further damage to the HPLC system, which includes the consequences of troubleshooting. It is therefore crucial to identify the point at which help is needed or whether an event is a case for the manufacturer's service (as most electronic problems are). Before calling the service engineer, the following sources of help can be utilized if a problem occurs:

Operation manual

Internal laboratory records, including the log-books

Troubleshooting guides

Other people in the laboratory

Manufacturer's technical support line.

If technical support from the manufacturer is needed, agree on precise appointment times, be there in order to learn from the support personnel, or alternatively, to challenge them. Brief them thoroughly, and have all of the activities recorded for further reference. Check on warranty times of parts and on proper invoicing.

With analytical thinking, and the following good practices, most of the problems can be solved:

Describe the problem in as unprejudiced a way as possible.

Observation of a problem should be confirmed twice before taking further action.

Operate the instrument under reference conditions, if possible.

Take notes of every change you make while trying to solve the problem.

Label all removed parts.

Make only one change at a time.

Only use replacement parts that have been proven not to be faulty or worn out.

Change a part back, if it did not resolve the problem. This does not apply if a risk exists to cause further damage to parts when they are replaced, if parts are inexpensive, if reinstallation creates the risk of damaging a module, or if parts are scheduled for replacement anyway. Document problem solution.

TERMINOLOGY

In this chapter, the nomenclature follows that proposed for the chromatographic sciences by the IUPAC recommendations (Ettre, 1994).

SUMMARY

In this overview, a variety of protocols and instrumental considerations have been introduced, and various factors involved in the correct selection of experimental procedures have been described. This information represents a starting point for good laboratory practices for the resolution of complex mixtures of peptides and proteins by HPLC methods—not the ultimate solution. As a consequence, the various sections have been prepared with the novice practitioners in mind, rather than the expert chromatographic scientist or peptide/protein chemist with advanced chromatographic skills. These introductory sections should thus facilitate the successful development by biologists and other life scientists with little formal training in the modern separation sciences, but who nevertheless face numerous experimental challenges requiring the high-resolution separation of complex mixtures of peptides and proteins by HPLC techniques.

Reversed-Phase Isolation of Peptides

UNIT 10.14

Reversed-phase high-performance liquid chromatography (HPLC) is a fundamental tool for the isolation and analysis of peptides. Peptides are separated on a hydrophobic stationary phase and eluted with a gradient of increasing organic solvent concentration. Peptides in 5- to 500-pmol quantities are separated on a narrow-bore (2-mm-i.d.) or microbore (1-mm-i.d.) column (see Basic Protocol 1). Separation of peptides in quantities <5 pmol can be accomplished using capillary HPLC columns (see Basic Protocol 2). Capillary HPLC columns, however, require a gradient flow rate of 3 to 5 $\mu\text{l}/\text{min}$, which most current HPLC pumps cannot attain without modifications. A procedure is therefore provided for constructing a capillary HPLC system using readily available components (see Support Protocol).

HPLC peaks that appear to be symmetrical may actually contain coeluting peptides. Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry (see Basic Protocol 3 and Alternate Protocol; also see *UNITS 10.21 & 10.22*) and capillary electrophoresis (see Basic Protocol 4; also see *UNIT 10.20*) can be used to analyze a small portion of an HPLC fraction and to determine the number of components present in a small sample. These methods can be utilized to screen fractions prior to automated sequencing.

REVERSED-PHASE PEPTIDE SEPARATION AT THE 5- TO 500-PMOL LEVEL

**BASIC
PROTOCOL 1**

A 2-mm narrow-bore column requires a flow rate of 100 to 200 $\mu\text{l}/\text{min}$. Many commercial HPLC instruments are capable of providing flow rates in this range, although some have tubing with a large internal volume that may add excessive delay time to the separation. Some HPLC instruments that are suitable without modification for 1- and 2-mm columns are listed in the materials section below. Many older HPLC instruments can be utilized for 2-mm columns, but most cannot reproducibly deliver the 50- to 100- $\mu\text{l}/\text{min}$ flow rates required by 1-mm columns.

Materials

Mobile-phase solvent A: 0.1% (v/v) trifluoroacetic acid (TFA; Pierce) in Milli-Q water (TFA sold for protein sequencing may not be suitable because some manufacturers add antioxidants that can generate artifacts)

Mobile-phase solvent B: 0.07% to 0.1% (v/v) TFA (Pierce) in acetonitrile or 1- or 2-propanol (Burdick & Jackson or Baker; HPLC-grade)

Solvent modifier: TFA (Pierce)

Milli-Q grade water or equivalent (distilled water is not suitable)

Peptide sample

HPLC peptide standards, commercial (e.g., PE Biosystems) *or* tryptic digest (see Troubleshooting), for testing column

HPLC system (e.g., Hewlett-Packard HP-1090 liquid chromatograph; PE Biosystems model 170A; Michrom BioResources Ultrafast Microprotein Analyzer; Beckman System Gold; Waters Alliance System)

Detector flow cell (see recipe)

2-channel strip-chart recorder (Kipp & Zonen or equivalent)

C18, C8, or C4 reversed-phase columns, 300 Å, 1- or 2-mm i.d. (e.g., Micra Scientific or Vydac; many other columns from numerous manufacturers can be used)

**Analysis of
Proteins**

10.14.1

1. Prepare and degas the mobile phase and set up an appropriate gradient of mobile-phase solvents A and B. Select a gradient based on number of peaks expected and resolution desired.

Normal gradient: 0% to 70% solvent B in 70 min

Fast gradient: 0% to 70% solvent B in 35 min

Slow gradient: 0% to 70% solvent B in 90 to 140 min.

A normal, fast, or slow gradient should be used when the expected number of peaks is ~30 to 60, <30, or >60, respectively.

2. Program flow rate to 200 $\mu\text{l}/\text{min}$ or 100 $\mu\text{l}/\text{min}$ for 2-mm- or 1-mm-i.d. columns, respectively. Set detector to 0.1 and 0.02 AUFS and the wavelengths on chart recorder to 214 and 280 nm for channels 1 and 2, respectively. Equilibrate column with initial conditions and establish a flat baseline.

The 280-nm pen on the chart recorder should be set to a scale five times more sensitive than the 214-nm pen. If only one wavelength is available, use 214 nm.

3. Fill injector loop with starting solvent and run a blank gradient consisting of the same gradient as will be utilized for separation of sample.

This will wash the column, removing any peptides that may be present from previous injections.

4. Prepare sample for injection as follows (or prepare peptide standards, when using a new column or when troubleshooting):

- a. If the sample contains organic solvent, lower the organic solvent concentration to <10% (v/v) by evaporating it in a Speedvac evaporator or by diluting it with water or aqueous buffer.
- b. Check that the sample volume is appropriate for the volume of the injector sample loop; if not, either reduce the sample volume by evaporation or change to a larger sample loop.
- c. Spin the sample in a microcentrifuge to remove particulates prior to injection.

The presence of organic solvent in the sample may prevent peptides from adsorbing to the stationary phase.

The size of the sample loop will not have a significant effect on the separation. However, if a larger loop is used, an appropriate delay should be added to the gradient program to allow the entire sample volume to load on the column and to allow salts that may be in the sample to wash off the column before the gradient begins.

5. Change injector to load position and rinse injector with starting solvent (mobile-phase solvent A).

If the sample loop was switched from inject to load position during the gradient run, the sample loop will contain organic solvent. If the sample only partially fills the sample loop, the presence of organic solvent in the loop might prevent the sample from binding to the column; rinsing with starting solvent averts this.

6. Inject sample, being careful to avoid injecting air into sample loop.

Air that is injected onto the column can produce air bubbles that may lodge in the detector.

7. Prepare a rack with 1.5-ml microcentrifuge tubes for collecting peak fractions. Number tubes with felt-tipped pen.

8. Calculate the delay for peak collection by dividing the volume of tubing exiting the flow cell by the flow rate.

Table 10.14.1 Volumes of Tubing Exiting Flow Cell

Tubing inner diameter	Volume ($\mu\text{l}/\text{cm}$)
0.075-mm (75- μm) FSC	0.045
0.005-in. (127- μm) PEEK	0.127
0.007-in. (178- μm) PEEK	0.249

This is particularly important to prevent miscollection of peaks with low flow rates (<200 $\mu\text{l}/\text{min}$). Table 10.14.1 provides a list of volumes for different diameters of PEEK and FSC tubing.

Powder-free gloves should be worn during peak collection to avoid sample contamination by free amino acids.

9. Collect peaks by monitoring absorbance change on a strip-chart recorder and allowing appropriate delay time (calculated in step 8) before changing tubes.

A stopwatch can be used to accurately measure the delay time when collecting poorly resolved peaks. Data systems on most HPLC systems have signal processing delays that can make manual peak collection difficult. Monitoring a strip-chart recorder provides a real-time measurement of absorbance and eliminates this problem.

REVERSED-PHASE PEPTIDE SEPARATION AT ≤ 5 PMOL

Separation of peptides that are present in quantities ≤ 5 pmol requires the use of a capillary column. These columns have internal diameters <1 mm and provide high-resolution peptide mapping of peptides collected from in gel or in situ digests of proteins electroblotted from one- and two-dimensional gels. A 0.32-mm-i.d. capillary column is capable of separating peptides at the 500-fmol level, but requires a flow rate of 3 to 5 $\mu\text{l}/\text{min}$. Several commercial HPLC systems are currently available that are capable of delivering gradient flow rates in this range; other HPLC pumps can be adapted to deliver capillary gradient flow rates using a flow splitter (see Support Protocol).

Materials

Solvent A: 0.1% (v/v) trifluoroacetic acid (TFA) in Milli-Q water

Solvent B: 0.05% to 0.1% (v/v) TFA in acetonitrile

Peptide sample

Detector flow cell (LC Packings)

Strip-chart recorder (Kipp & Zonen or equivalent)

Capillary HPLC system (see Support Protocol)

Graduated 10- μl Hamilton glass syringe connected to outlet of flow cell with 0.25-mm-i.d. Teflon tubing (LC Packings)

Two stopwatches

Additional reagents and equipment for reversed-phase peptide separation at 5 to 500 pmol (see Basic Protocol 1) and capillary HPLC system assembly (see Support Protocol)

1. Prepare and degas the mobile phase (see Basic Protocol 1, step 1).
2. Set detector to 0.1 AUFS and the wavelength on the chart recorder to 195 nm.
3. Equilibrate capillary column in solvent A until a flat baseline is established. Connect a graduated 10- μl Hamilton glass syringe to the outlet tubing of capillary flow cell

BASIC PROTOCOL 2

with 0.25-mm-i.d. Teflon tubing. Measure the time it takes for liquid to reach a given volume and calculate flow rate as follows: flow rate (in $\mu\text{l}/\text{min}$) = volume/time.

4. Accurately measure the length of tubing from the flow cell to its outlet end and calculate the delay according to the following formula: delay (min) = volume of outlet tubing (μl)/flow rate ($\mu\text{l}/\text{min}$).

See Table 10.14.1 for a list of tubing internal volumes. A typical delay time is 35 sec.

5. If necessary, adjust the flow rate to between 3 and 5 $\mu\text{l}/\text{min}$ (see Support Protocol, step 1).
6. Run blank gradient, prepare sample, and inject (see Basic Protocol 1, steps 3 to 6).
7. Collect peaks in 0.5-ml microcentrifuge tubes using two stopwatches. Mark the start of the peak with one stopwatch and time the end of the peak with the second watch.

Peak collection is the most difficult aspect of preparative capillary HPLC and requires a little practice. However, the degree of peak purity will be surprisingly high for closely eluting peaks if the delay time is calculated accurately. With Z-shaped flow cells, the flow cell is a length of fused silica capillary tubing. Very minor resolution loss occurs as the peaks travel from the end of the column to the outlet of the detector tubing.

Only one stopwatch will be needed if the capillary flow cell is modified as described for capillary HPLC assembly (see Support Protocol, step 3b).

SUPPORT PROTOCOL

CAPILLARY HPLC SYSTEM ASSEMBLY

Peptide separations at the low picomole level require columns with an i.d. of <1 mm, which are called capillary columns. A 0.32-mm-i.d. capillary column is capable of separating peptides at the 500-fmol level. However, these columns require a flow rate of 3 to 5 $\mu\text{l}/\text{min}$, and at present only a few commercial HPLC systems can deliver gradient flow rates in this range without modifications. Using the material listed below, it is quite easy to construct or modify an existing HPLC using readily available components. PE Biosystems, Waters Associates, MicroTech Scientific, and Michrom Bioresources have capillary HPLC pumps.

Materials

Capillary flow cell (LC Packings)

Piston- or syringe-pump splitter (LC Packings) *or* laboratory-constructed splitter:

1/16 in. tee (Valco); fingertight fittings; 0.012-in.-i.d. sleeve for capillary tubing; fingertight fitting for 0.012-in. sleeve (Upchurch Scientific); and 150 cm of 0.05-mm-i.d., 300-mm-o.d. FSC tubing (Polymicro Technologies) *or* 0.250-mm-i.d. Teflon tube inserted into a PEEK fingertight nut and ferrule

Capillary pump (PE Biosystems 140-D) *or* HPLC piston pump (see Basic Protocol 1) for use with an LC Packings splitter, *or* HPLC syringe pump (PE Biosystems models 120A, 140A, or 170A) for use with a laboratory-constructed splitter

Injector equipped with a 20- μl loop (Rheodyne)

In-line precolumn filter (Upchurch Scientific)

0.32-mm \times 15-cm C18 column (LC Packings, Keystone Scientific, Metachem Technologies, Micro-Tech Scientific, or Michrom Bioresources)

- 1a. *If using a capillary pump that can provide a flow rate of 3 to 5 $\mu\text{l}/\text{min}$:* Proceed to step 3a or 3b.
- 1b. *If assembling a splitter:* Connect a 150-cm length of 0.05-mm-i.d. FSC tubing to Valco tee with a 0.012-in.-i.d. sleeve *or* with a 0.250-mm-i.d. Teflon tube inserted

into a PEEK fingertight nut and ferrule. Connect the inlet side of splitter to HPLC pump with 0.005-in.-i.d. PEEK tubing.

A schematic diagram of the capillary fittings and the splitter assembly is shown in Figure 10.14.1.

A splitter must be connected to the HPLC pump to allow the flow rate to be reduced from 50 to 200 $\mu\text{l}/\text{min}$ to the 3 to 5 $\mu\text{l}/\text{min}$ required for a 0.32-mm-i.d. column. A splitter can be purchased commercially or assembled as described. The split ratio is controlled by varying

Figure 10.14.1 Modifications for capillary HPLC system. **(A)** Assembly of capillary fittings and splitter. **(B)** Modification of U or Z flow cell.

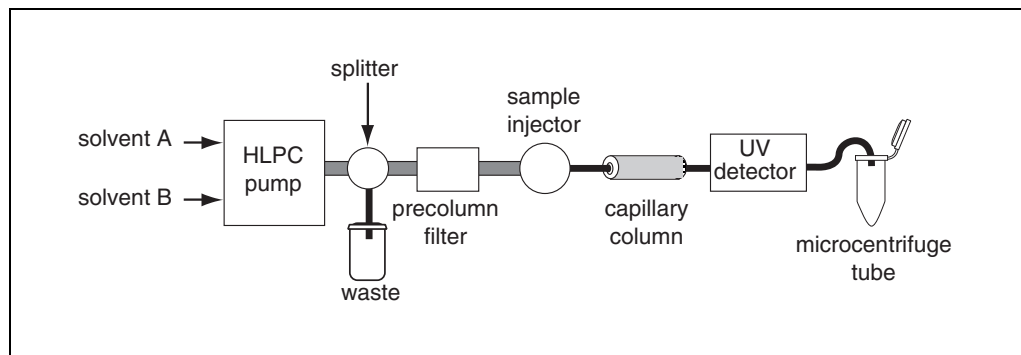

Figure 10.14.2 Capillary HPLC system.

the flow rate from the pump or by adjusting the length of the 0.05-mm-i.d. capillary tubing connected to the Valco tee. The pump flow rate should be set to the lowest flow that the pump can reliably deliver. A homemade splitter requires a pulse-free pump that can reliably deliver a flow rate of <math> < 200 \mu\text{l}/\text{min}</math>. PE Biosystems syringe pumps can accurately deliver a pulse-free flow rate of $70 \mu\text{l}/\text{min}</math>. These pumps have a dynamic mixer and a static mixer, which are removed to reduce the gradient delay caused by their large internal volumes. The high-pressure outlet of the mixing tee is connected directly to the splitter. Figure 10.14.2 shows a schematic diagram of the capillary HPLC system.$

2. Connect outlet of splitter to injector and connect the injector to the in-line precolumn filter with 0.005-in.-i.d. PEEK tubing.

The precolumn filter protects the capillary tubing and the column from clogging. The injector is fitted with a 20- μl sample loop. Any size sample loop can be used; however, a large loop will require a long wait for the sample to load on a 0.32-mm-i.d. column at a flow rate of 3 to 5 $\mu\text{l}/\text{min}</math>.$

- 3a. Install capillary flow cell.

The small peak volumes of capillary HPLC prevents the use of conventional flow cells. Instead, a length of capillary tubing with a short section of its polyamide coating removed is used as a flow cell. LC Packings has developed a capillary tube that is bent in the shape of a U or Z. The UV beam is aligned with the short axis of the U, increasing the path length of the flow cell. Although these flow cells have shorter path lengths than many conventional ones, the short path length and thin walls of the capillary tubing allow peptide detection at 195 nm.

- 3b. *Optional:* Modify the capillary flow cell (Fig. 10.14.1B) to reduce the delay volume by carefully cutting the 0.075-mm-i.d. outlet tubing of the flow cell, leaving ~1 to 2 cm adjacent to the Z cell (the fused silica tubing can be easily cut with a ceramic tubing cutter). Connect a 30-cm length of 0.025-mm-i.d., 0.280-mm-o.d. fused silica tubing with a 0.25-mm-i.d. Teflon sleeve to the remaining short outlet of the Z cell. The connection should be made inside the detector housing and the lengths of glass capillary tubing must be touching each other to avoid introducing any dead volume.

This modification eliminates the need for two stopwatches for peak collection. The flow cell modification reduces the delay volume to 0.45 μl , corresponding to a delay of 6 sec for a flow rate of 3.5 $\mu\text{l}/\text{min}</math>. The short delay greatly facilitates hand collection of HPLC fractions and the small-i.d. outlet tubing provides back-pressure that prevents bubble formation in the flow cell.$

4. Connect the 0.32-mm-i.d. C18 capillary column to the sample prefilter with the $\frac{1}{16}$ -in. PEEK fitting supplied with the column. Connect outlet tubing (75- μm -i.d.) of capillary column to capillary flow cell with a short length of 0.25-mm-i.d. Teflon tubing, also supplied with the column.

The 0.32-mm × 15-cm C18 column from LC Packings is the best general-purpose column for tryptic peptides. Keystone Scientific, Metachem Technologies, and Micro-Tech Scientific also sell capillary columns.

The Teflon tubing slips over the ends of the capillary tubing, creating a zero-dead-volume union between the column outlet and the detector union. Resolution will be significantly diminished if a gap is present between the adjacent pieces of capillary tubing.

5. Prepare the capillary HPLC system for sample run (see Basic Protocol 2).

PEPTIDE MAPPING BY MATRIX-ASSISTED LASER DESORPTION/IONIZATION (MALDI) MASS SPECTROMETRY

**BASIC
PROTOCOL 3**

Protein digests are mass analyzed either directly as an unfractionated mixture or as individual fractions from reversed-phase HPLC. The peptide-containing solution is mixed with a UV-absorbing matrix and applied to the sample stage of the mass spectrometer. Crystals of the peptide/matrix mixture form on the stage. This stage is inserted into the time-of-flight mass spectrometer vacuum system and irradiated with a UV laser to obtain a spectrum (UNITS 10.21 & 10.22). Greater mass accuracy is achieved by addition of known peptide(s) as internal mass standards. Alternate protocols are found in UNIT 16.3.

Materials

Peptide sample

30% (v/v) acetonitrile/0.1% (v/v) trifluoroacetic acid (TFA)

MALDI matrix solution (see recipe)

Mass standard solution (see recipe)

Time-of-flight mass spectrometer (e.g., PE Biosystems, Amersham Pharmacia Biotech, Micromass, Bruker, or Kratos)

1. Dilute samples in 30% acetonitrile/0.1% TFA to a final concentration of 0.05 to 5 pmol/μl.

Salt and buffer concentrations should be <50 mM. Most detergents, especially SDS, are not tolerated. If necessary, reduce the ionic strength by dilution, HPLC (UNITS 10.12 & 10.13), or size-exclusion chromatography (UNITS 10.9 or UNIT 10.13). If volatile buffers have been used, they may be removed by lyophilization and the dried sample redissolved in 2% TFA/50% acetonitrile.

2. Mix 2 μl of sample with 2 μl MALDI matrix solution in a 0.5-ml microcentrifuge tube.
3. Apply 1 to 2 μl of the mixture to the sample target, depending on the target size. Allow sample to dry completely and crystals to form without heating or applying vacuum.

Alternatively, 0.5 μl of sample solution and 0.5 μl of matrix solution may be mixed directly on the target. The solutions should be mixed well by repeatedly drawing the liquid into a pipettor.

The α-cyano-4-hydroxycinnamic acid (4HCCA) matrix solution works well for most peptides. An alternative is 2,5-dihydroxybenzoic acid (DHB). Another alternative is 3,5-dimethoxy-4-hydroxy-trans-cinnamic acid (sinapinic acid), but this produces a large background below 2000 Da and is not recommended for smaller peptides. Sinapinic acid or 4HCCA work best for larger peptides (>3000 Da). Due to preferential ionization of particular peptides in mixtures, it is advisable to obtain spectra for peptide mixtures with more than one matrix.

4. Insert sample into vacuum chamber of the mass spectrometer and follow the mass measurement procedure recommended by the instrument's manufacturer.

**Analysis of
Proteins**

10.14.7

Laser intensity (fluence) should be set just above the threshold for appearance of ion intensity. The observed signal (m/z) corresponds to $M+H^+$. Larger peptides may yield some $(M+2H)^{2+}$, which will appear at half the peptide mass ($M/2$). At high laser fluence, dimers may be formed as artifacts of the ionization process. Peptide mixtures may display preferential ionization for some peptides, and the relative peptide levels may vary from crystal to crystal. For this reason, spectra should be acquired from several different crystals on the target to obtain a representative display of peaks. The relative peak abundances in some cases (but not always!) give a semiquantitative image of the relative concentrations of peptides in the mixture, but they should not be relied upon for quantitation. Additional spectra acquired from the peptide mixture in a different matrix sometimes provide signals for peptides with suppressed ionization.

5. Calibrate the mass spectrometer with a mixture of peptides of known mass. Obtain calibrant peptide mass spectra as described in steps 2 to 4. Calibrate the instrument according to the manufacturer's recommendation.

An equimolar solution (~1 pmol/ μ l of each component) of des-Arg-bradykinin (e.g., Sigma) and ACTH-CLIP (18-39) provides two peaks that cover the masses of most peptides. The centroid of the peak corresponds to the isotopically averaged mass and should be used for calibration and mass assignment. The average masses ($M+H^+$) for des-Arg-bradykinin (905.1 Da) and ACTH-CLIP (18-39) (2466.7 Da) are generally reliable as calibrants. When sufficient resolution is available, the monoisotopic peaks should be used for calibration: des-Arg-bradykinin 904.468, ACTH-CLIP (18-39) 2465.199. Mass accuracy is best when the calibration peaks are close in mass and abundance to the unknown sample being analyzed. The laser fluence should be constant for the calibrant and unknown sample spectra.

- 6a. *If >500 fmol of unknown peptide sample is available:* Mix an equimolar concentration of des-Arg-bradykinin/ACTH-CLIP (18-39) standard solution with the unknown sample. Repeat mass analysis of sample with internal mass standards as described in steps 2 to 4.
- 6b. *If no additional unknown peptide sample is available:* Redissolve sample and matrix remaining on target after analysis in step 4 with 1 μ l of 2% TFA/50% acetonitrile. Add an equimolar concentration of mass standard solution. Allow mixed sample to dry on sample target and repeat mass analysis as described in step 4.

Internal mass calibration provides greater mass accuracy than external calibration. The amount of internal standard may need to be varied in several samples in order to obtain peak intensities that are approximately the same for the standard and the unknown sample. Avoid adding an excess of internal standard, which can suppress ionization of the unknown sample.

ALTERNATE PROTOCOL

PEPTIDE MAPPING BY MALDI MASS SPECTROMETRY USING THE MATRIX FAST-EVAPORATION METHOD

Preparation of a thin layer of matrix onto which the sample is applied offers advantages for small quantities of peptides and for contaminated samples. Matrix is applied to the sample stage in a highly volatile solvent that leaves a thin layer of matrix after evaporation. The uniform layer yields more uniform, intense signal across the sample. The sample is easily washed for efficient removal of contaminating salts and other buffer components that may interfere with ionization. Nitrocellulose is added to the matrix to provide greater peptide binding during the rinse step and to give greater structural support to the matrix, especially in the presence of higher concentrations of organic solvent that readily dissolve the matrix. This method is applicable to any type of MALDI instrument and gives superior results for a broad range of peptide and protein samples.

Additional Materials (also see Basic Protocol 3)

Fast-evaporation MALDI matrix solution (see recipe)
10% and 0.1% formic acid

1. Apply 0.5 to 2.0 μl fast-evaporation MALDI matrix solution to a clean sample target.

The solution must be applied quickly due to the high volatility of the acetone. A uniform, white surface 3 to 5 mm in diameter will form in 3 to 5 sec.

2. Apply 0.3 to 2.0 μl peptide sample to target surface. Allow sample to dry completely.

The matrix dissolves easily in basic solution or in the presence of a high concentration of organic solvent (e.g., >30% acetonitrile). If the peptide sample is not already acidic, apply 1.0 μl of 10% formic acid to the target before applying sample. For samples that contain high concentrations of organic solvent, apply 1.0 μl of water to the target before applying the sample.

3. Rinse sample with 4.0 μl cold 0.1% formic acid. After 10 sec, carefully remove the solution from the target surface with a pipet, or blow solution off target with a stream of nitrogen. Repeat rinse.

Rinse step may be eliminated if the peptide sample is free of salts. If the salt content of the sample is unknown, try to obtain signal without rinsing. If the results are unsatisfactory, remove the sample from the mass spectrometer and perform the rinse steps.

4. Insert sample into vacuum chamber of the mass spectrometer and follow the mass measurement procedure recommended by the instrument's manufacturer (see Basic Protocol 3).

Best results are obtained when samples are analyzed immediately. The authors have observed a decrease in signal intensity when samples are stored >24 hr. They have not observed any decrease in signal when samples are prepared according to Basic Protocol 3 using α -cyano-4-hydroxycinnamic acid (4HCCA).

5. Calibrate the mass spectrometer with a mixture of peptides of known mass (see Basic Protocol 3).

Because the peptide sample often covers only a part of the matrix spot, a small volume (0.1 to 0.3 μl) of the mass standard solution may be applied to the side of the matrix spot (after the peptide sample is dried on the other side of the matrix spot and rinsed) to provide a pseudo-internal standard. The mass spectrum of this small calibration sample may be taken immediately before or after the peptide spectrum to provide an external calibration with high accuracy. Alternatively, the signal from this sample may be included in the sample spectrum to provide internal calibration without the risk of ion suppression by the calibration compounds.

CAPILLARY ELECTROPHORESIS ANALYSIS

Capillary electrophoresis (also see *UNIT 10.20*) separates peptides by electrophoretic migration and electroosmotic flow using a high-voltage electric field in a fused silica capillary. The high voltage (20 to 25 kV) and the small internal volume of the fused silica capillary provide resolution that often exceeds 100,000 plates/meter. This high resolution combined with a different separation mechanism will often provide baseline resolution of peaks that coeluted during a reversed-phase HPLC separation. Very small volumes are required (10 to 200 nl), allowing the majority of the sample to be used for other methods of analysis or, if necessary, for repurification.

Materials

- 0.1 N NaOH
- Peptide sample
- 20 mM sodium phosphate, pH 2.5
- Capillary electrophoresis (CE) instrument
- 75- μ m-i.d. uncoated capillary column with separating length of 50 cm (from manufacturer of CE instrument or Polymicro Technologies)

1. Set detector wavelength to 200 nm.
If excessive baseline noise occurs at 200 nm, increase wavelength to 214 nm.
2. Wash capillary with 0.1 N NaOH for 1 min, followed by Milli-Q water for 1 to 2 min.
3. Equilibrate capillary with 20 mM sodium phosphate buffer, pH 2.5, for 5 min or until a stable baseline is established.

4. Inject sample using a pressure or vacuum injection of 5 to 30 sec.

*Some instruments inject the sample by creating a vacuum, whereas others apply a gas pressure to the sample reservoir. Both methods are capable of producing reproducible injections. Other instruments employ electrokinetic injection, in which an electric field is used to move the sample into the separating capillary. A drawback to this procedure is that the velocity of sample migration is dependent on the charge of the sample. This can result in a disproportionate injection of the sample components that have a higher charge. Also see *UNIT 10.20*.*

The peptide sample does not generally require any special preparation before injection.

5. Separate the components of the sample at 20 to 25 kV.
6. Repeat steps 2 to 5 for each additional sample. Replace capillary inlet and outlet buffer reservoir with fresh 20 mM sodium phosphate after every five runs.

Buffer ion depletion can affect the reproducibility of the separation.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.*

Detector flow cell

A flow cell with an internal volume <12 μ l is required for 2-mm columns and with internal volume <5 μ l for 1-mm columns. Many of the newer HPLC systems designed for 2-mm columns are supplied with flow cells that have appropriately small (0.005-in.-i.d.) outlet tubing that allows peaks to be collected without loss of resolution caused by mixing. Older instruments designed only for 4.6-mm-i.d. columns, such as the Hewlett-Packard HP-1090, may need to be modified. This can easily be accomplished for most instruments by connecting 75- μ m-i.d. FSC tubing

continued

(Polymicro Technologies) or 0.005-in.-i.d. PEEK tubing (Upchurch Scientific) to the outlet of the flow cell. This tubing should be kept as short as possible to prevent loss of resolution from mixing and to minimize back-pressure on the flow cell (excessive back-pressure can result in a broken flow cell).

Fast-evaporation MALDI matrix solution

5 mg nitrocellulose

20 mg α -cyano-4-hydroxycinnamic acid (4HCCA)

Dissolve nitrocellulose and 4HCCA in 500 μ l acetone in a 1.5-ml microcentrifuge tube. Add 500 μ l isopropanol and mix completely. Store at -20°C 1 to 2 months. Keep the cap tightly sealed at all times—evaporation of the solvent is the main problem encountered in repeated use.

Before adding isopropanol, it may be necessary to vortex the material for 1 to 2 min to dissolve the nitrocellulose completely.

Use only pure nitrocellulose (e.g., from Schleicher & Schuell). Some nitrocellulose membranes contain other material supports.

MALDI matrix solution

Prepare in 30% (v/v) acetonitrile/0.1% (v/v) trifluoroacetic acid either:

1. 20 mg/ml α -cyano-4-hydroxycinnamic acid (use only the supernatant as matrix solution); *or*
2. 50 mg/ml 2,5-dihydroxybenzoic acid (DHB); *or*
3. Saturated solution of 3,5-dimethoxy-4-hydroxy-*trans*-cinnamic acid (sinapinic acid; use only the supernatant as matrix solution).

Trifluoroacetic acid from Pierce is recommended because some manufacturers add antioxidants that can generate artifacts.

The 4HCCA may yield better signal if it is further purified by recrystallization.

Mass standard solution

Dissolve 1 pmol/ml des-Arg-bradykinin (e.g., Sigma) and 2 pmol/ml ACTH-CLIP (18-39) in 30% (v/v) acetonitrile/0.1% (v/v) trifluoroacetic acid (Pierce).

COMMENTARY

Background Information

Reversed-phase HPLC has been widely utilized for analysis and preparative fractionation of peptides. Although many different buffers have been described in the literature, trifluoroacetic acid (TFA) has become the most widely used ion-pairing agent for reversed-phase chromatography of peptides. The volatility of TFA enables it to be compatible with many analytical methods including protein sequencing, on-line electrospray mass spectrometry, amino acid analysis, and capillary electrophoresis.

The development of columns with small internal diameters (2 and 1 mm) has greatly facilitated the ease of handling of small amounts (<200 pmol) of proteolytic digests of proteins (see Basic Protocol 1; Schlabach and Wilson, 1987). The use of 2-mm-i.d. columns generally results in resolution equivalent or superior to that obtained on a 4.6-mm-i.d. col-

umn, with significant cost savings in solvent purchase and disposal. Another advantage of smaller-i.d. columns is the increase in sensitivity they provide. The increase in detector signal is a function of the inverse square of the column radius. Reducing the column diameter from 4.6 to 1 mm results in a signal that is 20 times larger.

Microbore 1-mm-i.d. columns have been more problematic than 2-mm-i.d. columns. The inability of many HPLC pumps to deliver samples at a rate of 50 to 100 μ l/min reliably has prevented widespread use of these smaller columns. Many commercially packed 1-mm-i.d. columns have had low theoretical plate counts compared to 2-mm-i.d. columns. This is primarily due to difficulty in packing these columns in small stainless steel tubes.

The problems associated with packing 1-mm stainless steel columns are generally not observed with columns of diameters <1 mm.

These columns are packed into fused silica capillaries that have extremely smooth walls compared to stainless steel tubing. Capillary columns have a high theoretical plate count that often exceeds 100,000 plates per meter, resulting in higher resolution than can usually be achieved in a 1- or 2-mm-i.d. column. The high resolution and small internal diameters of capillary columns are ideal for high-sensitivity peptide mapping at the 5-pmol level and below (see Basic Protocol 2; Cobb and Novotny, 1989; Davis and Lee, 1992). Capillary columns can be fabricated in the laboratory using a slurry packing technique with an HPLC pump (Moritz and Simpson, 1992). Many different types and sizes of capillary columns are commercially available. Capillary columns of 0.8-mm i.d. can be used on some HPLC systems without using a splitter. These HPLC systems must be capable of delivering a flow rate of 25 to 50 $\mu\text{l}/\text{min}$ and be equipped with a micro flow cell ($<1 \mu\text{l}$) to prevent a loss of resolution caused by mixing in the flow cell. The short path-length of these flow cells can often outweigh any gain in sensitivity.

Replacing a micro flow cell with a 200- μm -i.d. U-shaped capillary cell can increase detector sensitivity. This type of capillary cell is available for a variety of UV detectors from LC Packings. An 0.32-mm-i.d. capillary column can provide high sensitivity and good recovery for analytical and micropreparative collection of peptides from in situ digests of proteins electroblotted on one- and two-dimensional gels (UNITS 10.2 & 10.3; Wong et al., 1993). A 0.32-mm-i.d. capillary column requires a capillary flow cell to prevent loss of resolution from mixing.

Although capillary flow cells typically have short path lengths, the thin walls of the capillary and the short path length of the detector cell allow transmission of UV light at 195 nm. The shorter wavelength allows higher-sensitivity peptide detection than can be obtained at 214 nm.

Peak collection of capillary HPLC fractions can be tedious. However, a significant advantage to this method is the high concentration present in the collection tube as a result of the small peak volumes (0.5 to 3 μl). The high concentration in the sample tube minimizes sample loss by adsorption to the tube walls. When a 5-pmol sample is diluted to 100 to 200 μl —the typical peak volume obtained from a separation on a 1- to 2-mm column—adsorption to the tube walls may occur.

Despite the small internal volume of capillary columns, the capacity can be relatively

large ($>1 \text{ nmol}$). Large-volume injections ($>1 \text{ ml}$) may require a wait of several hours for the sample to load on the column. The increased volume will not have a significant effect on resolution for peptide separations, however, because of the absorption/desorption mechanism of peptide retention. Another advantage of capillary HPLC is its compatibility with on-line electrospray ionization mass spectrometry (UNIT 10.21), a result of the low flow rates (3 to 5 $\mu\text{l}/\text{min}$) employed with these columns. On-line electrospray ionization mass spectrometry allows mass measurement of each component that elutes from the column and in some cases provides sequence information (Griffin et al., 1991; Huang and Henion, 1991; Hess et al., 1993).

Small-i.d. columns can provide high-resolution separations, but some peaks may still contain multiple components. MALDI mass spectrometry (see Basic Protocol 3) and capillary electrophoresis (see Basic Protocol 4) are rapid methods for analyzing peak purity. MALDI mass spectrometry (Hillenkamp et al., 1991; Beavis and Chait, 1996; UNIT 10.22) is capable of analyzing low-femtomole quantities of peptide mixtures or isolated peptide fractions (Billeci and Stults, 1993). For example, an in situ tryptic digest of 2 to 5 pmol of a PVDF-electroblotted protein may yield 1- to 2-pmol peptide fractions after enzymatic digestion and separation on a capillary HPLC column. Only a small aliquot (1% to 10%) of a 1-pmol peptide fraction is usually required to determine both purity and molecular weight by MALDI mass spectrometry (Henzel et al., 1993). This information can be useful in deciding which peptide fraction to sequence as well as deciding on the number of cycles with which to program the sequencer. The peptide mass is indispensable for corroborating sequence data and identifying post-translational modifications (Geromanos et al., 1994). Peptide masses may also be used for protein identification by peptide mass mapping (Henzel et al., 1993; Patterson and Aebersold, 1995; Gevaert and Vandekerckhove, 2000).

Capillary electrophoresis (CE; UNIT 10.20) can also provide an indication of peak purity. The electropherogram (chromatogram) produced by the CE instrument can be used to approximate the degree of purity of peptide fractions. This is in contrast to MALDI mass spectrometry, which is not quantitative and in which two components with the same concentration may result in significantly different signals. CE generally requires a peptide concentration of 10

Figure 10.14.3 Effects of pore size and alkyl chain length on the resolution and recovery of peptides.

pmol/ μ l, which is 2 to 3 orders of magnitude larger than that required by MALDI mass spectrometry. Although some progress has been made in injecting larger volumes by concentrating the sample within the CE column (Aebersold and Morrison, 1990; Chien and Burgi, 1992; Figeys et al., 1996; Tomlinson et al., 1996), CE injection volumes are generally limited to <50 nl.

Critical Parameters

Selection of stationary phase

A large variety of reversed-phase stationary phases have been developed. The most commonly employed packings for peptide separation are based on porous silica derivatized with C4, C8, or C18. These columns are available with pore sizes ranging from 100 to 4000 Å. Columns of small particles containing small pores generally provide higher resolution than columns made of materials with larger pores, but peptide recovery is often lower. Peptides obtained from trypsin, chymotrypsin, or pepsin digests, which are often short (<15 residues), are preferably separated on a C18 column. Peptides from Lys-C and cyanogen bromide cleavages, which are often >15 residues long, are usually separated on a C4 column with 300- or 1000-Å pores.

Selection of mobile-phase solvent

Another important variable is the choice of the mobile phase. Mixtures of trifluoroacetic acid (TFA) in water with either acetonitrile or propanol as the organic solvent are the most widely utilized types of mobile phase for peptide separation. The choice of acetonitrile or propanol can affect peptide recovery and resolution. Acetonitrile will generally result in greater resolution than propanol; however, propanol usually provides higher peptide re-

covery. Complex peptide separations resulting from digestion of large proteins (>100 kDa) demand high-resolution separations and hence are best done using acetonitrile.

Increasing the length of the gradient can significantly increase resolution. A tryptic digest of a 100-kDa protein may require a 2- to 3-hr gradient. Peptides that fail to resolve in the course of an extended gradient can often be separated by repeating the chromatography using a different column (C4 or C8 in place of C18). The selectivity of the separation also can be affected by substituting a different organic solvent (i.e., propanol in place of acetonitrile) or by changing the pH of the separation. Rechromatography on the same column using a different organic modifier will often resolve coeluting peaks. Rechromatography can be repeated as many times as necessary but at the expense of some losses with each step. The sample must be diluted with water or concentrated in a Speedvac evaporator to lower the organic solvent concentration prior to rechromatography in order to allow the peptides to adsorb to the reversed-phase column. Figure 10.14.3 shows the relationship of pore size and alkyl chain length to resolution and peptide recovery.

Sample preparation and storage

Peptide fractions should be stored at 5°C in polypropylene tubes, not in polystyrene or glass. Prolonged storage can result in some evaporation of organic solvent from the sample, which may lead to sample adsorption to the microcentrifuge tube. Adding neat TFA to the sample tube (33% final concentration) can resolubilize peptides that may have precipitated or adsorbed to the tube walls (Erdjument-Bromage et al., 1993).

Solubility of peptides for MALDI can also be enhanced by addition of up to 50% acetonitrile.

trile and 2% TFA. Alternatively, up to 1% octyl- β -glucoside may assist in solubilization and is compatible with MALDI (Gharahdaghi et al., 1996). As fractions isolated by RP-HPLC with a volatile mobile phase are normally quite clean, no further cleanup of the sample is usually needed before analysis by MALDI. Preparation of samples for MALDI is easily done by taking a 0.3- to 0.6- μ l aliquot of an HPLC fraction straight from the fraction collection tube and mixing it with matrix directly on the sample target.

Mass measurement of unfractionated proteolytic digests is useful for rapidly confirming the sequence of known proteins (Billeci and Stults, 1993), for identifying proteins by searching a sequence database with peptide masses (Henzel et al., 1993; *UNIT 19.2*), and for assessing completeness of digestion. The digestion is preferably performed in a volatile buffer, such as ammonium bicarbonate, ammonium acetate, or *N*-ethylmorpholine. The buffer should be removed by vacuum centrifugation and the peptides solubilized in 50% acetonitrile/2% TFA. If nonvolatile buffer components are used, they must be diluted below 50 mM. Samples can be washed after application when the fast-evaporation matrix is used (Shevchenko et al., 1996; see Alternate Protocol). Analysis of subpicomole amounts of peptide may only be successful at substantially lower buffer concentrations. Buffer components may also be removed by pipet tip purification methods (Erdjument-Bromage et al., 1988; Gobom et al., 1999). Similar pipet tips are available as ZipTips from Millipore. Additional details on sample preparation are found in *UNITS 10.21 & 10.22*.

Special consideration for MALDI and CE

Mass accuracy for peptide measurement (1- to 3-kDa peptides) with a linear time-of-flight instrument is typically ± 1 to 2 Da with external calibration of the mass axis. Higher mass accuracy is achieved by measuring the sample with an internal mass standard, usually a pair of peptides of known mass with signal intensity approximately the same as the unknown sample. Repeated experiments may be necessary to achieve the proper ratio of standard to sample. With proper internal mass standards and an adequate signal-to-noise ratio, the mass accuracy can be $\pm 0.01\%$ (± 0.2 Da at m/z 2000). Higher mass accuracy and resolution may be obtained with reflector instruments (*UNIT 10.21*) or delayed extraction (Vestal et al., 1995).

The main variable in capillary electrophoresis of peptides is the choice of the separation buffer. Peptides that comigrate can often be separated by changing the pH of the buffer (Grossman et al., 1988). Changing the pH from 2.5 to 7.0 will often have a major effect on the separation. The ionic strength of the buffer can be increased for peptides that have slow migration rates. A different buffer can be tried when pH and ionic strength fail to improve the separation. Buffer additives can also be utilized to further enhance selectivity (Cobb and Novotny, 1992).

Troubleshooting

One of the main problems associated with reversed-phase HPLC is the occurrence of a drifting baseline. This is usually the result of contaminants in the mobile phase or inadequate mobile phase degassing. It is essential to use high-purity HPLC reagents and Milli-Q-quality water and to wear powder-free gloves for all manipulations. A baseline rise that increases with increasing organic modifier (solvent B) can be corrected by adjusting the amount of TFA added to the organic solvent. Titrating the amount of TFA in the solvents is especially important for capillary HPLC. In general a concentration of 0.05% to 0.08% TFA in solvent B will usually result in an acceptable baseline.

Baseline artifacts, which may appear as negative fluctuations in the baseline, can be caused by a number of HPLC pump malfunctions, including leaks (Dolan, 1991). It is essential to keep HPLC pumps in optimum condition for high-sensitivity HPLC. It is sometimes difficult to detect minor leaks, which can cause a major baseline disturbance during use of capillary HPLC columns. These leaks can usually be detected by placing a dry Kimwipe on the suspected fitting.

Occasionally the reversed-phase column can become contaminated by the sample, causing ghost peaks to appear. These are peaks that appear in blank runs when a gradient is run without injecting a sample. Sometimes several blank runs may be necessary before the ghost peaks completely disappear. Extended washing with 80% to 100% organic modifier can also be tried. Another method of cleaning columns, tubing, and flow cell is the use of methanol as a solvent. The HPLC is run in isocratic mode with 100% methanol in solvents A and B for 30 to 60 min. If all of the above methods have been tried without success, the column should be replaced.

Increased back-pressure (>500 p.s.i.) above the normal back-pressure of the column may indicate a clogged frit or a contaminated column. Use of a precolumn filter can prevent the column frit from clogging. The precolumn filter is easily replaced and relatively inexpensive. Column inlet frits can be replaced, but care must be exercised to prevent loss of column packing material. Capillary columns are particularly prone to clogging and should always be used in conjunction with a precolumn filter.

Peptide standards have been developed to monitor HPLC performance. Commercial standards (e.g., PE Biosystems) should be run when a new column is first utilized and when resolution appears to deteriorate (Mant and Hodges, 1990). Alternatively, a tryptic digest of a protein that results in well-resolved peptides on reversed-phase chromatography can be utilized to monitor column resolution. The digest should be solubilized in 0.1% TFA and stored frozen at -70°C between uses.

Reversed-phase columns should be stored in organic solvent that does not contain TFA, as TFA can slowly dissolve silica. Capillary columns will last significantly longer if this practice is followed.

Unsuccessful mass measurement by MALDI may be due to insufficient sample (<10 to 50 fmol). Sample loss is often a result of poor solubility of the peptide or the presence of contaminants that suppress ionization or crystal formation. Peptide solubility is aided by addition of acid, organic solvent, or octyl- β -glucoside. Alternative solvents such as formic acid or methanol may also assist in solubility and ionization (Cohen and Chait, 1996). In the case of an unfractionated digest or a nonvolatile buffer system, incompatible buffer components may be accommodated simply by dilution of the sample, if the peptide concentration permits, or by pipet tip purification. Alternatively, salts and buffers are often excluded from the less soluble peptide/matrix crystal, so a brief (~5-sec) wash of the sample target with cold water may remove many of the interfering salts.

CE instruments are relatively simple and are less problematic than HPLC equipment. The two major problems in CE are clogging of the capillary tubing and artifacts resulting from reagent or sample contaminants. Complete absence of current flow usually indicates a blocked capillary. The clog is often found on the sample inlet side and can be usually corrected by removing a short section (2 to 5 mm) of capillary from the column inlet end. The high sensitivity of CE requires high-purity reagents.

A number of chemical distributors now sell CE-purity reagents.

Anticipated Results

Reversed-phase HPLC should result in resolution and good recovery of the majority of the peptides (<30 residues) present in a typical proteolytic digest of a protein (<30 kDa). The use of capillary HPLC for tryptic peptides should allow recovery of peptides at the 1- to 2-pmol level. CE should be capable of separating peptides that coelute as a single peak on HPLC; however, the concentration must be at least 10 pmol/ μl . Peptides in the concentration range of 10 fmol/ μl to 50 pmol/ μl can be analyzed by MALDI mass spectrometry.

Time Considerations

Reversed-phase separations usually require 30 min to 1 hr per analysis. When additional blank gradients are run, several hours may be required. CE analysis of a purified peptide fraction may require from 15 to 60 min, depending on the charge and mass of the sample and the buffer utilized. Mass analysis by MALDI requires 1 to 2 min for preparation of each sample target, 5 to 10 min drying time, and 2 to 5 min per sample for data acquisition. Data processing may add an additional 5 to 10 min.

Purification of Recombinant Proteins and Study of Protein Interaction by Epitope Tagging

UNIT 10.15

A protein molecule can be engineered to include a short stretch of residues corresponding to an epitope to facilitate its subsequent biochemical and immunological analysis; a technique often referred to as “epitope tagging.” This is achieved by appending the sequence of the epitope tag to the protein-coding sequence in an appropriate expression vector. Several short epitope tags are currently available (Table 10.15.1) and have been widely used. Epitope-tagged proteins can be affinity purified using highly specific antibodies raised against various tags, which are also readily available. Basic Protocol 1 provides a general protocol for small-scale immunoprecipitation of epitope-tagged recombinant proteins expressed in transiently transfected mammalian cells. The immunoprecipitant can then be analyzed by SDS-PAGE (UNIT 10.2). Basic Protocol 2 provides an immunoprecipitation protocol that has been optimized for use with a baculovirus over-expression system.

In many cases, formation of a protein complex is required to execute, and thus to study, a particular biological function. Assembly of a functional complex *in vitro* offers a powerful tool for revealing the activities of the complex. Epitope tagging provides an efficient means of assembling such protein complexes (see Alternate Protocol). Briefly, one of the proteins is chosen as the “core” subunit or foundation for building the complex. This core subunit is bound to the affinity resin, and only the core subunit possesses the epitope tag that is recognized by the antibody-linked beads. One by one, each successive subunit is allowed to bind to the immobilized core subunit or to intermediate complexes. This process results in the assembly of a high-purity complex, even when the starting materials are relatively crude.

Table 10.15.1 Commonly Used Epitopes

Epitope	Peptide sequence	Antibody sources ^a	Affinity matrix source
FLAG	DYKDDDDK	Eastman Kodak ^b and BAbCO (M); Santa Cruz Biotechnology (P)	BAbCO
HA	YPYDVPDYA	BAbCO and Boehringer Mannheim (M); Santa Cruz Biotechnology (P)	BAbCO
c-Myc	EQKLISEEDL	BAbCO, Invitrogen, Boehringer Mannheim, and Sigma (M); Santa Cruz Biotechnology (P, M)	Santa Cruz Biotechnology
6-His	HHHHHH	BAbCO, Invitrogen ^c , and Sigma (M); Santa Cruz Biotechnology (P)	Qiagen ^d
AU1	DTYRYI	BAbCO (M)	BAbCO

^aM, monoclonal; P, polyclonal.

^bThree types of anti-FLAG monoclonal antibodies (M1, M2, M5) are available. Their specificities are dependent on the location of FLAG in the fusion protein.

^cThis antibody recognizes only the oligohistidine amino acid sequence at the carboxy-terminus of the fusion protein.

^dMetal-chelate affinity resin is used for purification of recombinant protein containing a polyhistidine tag (UNIT 10.11B).

Supplement 41

IMMUNOPRECIPITATION OF EPITOPE-TAGGED RECOMBINANT PROTEINS

This protocol describes immunoprecipitation of the epitope-tagged recombinant protein of interest. The protein is complexed with anti-epitope antibodies. It is a general procedure that can be used with a variety of transfection systems. The calcium phosphate–DNA precipitation method (UNIT 9.1) is recommended for transient transfection of mammalian cells with the recombinant plasmid vector, although other transfection methods may also be used. For detailed protocols addressing transfection of mammalian cells, see Chapter 9.

Materials

- Transfected cells (see Chapter 9), adherent (on a 100-mm plate) or nonadherent, expressing epitope-tagged protein of interest
- PBS (APPENDIX 2), ice cold, with and without 0.02% NaN_3
- Lysis buffer (see recipe)
- Protein A- or protein G-conjugated agarose beads (Pharmacia Biotech)
- Normal mouse IgG
- Epitope-specific antibody (see Table 10.15.1)
- 1.5× SDS sample buffer (prepare as a dilution of 2× SDS sample buffer; see UNIT 10.2)
- 10- and 15-ml centrifuge tubes
- Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (SDS-PAGE; UNIT 10.2)

Prepare lysate from transfected cells

For adherent cells

- 1a. At 36 to 48 hr posttransfection, aspirate the media from a 100-mm plate containing transfected cells that have been grown to 80% to 90% confluency ($0.5\text{--}2 \times 10^7$ cells, depending on the cell type), and wash the cells twice with 10 ml ice-cold PBS.
- 2a. Remove PBS and add 1 ml lysis buffer. Scratch the cells to one side of the dish with a rubber policeman.
- 3a. Transfer the lysate into a 1.5-ml microcentrifuge tube and incubate 10 min on ice.

For nonadherent cells

- 1b. At 48 hr posttransfection, transfer $\sim 2 \times 10^7$ cells into a 10-ml centrifuge tube and centrifuge 5 min at $2000 \times g$, 4°C .
- 2b. Remove the supernatant by aspiration, and resuspend the cell pellet in 1 ml ice-cold PBS. Transfer cells to a 1.5-ml microcentrifuge tube prechilled on ice and centrifuge 2 min at $2000 \times g$, 4°C .
- 3b. Aspirate the supernatant and resuspend the cell pellet in 1 ml lysis buffer by pipetting up and down several times. Incubate the sample 10 min on ice.
4. Microcentrifuge cells 10 min at $14,000 \times g$, 4°C .
5. Transfer the supernatant to a new microcentrifuge tube.

At this stage, the sample can be used immediately (step 9) or stored up to 1 year at -70°C . Thaw frozen samples on ice before use.

Protein expression should be monitored directly through immunoblot analysis (UNIT 10.8) using epitope-specific antibodies. To express two or more proteins with different epitope tags through cotransfection, each of the epitope-tagged recombinant proteins needs to be examined for its level of expression using epitope-specific antibodies.

Table 10.15.2 Relative Affinities of Protein A/G for Antibodies

Species and subclasses	Antibody	Affinity for protein A	Affinity for protein G
Rabbit	polyclonal	++++	+++
Mouse IgG1	monoclonal		++++
Mouse IgG2a	monoclonal	++++	++++
Mouse IgG2b	monoclonal	+++	+++
Mouse IgG3	monoclonal	+	+++

Prepare protein A- or protein G-agarose beads

- Transfer 0.5 ml (bed volume) of protein A- or protein G-agarose beads to a 15-ml centrifuge tube.
- Add 10 ml PBS and centrifuge 5 min at $2000 \times g$, 4°C . Discard the supernatant. Repeat twice (total three washes).
- Suspend beads in 0.5 ml PBS/0.02% NaN_3 .

At this stage, the 50% (v/v) slurry can be used immediately (step 9) or stored up to 6 months at 4°C .

Protein A and protein G may have different affinities for antibodies depending on their sources and subclasses (see Table 10.15.2). In addition to protein A/G-linked matrices, other matrices covalently linked directly to epitope-specific monoclonal antibodies are also available (see Table 10.15.1) and can be used for affinity purification of epitope-tagged proteins (see Basic Protocol 2).

Perform selection with epitope-specific antibody

- Preclarify 1 ml sample (step 5) by adding 50 μl of 50% (v/v) protein A- or protein G-agarose slurry (step 8) plus 5 μg normal mouse IgG. Shake 40 min at 4°C on an orbital shaker.

Preclarifying removes nonspecifically bound proteins from the extract. Antibodies raised against an irrelevant protein can also be used for this purpose.

- Centrifuge 2 min at $2000 \times g$, 4°C .
- Transfer the supernatant to a clean tube (discarding the pellet) and add 1 μg epitope-specific antibody.
- Shake the mixture 3 to 4 hr at 4°C on an orbital shaker.
- Centrifuge 2 min at $2000 \times g$, 4°C , to collect the immunoprecipitate. Discard the supernatant.
- Wash pellet with 1 ml lysis buffer and centrifuge 2 min at $2000 \times g$, 4°C . Discard supernatant and repeat twice (total three washes). Discard as much supernatant as possible after the last wash.
- Add 40 μl of 1.5 \times SDS sample buffer to the pellet and boil 5 min to denature the protein.
- Briefly centrifuge to pellet the debris. Electrophorese 20 μl of the supernatant by SDS-PAGE.

When performing immunoprecipitation with extracts prepared from metabolically labeled cells that have been transfected with an expression vector, the sample separated by

SDS-PAGE should be checked by autoradiography (APPENDIX 3A) to determine the presence of any coimmunoprecipitated proteins. If the aim of the study is to confirm whether two proteins interact in vivo, immunoprecipitants prepared from cells cotransfected with different expression constructs can be analyzed by immunoblotting (UNIT 10.8). The expressed recombinant proteins can be tagged with different epitopes, and their interaction can be tested by immunoprecipitation with an antibody against one epitope followed by immunoblotting with an antibody against the other.

IMMUNOPRECIPITATION OF EPITOPE-TAGGED RECOMBINANT PROTEINS FROM A BACULOVIRUS OVEREXPRESSION SYSTEM

This affinity purification protocol has been optimized for use with proteins that have been overexpressed using baculovirus-infected cells (UNIT 16.11). Additionally, the immunoprecipitation is performed using protein-A–Sepharose beads to which the anti-epitope antibody is already conjugated. This method can be modified to allow stepwise assembly of protein complexes (see Alternate Protocol).

Materials

- Baculovirus-infected Sf9 cells (UNIT 16.11), expressing epitope-tagged protein of interest
- PBS (APPENDIX 2), ice cold
- Binding buffer (see recipe), prepared as indicated *and* with an additional 60 mM KCl
- 50% (v/v) slurry of anti-epitope beads
- Normal mouse IgG
- Epitope elution buffer (see recipe)

Prepare lysate from transfected cells

1. Centrifuge $\sim 2 \times 10^7$ baculovirus-infected Sf9 cells 10 min at $2000 \times g$, 4°C.
2. Gently suspend the cell pellet in 10 ml ice-cold PBS. Centrifuge 10 min at $2000 \times g$, 4°C.
3. Aspirate the supernatant and repeat step 2.
4. Aspirate the supernatant. Add 1 ml binding buffer to the pellet and sonicate the sample twice for 15 seconds, as described (UNIT 16.5). Incubate 30 min on ice.
5. Centrifuge 10 min at $14,000 \times g$, 4°C.
6. Transfer the supernatant to a new tube. Preclear the sample (see Basic Protocol 1, steps 9 and 10) and transfer the supernatant to a new tube.

If desired, the sample can be stored up to 1 year at -70°C .

Precipitation caused by freezing and thawing can be removed by centrifugation as above. Ultracentrifugation (e.g., $100,000 \times g$) is recommended if nonspecific background proteins are detected in the resulting complex.

Bind sample to epitope-specific antibody beads

7. Add 50 μl of a 50% (v/v) slurry of anti-epitope beads to a 1.5-ml microcentrifuge tube. Wash the beads three times with PBS (see Basic Protocol 1, step 7).

Epitope-specific antibodies are covalently conjugated to protein A–Sepharose beads as described by Harlow and Lane (1988). For some epitopes, antibody affinity matrices are also commercially available (see Table 10.15.1).

8. Add 1 ml binding buffer and gently resuspend the beads.

9. Centrifuge 1 min at $2000 \times g$, 4°C , and discard the supernatant.
10. Add 1 ml cell lysate (step 6) to the beads.
11. Suspend the beads gently and incubate 2 hr at 4°C on an orbital shaker.
12. Centrifuge 1 min at $2000 \times g$, 4°C to recover the beads.
13. Wash the beads twice as in steps 8 and 9, using 1 ml binding buffer with a final of 160 mM KCl.

Elute protein of interest

14. Add 100 μl epitope elution buffer and resuspend the pellet. Incubate 2 hr at 4°C on an orbital shaker.

Epitope peptides are usually used for competitive elution of recombinant proteins bound to the affinity resin. The concentration of the peptide in the elution buffers is usually between 0.1 and 1.0 mg/ml. The complex can be eluted at room temperature if the elution efficiency at 4°C is low.

15. Centrifuge 1 min at $2000 \times g$, 4°C , and collect the supernatant.

Any residual beads in the supernatant can be removed by passing the supernatant through a suitable spin column (e.g., 1-ml Bio-spin, Bio-Rad).

16. Divide the eluted complex into 10- to 20- μl aliquots, quickly freeze the tubes in liquid nitrogen, and store the samples up to several months at -70°C .

STEPWISE ASSEMBLY OF PROTEIN COMPLEXES

Multisubunit complexes can be assembled by starting with a core protein (protein I) affixed to beads via an epitope tag (see Basic Protocol 2), and adding the other members of the complex in a stepwise manner. Protein II and subsequent members of the complex may be purified by conventional methods. It is not necessary to purify each of the participating proteins to homogeneity (see Critical Parameters and Troubleshooting); crude cell extracts may be also used. The necessity and/or degree of purification must be determined empirically. If protein II and/or successive proteins are affinity purified (see Basic Protocol 2), a different epitope from that used to affix the multisubunit complex to the beads must be employed.

Materials (also see Basic Protocol 2)

Baculovirus-infected Sf9 cell lines (UNIT 16.11), each expressing an additional epitope-tagged protein of interest (protein II and subsequent complex proteins)

1. Prepare cell lysates for all proteins to be complexed (see Basic Protocol 2, steps 1 to 6).

Alternatively, for protein II and any successive proteins, prepare purified or partially purified protein by other conventional chromatography methods (UNITS 10.9-10.11), as desired. Dialyze the sample against binding buffer prior to the assembly process.

2. Perform binding of protein I to anti-epitope beads (see Basic Protocol 2, steps 7 to 13).
3. Add 0.1 to 1 ml protein II cell lysate/extract to the tube and suspend the beads gently. Repeat the binding and washing procedure (see Basic Protocol 2, steps 11 to 13).

To assemble a protein complex that involves more than two proteins, repeat the above assembly process, incorporating each of the protein components into the complex in a stepwise fashion.

**ALTERNATE
PROTOCOL**

4. Wash the beads two more times.

These additional washes are required only after the final protein has been complexed.

5. Elute the formed complex (see Basic Protocol 2, steps 14 to 16), using epitope elution buffer that contains the peptide used to tag protein I.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Binding buffer

25 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), pH 7.6
0.1 mM EDTA
100 mM KCl
12.5 mM MgCl₂
10% glycerol
0.1% Nonidet P-40 (NP-40)
Store up to 6 months at 4°C
Add DTT and proteinase inhibitors at 1:1000 from the following stock solutions immediately before use
1.0 M DTT (store up to several months at –20°C)
0.2 M 4-(2-aminoethyl)-benzenesulfonyl fluoride (AEBSF) hydrochloride (Calbiochem-Novabiochem; store up to 6 months at 4°C)
1 M sodium metabisulfite (store up to 6 months at –20°C)
2.7 mg/ml pepstatin in methanol (store up to 3 months at –20°C)
2 mg/ml leupeptin (store up to 3 months at –20°C)

Epitope elution buffer

Add purified epitope peptide to binding buffer (see recipe) immediately before use.

Use the same peptide that is used as the epitope tag. Use FLAG peptide at 0.2 mg/ml; use HA peptide at 1 mg/ml. The concentrations of other peptides in the elution buffer are usually between 0.1 and 1.0 mg/ml. The optimal concentration should be determined empirically. See Table 10.15.1 for peptide sequences.

Lysis buffer

50 mM *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), pH 7.5
1% Nonidet P-40 (NP-40)
0.5% sodium deoxycholate
150 mM NaCl
1 mM EDTA
0.1 mM Na₃VO₄
Store up to 6 months at 4°C
Add proteinase inhibitors at 1:1000 from the stock solution immediately before use

COMMENTARY

Background Information

Advantages of epitope tagging methodologies

Expression of proteins from newly cloned cDNAs in mammalian cell lines is an essential step towards a functional analysis of the proteins (Pati, 1992; Witzgall et al., 1994). In many instances, however, this is hindered by the difficulty in purifying the expressed protein and/or the lack of specific antibodies against the protein. To circumvent these problems, a technique known as epitope tagging has been developed. A recombinant fusion protein is generated, in which an epitope is appended at either the N- or C-terminus of the coding region of the protein of interest. The proteins expressed can be easily identified in whole cell extracts and can be purified by immunoprecipitation using antibodies against the epitope (Sells and Chernoff, 1995; Chubet and Brizzard, 1996).

Epitope tagging has been widely adopted as a technique for the detection, characterization, and purification of recombinant proteins for a number of reasons (Brown et al., 1995; Murray et al., 1995; Dear et al., 1997). First, it obviates the need for conventional methods of protein purification and animal immunization to generate antibodies, which are often more tedious and time-consuming. Second, the small size of the epitope presents little risk of disrupting the native conformation of the recombinant protein, which generally ensures the recovery of a biologically active protein. Third, highly specific antibodies raised against various tags are readily available. When a protein encoded by a gene of interest is epitope-tagged, it can be affinity purified before specific antibodies have been raised against it. This is particularly useful for studying proteins encoded by newly isolated genes. Fourth, expression and purification of epitope-tagged proteins has met with success in cell types as diverse as *E. coli*, yeast, insect cells, and mammalian cells.

Applications

Epitope-specific antibodies, when used in combination with secondary polyclonal antibodies and protein A or protein G conjugated with horseradish peroxidase (HRP), alkaline phosphatase (AP), or fluorescein isothiocyanate (FITC), have been applied in a variety of assays including immunoblotting (UNIT 10.8), immunoprecipitation (UNIT 10.16) and immunoprecipitation, enzyme-linked immunosor-

bant assays (ELISAs), fluorescence microscopy, gel retardation, mobility shift assays (UNIT 12.2), and fluorescence-activated cell sorting (FACS). Some specific examples of biological applications for epitope tagging methodology include: determining the size, intracellular localization, and abundance of proteins (Molloy et al., 1994; Canfield et al., 1996); monitoring posttranslational modification; analyzing the function of individual protein domains; studying receptor binding and internalization of exogenous proteins (Brown et al., 1995); and establishing the identity of a protein within a protein complex (Zhou et al., 1992).

For example, immunoprecipitants from cells transfected with the recombinant expression vector can be compared by SDS-PAGE with those from control cells transfected with the vector alone. This allows the detection of proteins that interact *in vivo* with a protein of interest in the cell (Murray et al., 1995; Thibault et al., 1997). Because these experiments can be carried out using transient transfection, they can be performed quickly and lead to the purification of the interacting protein(s) for further characterization. By cotransfecting multiple expression constructs, the *in vivo* interaction between proteins encoded by different genes can also be confirmed.

Proteins that have been epitope tagged can be purified following expression in any overexpression system (see Chapter 16). An appropriate lysis procedure must be used to solubilize the epitope-tagged protein, which can then be purified using the procedures described in Basic Protocol 1 or 2. In addition, epitope-tagged subunits can be used to generate purified multiprotein complexes in an intact form (see Alternate Protocol). In this case, one protein of a complex is tagged and expressed in a cell type that normally expresses that protein. The complex is then purified by techniques similar to those described in Basic Protocol 2. For this to be successful, the epitope on the tagged protein must be exposed to solution, and hence available to the antibody, when the protein is incorporated in the complex. This technology has been successful in purifying multiprotein complexes such as TFIID from human cells following expression of a tagged subunit by retrovirus-mediated expression (Zhou et al., 1992; also see Chapter 9) or from *Drosophila* embryos following expression of a tagged subunit by P element-mediated expression (Burke and Kadonaga, 1996).

Critical Parameters and Troubleshooting

Transfection and protein expression. The calcium phosphate–DNA precipitation method is recommended for transient transfection of recombinant expression vectors into most mammalian tissue culture cell lines. The level of protein expression may vary dramatically among different proteins being expressed. When the level of expression of a tagged protein is too low to be analyzed by immunoblotting, tandem repeats of epitope tags can be used to improve the sensitivity of detection (Nakajima and Yaoita, 1997). Alternatively, recombinant protein with multiple tags can be produced and purified in a sequential manner using epitope-specific antibodies against each tag (Pathak and Imperiali, 1997). Proteolysis should be minimized following cell lysis. This can be achieved by adding EDTA and proteinase inhibitors to the lysis buffer and by keeping the samples at 4°C. Proteinase inhibitors should be added fresh each time.

Cross-reactivity. One common problem in studies using epitope-specific antibodies is the presence of cross-reactivity. The reagents used to detect antibodies on the membrane often cross-react to the precipitating antibodies. This becomes worse when the secondary antibodies react to the antibodies used for immunoprecipitation. Therefore, it is necessary to carry out pilot experiments to optimize the quantity of protein extract and concentration of epitope-specific antibodies in order to minimize any adverse effects caused by this problem. If both monoclonal and polyclonal epitope-specific antibodies are available, cross-reactivity can be reduced by performing immunoprecipitation with a monoclonal antibody and analyzing the resulting products with the polyclonal antibodies.

Protein complexes. When assembling a protein complex, having a sufficient level of protein expression from each individual protein is likely to be the most critical factor that determines success. Expression in baculovirus-infected (see Chapter 16) or *E. coli* systems is thus recommended. Optimal conditions for the expression of each protein need to be determined empirically. The concentration and quality of protein subunits in the starting material are usually more important than their absolute purity. Thus, in some cases, pure complexes can be obtained using proteins derived from crude cell extracts. However, if the assembled protein complexes have a high level of impurities or the efficiency of generating the final assembled

products is very low, each of the protein components should be further purified prior to the assembly process.

Anticipated Results

Immunoprecipitated products are ready for electrophoresis by SDS-PAGE (UNIT 10.2). Analysis by immunoblotting (UNIT 10.8) should detect the transiently expressed recombinant protein using an epitope-specific antibody. Silver staining (UNIT 10.6) of the immunoprecipitants will reveal the protein profiles of the final product. Since nonspecific background is a common problem, the results should be interpreted with caution and proper control experiments should also be performed.

To determine the stoichiometry and purity of the assembled complexes, 5 to 10 μ l of eluted material can be analyzed by SDS-PAGE, followed by silver staining or immunoblotting. The integrity of the eluted complexes can be verified by reimmunoprecipitation using antibodies directed against different subunits. A relatively large amount (>60 μ l) of the eluted complexes is required for one reimmunoprecipitation.

Time Considerations

Preparation of the cell lysate takes 1 hr; an additional 4 to 5 hr are required to immunoprecipitate the recombinant protein from the cell lysate. The sample can be fractionated by SDS-PAGE on the same day and analyzed by immunoblotting on the following day. Preparation of epitope antibody–conjugated beads takes about 4 hr. The protein complex assembly process takes one day.

Immunoprecipitation

UNIT 10.16

Immunoprecipitation is a technique in which an antigen is isolated by binding to a specific antibody attached to a sedimentable matrix. The source of antigen for immunoprecipitation can be unlabeled cells or tissues, metabolically or extrinsically labeled cells (UNIT 10.18), subcellular fractions from either unlabeled or labeled cells (see Chapter 3), or *in vitro*-translated proteins (UNIT 10.17). Immunoprecipitation is also used to analyze protein fractions separated by other biochemical techniques such as gel filtration (UNIT 10.9) or sedimentation on density gradients. Either polyclonal or monoclonal antibodies from various animal species can be used in immunoprecipitation protocols. Antibodies can be bound noncovalently to immunoabsorbents such as protein A- or protein G-agarose, or can be coupled covalently to a solid-phase matrix.

Immunoprecipitation protocols consist of several stages (Fig. 10.16.1; see Basic Protocol 1). In stage 1, the antigen is solubilized by one of several techniques for lysing cells. Soluble and membrane-associated antigens can be released from cells grown either in suspension culture (see Basic Protocol 1) or as a monolayer on tissue culture dishes (see Alternate Protocol 1) with nondenaturing detergents. Alternatively, cells can be lysed under denaturing conditions (see Alternate Protocol 2). Soluble antigens can also be extracted by mechanical disruption of cells in the absence of detergents (see Alternate Protocol 3). All of these procedures are suitable for extracting antigens from animal cells. By contrast, yeast cells require disruption of their cell wall in order to allow extraction of the antigens (see Alternate Protocol 4).

In stage 2, a specific antibody is attached, either noncovalently or covalently, to a sedimentable, solid-phase matrix to allow separation by low-speed centrifugation. In this unit, two methods for achieving this are described: the noncovalent attachment of antibody to protein A- or protein G-agarose beads (see Basic Protocol 1) and covalent coupling to Sepharose (see Alternate Protocol 5 and Support Protocol).

Stage 3 is the actual immunoprecipitation, which can be achieved by incubating the solubilized antigen from stage 1 with the immobilized antibody from stage 2, followed by extensive washing to remove unbound proteins (see Basic Protocol 1). Another method is to precipitate the immune complexes using antibodies contained in an anti-immunoglobulin (anti-Ig) serum (see Alternate Protocol 6). Immunoprecipitated antigens can be dissociated from antibodies and reprecipitated by a protocol referred to as "immunoprecipitation-recapture" (see Basic Protocol 2). This procedure can be used with the same antibody for further purification of the antigen, or with a second antibody to identify components of multisubunit complexes or to study protein-protein interactions (Fig. 10.16.3). Immunoprecipitated antigens can be analyzed by one-dimensional electrophoresis (UNIT 10.2), two-dimensional electrophoresis (UNITS 10.3 & 10.4), or immunoblotting (UNIT 10.8). In some cases, immunoprecipitates can be used for structural or functional analyses of the isolated antigens. Immunoprecipitates can also be used as sources of immunogens for production of monoclonal or polyclonal antibodies.

IMMUNOPRECIPITATION USING CELLS IN SUSPENSION LYSED WITH A NONDENATURING DETERGENT SOLUTION

In this protocol, cells in suspension (labeled or unlabeled) are extracted by incubation in nondenaturing lysis buffer containing the nonionic detergent Triton X-100 (steps 1 to 7). This procedure results in the release of both soluble and membrane proteins; however, many cytoskeletal and nuclear proteins, as well as a fraction of membrane proteins, are

Supplement 48

not efficiently extracted under these conditions. The procedure allows immunoprecipitation with antibodies to epitopes that are exposed in native proteins.

For immunoprecipitation, a specific antibody is immobilized on a sedimentable, solid-phase matrix (steps 8 to 14). Although there are many ways to attach antibodies to matrices (see Commentary), the most commonly used methods rely on the property of immunoglobulins to bind *Staphylococcus aureus* protein A, or protein G from group G *Streptococcus* (Table 10.16.1). The best results are obtained by binding antibodies to protein A or protein G that is covalently coupled to agarose beads. In this protocol, Sepharose beads are used (Sepharose is a more stable, cross-linked form of agarose). Immunoprecipitation is most often carried out using rabbit polyclonal or mouse monoclonal antibodies, which,

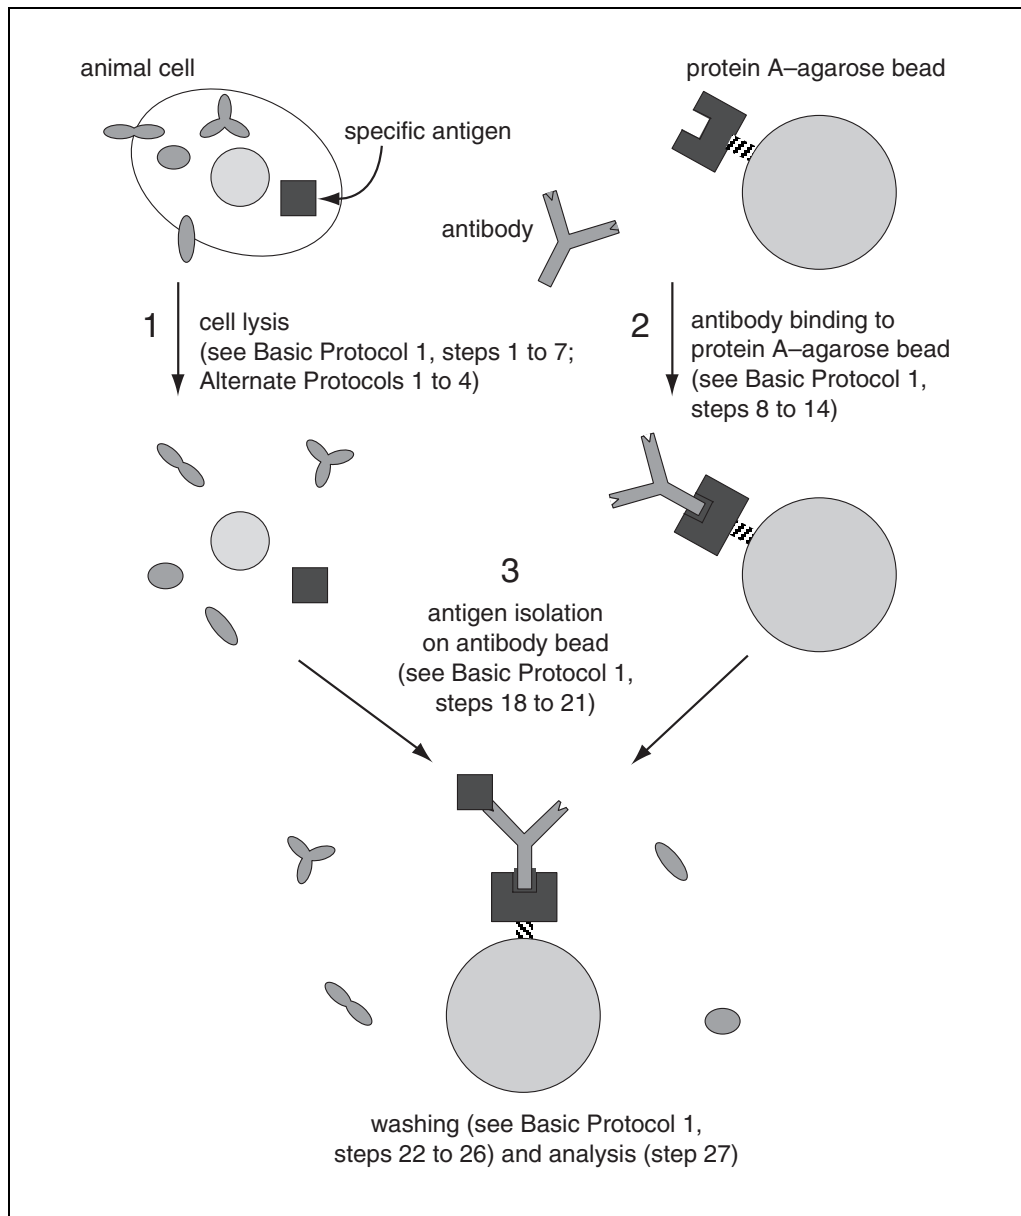

Figure 10.16.1 Schematic representation of the stages of the immunoprecipitation protocol presented in Basic Protocol 1. (1) Cell lysis: antigens are solubilized by extraction of the cells in the presence or absence of detergents. To increase specificity, the cell lysate can be precleared with protein A-agarose beads (steps 15 to 17, not shown). (2) Antibody immobilization: a specific antibody is bound to protein A-agarose beads. (3) Antigen capture: the solubilized antigen is isolated on antibody-conjugated beads.

with some exceptions (e.g., mouse IgG1), bind well to protein A (Table 10.16.1). Antibodies that do not bind to protein A–agarose can be adsorbed to protein G–agarose (Table 10.16.1) using exactly the same protocol. For optimal time management, incubation of antibodies with protein A–agarose can be carried out either before or during lysis of the cells.

The final stage in immunoprecipitation is combining the cell lysate with the antibody-conjugated beads and isolating the antigen (steps 18 to 26). This can be preceded by an optional preclearing step in which the lysate is absorbed with either “empty” protein A–agarose beads or with an irrelevant antibody bound to protein A–agarose (steps 15 to 17). The need for preclearing depends on the specific experimental system being studied and the quality of the antibody reagents. The protocol described below incorporates a preclearing step using protein A–agarose. Protein fractions separated by techniques such

^a++, moderate to strong binding; +, weak binding; –, no binding.

^bA hybrid protein A/G molecule that combines the features of protein A and protein G, coupled to a solid-phase matrix, is available from Pierce.

^cInformation from Harlow and Lane (1999), and from Amersham Pharmacia Biotech, Pierce, and Jackson ImmunoResearch.

^dNative protein G binds albumin from several animal species. Recombinant variants of protein G have been engineered for better binding to rat, mouse, and guinea pig IgG, as well as for avoiding binding to serum albumin.

^eProtein A binds some IgM, IgA, and IgE antibodies in addition to IgG, whereas protein G binds only IgG.

as gel filtration (UNIT 10.9) or sedimentation on sucrose gradients can be used in place of the cell lysate at this stage. After binding the antigen to the antibody-conjugated beads, the unbound proteins are removed by successive washing and sedimentation steps.

Materials

Unlabeled or labeled cells in suspension
PBS (APPENDIX 2), ice cold
Nondenaturing lysis buffer (see recipe), ice cold
50% (v/v) protein A–Sepharose bead (Sigma, Amersham Pharmacia Biotech)
slurry in PBS containing 0.1% (w/v) BSA and 0.01% (w/v) sodium azide
(NaN₃)
Specific polyclonal antibody (antiserum or affinity-purified immunoglobulin) or
monoclonal antibody (ascites, culture supernatant, or purified immunoglobulin)
Control antibody of same type as specific antibody (e.g., preimmune serum or
purified irrelevant immunoglobulin for specific polyclonal antibody; irrelevant
ascites, hybridoma culture supernatant, or purified immunoglobulin for specific
monoclonal antibody; see Critical Parameters)
10% (w/v) BSA
Wash buffer (see recipe), ice cold

Microcentrifuge with fixed-angle rotor (Eppendorf 5415C or equivalent)
Tube rotator (capable of end-over-end inversion)
Pasteur pipet attached to a vacuum trap

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see APPENDIX 1F).

NOTE: All solutions should be ice cold and procedures should be carried out at 4°C or on ice.

Prepare cell lysate

1. Collect cells in suspension by centrifuging 5 min at 400 × g, 4°C, in a 15- or 50-ml capped conical tube. Place tube on ice.

Approximately 0.5–2 × 10⁷ cells are required to yield 1 ml lysate, which is the amount generally used for each immunoprecipitation.

Labeled cells are likely to have been pelleted earlier as part of the labeling procedure. If the cells are frozen, they should be thawed on ice before solubilization.

2. Aspirate supernatant with a Pasteur pipet attached to a vacuum trap.

CAUTION: Dispose of radioactive materials following applicable safety regulations (APPENDIX 1F).

3. Resuspend cells gently by tapping the bottom of the tube. Rinse cells twice with ice-cold PBS as in steps 1 and 2, using the same volume of PBS as in the initial culture.
4. Add 1 ml ice-cold nondenaturing lysis buffer per ~0.5–2 × 10⁷ cells and resuspend pellet by gentle agitation for 3 sec with a vortex mixer set at medium speed.

Do not shake vigorously, as this could result in loss of material or protein denaturation due to foaming.

5. Keep suspension on ice 15 to 30 min and transfer to a 1.5-ml conical microcentrifuge tube.

Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

6. Clear the lysate by microcentrifuging 15 min at $16,000 \times g$ (maximum speed), 4°C .

Centrifugation can be carried out in a microcentrifuge placed in a cold room or in a refrigerated microcentrifuge. Take precautions to ensure that the 4°C temperature is maintained during the spin (e.g., use a fixed-angle rotor with a lid, as the aerodynamics of this type of rotor reduces generation of heat by friction). If it is necessary to reduce background, the lysate can be spun for 1 hr at $100,000 \times g$ in an ultracentrifuge.

7. Transfer the supernatant to a fresh microcentrifuge tube using an adjustable pipet fitted with a disposable tip. Do not disturb the pellet, and leave the last 20 to 40 μl of supernatant in the centrifuge tube. Keep the cleared lysate on ice until preclearing (step 15) or addition of antibody beads (step 18).

NOTE: Resuspension of even a small amount of sedimented material will result in high nonspecific background due to carryover into the immunoprecipitation steps. A cloudy layer of lipids floating on top of the supernatant will not adversely affect the results of the immunoprecipitation.

When the lysate is highly radioactive—as is the case for metabolically labeled cells—the use of tips with aerosol barriers is recommended to reduce the risk of contaminating internal components of the pipet.

Cell extracts can be frozen at -70°C until used for immunoprecipitation. However, it is preferable to lyse the cells immediately before immunoprecipitation in order to avoid protein degradation or dissociation of protein complexes. If possible, freeze the cell pellet from step 3 rather than the supernatant from step 7.

Prepare antibody-conjugated beads

8. In a 1.5-ml conical microcentrifuge tube, combine 30 μl of 50% protein A–Sepharose bead slurry, 0.5 ml ice-cold PBS, and the following quantity of specific antibody (select one):

- 1 to 5 μl polyclonal antiserum
- 1 μg affinity-purified polyclonal antibody
- 0.2 to 1 μl ascitic fluid containing monoclonal antibody
- 1 μg purified monoclonal antibody
- 20 to 100 μl culture supernatant containing monoclonal antibody.

The quantities of antibody suggested are rough estimates based on the expected amount of specific antibodies in each preparation. Quantities can be increased or decreased depending on the quality of the antibody preparation (see Commentary).

Substitute protein G for protein A if antibodies are of a species or subclass that does not bind to protein A (see Table 10.16.1).

If the same antibody will be used to immunoprecipitate multiple samples (e.g., samples from a pulse-chase experiment; UNIT 10.18), the quantities indicated above can be increased proportionally to the number of samples and incubated in a 15-ml capped conical tube. In this case, the beads should be divided into aliquots just prior to the addition of the cleared cell lysate (step 18).

Antibody-conjugated beads can be prepared prior to preparation of the cell lysate (steps 1 to 7), in order to minimize the time that the cell extract is kept on ice.

9. Set up a nonspecific immunoprecipitation control in a 1.5-ml conical microcentrifuge tube by incubating 30 μl of 50% protein A–Sepharose bead slurry, 0.5 ml ice-cold PBS, and the appropriate control antibody (select one):

- 1 to 5 μl preimmune serum as a control for a polyclonal antiserum
- 1 μg purified irrelevant polyclonal antibody (an antibody to an epitope that is not present in the cell lysate) as a control for a purified polyclonal antibody
- 0.2 to 1 μl ascitic fluid containing irrelevant monoclonal antibody (an antibody to an epitope that is not present in the cell lysate and of the same species and immunoglobulin subclass as the specific antibody) as a control for an ascitic fluid containing specific monoclonal antibody
- 1 μg purified irrelevant monoclonal antibody as a control for a purified monoclonal antibody
- 20 to 100 μl hybridoma culture supernatant containing irrelevant monoclonal antibody as a control for a hybridoma culture supernatant containing specific monoclonal antibody.

The amount of irrelevant antibody should match that of the specific antibody and the antibody should be from the same species as the specific antibody.

10. Mix suspensions thoroughly. Tumble incubation mixtures end over end ≥ 1 hr at 4°C in a tube rotator.

Addition of 0.01% (w/v) Triton X-100 may facilitate mixing of the suspension during tumbling. Incubations can be carried out for as long as 24 hr. This allows preparation of the antibody-conjugated beads prior to immunoprecipitation.

11. Microcentrifuge 2 sec at $16,000 \times g$ (maximum speed), 4°C .
12. Aspirate the supernatant (containing unbound antibodies) using a fine-tipped Pasteur pipet connected to a vacuum aspirator.
13. Add 1 ml nondenaturing lysis buffer and resuspend the beads by inverting the tube three or four times.

For lysates prepared with detergents (this protocol and see Alternate Protocols 1 and 2), use 1 ml nondenaturing lysis buffer; for lysates prepared by mechanical disruption (see Alternate Protocol 3), use detergent-free lysis buffer (see recipe).

Use of a repeat pipettor is recommended when processing multiple samples.

14. Wash by repeating steps 11 to 13, and then steps 11 and 12 once more.

At this point the beads have been washed twice with lysis buffer and are ready to be used for immunoprecipitation. Antibody-bound beads can be stored up to 6 hr at 4°C until used.

Preclear lysate (optional)

15. In a microcentrifuge tube, combine 1 ml cell lysate (from step 7) and 30 μl of 50% protein A–Sepharose bead slurry.

The purpose of this step is to remove from the lysate proteins that bind to protein A–Sepharose, as well as pieces of insoluble material that may have been carried over from previous steps. If the lysate was prepared from cells expressing immunoglobulins—such as spleen cells or cultured B cells—the preclearing step should be repeated at least three times to ensure complete removal of endogenous immunoglobulins.

If cell lysates were frozen and thawed, they should be microcentrifuged 15 min at $16,000 \times g$ (maximum speed), 4°C , before the preclearing step.

16. Tumble end over end 30 min at 4°C in a tube rotator.
17. Microcentrifuge 5 min at $16,000 \times g$ (maximum speed), 4°C .

Immunoprecipitate

18. Add 10 μl of 10% BSA to the tube containing specific antibody bound to protein A–Sepharose beads (step 14), and transfer to this tube the entire volume of cleared lysate (from step 7 or 17). If a nonspecific immunoprecipitation control is performed, divide lysate in two $\sim 0.4\text{-ml}$ aliquots, one for the specific antibody and the other for the nonspecific control.

In order to avoid carryover of beads with precleared material, leave 20 to 40 μl of supernatant on top of the pellets in the preclearing tubes. Discard beads and remaining supernatant. The BSA quenches nonspecific binding to the antibody-conjugated beads during incubation with the cell lysate.

19. Incubate 1 to 2 hr at 4°C while mixing end over end in a tube rotator.

Samples can be incubated overnight, although there is an increased risk of protein degradation, dissociation of multiprotein complexes, or formation of protein aggregates.

20. Microcentrifuge 5 sec at 16,000 $\times g$ (maximum speed), 4°C.

21. Aspirate the supernatant (containing unbound proteins) using a fine-tipped Pasteur pipet connected to a vacuum aspirator.

The supernatant can be kept up to 8 hr at 4°C or up to 1 month at -70°C for sequential immunoprecipitation of other antigens or for analysis of total proteins. To reuse lysate, remove the supernatant carefully with an adjustable pipet fitted with a disposable tip. Before reprecipitation, preabsorb the lysate with protein A–Sepharose (as in steps 15 to 17) to remove antibodies that may have dissociated during the first immunoprecipitation.

CAUTION: *Dispose of radioactive materials following applicable safety regulations.*

22. Add 1 ml ice-cold wash buffer, cap the tubes, and resuspend the beads by inverting the tube 3 or 4 times.

Use of a repeat pipettor is recommended when processing multiple samples.

23. Microcentrifuge 2 sec at 16,000 $\times g$ (maximum speed), 4°C.

24. Aspirate the supernatant, leaving $\sim 20\ \mu\text{l}$ supernatant on top of the beads.

25. Wash beads three more times (steps 22 to 24).

Total wash time (steps 22 to 26) should be ~ 30 min, keeping the samples on ice for 3 to 5 min between washes if necessary (see Critical Parameters).

26. Wash beads once more using 1 ml ice-cold PBS and aspirate supernatant completely with a drawn-out Pasteur pipet or an adjustable pipet fitted with a disposable tip.

The final product should be 15 μl of settled beads containing bound antigen.

Immunoprecipitates can either be processed immediately or frozen at -20°C for later analysis. For subsequent analysis of the isolated proteins prior to electrophoresis (e.g., comparison of the electrophoretic mobility of the antigen with or without treatment with glycosidases), samples can be divided into two or more aliquots after addition of PBS. Transfer aliquots of the bead suspension to fresh tubes, centrifuge and aspirate as in the previous steps.

27. Analyze immunoprecipitates by one-dimensional electrophoresis (UNIT 10.2B), two-dimensional electrophoresis (UNIT 10.3 & 10.4), or immunoblotting (UNIT 10.8).

IMMUNOPRECIPITATION USING ADHERENT CELLS LYSED WITH A NONDENATURING DETERGENT SOLUTION

Immunoprecipitation using adherent cells can be performed in the same manner as with nonadherent cells (see Basic Protocol 1). This protocol is essentially similar to steps 1 to 5 of Basic Protocol 1, but describes modifications necessary for using the same nondenaturing detergent solution to lyse cells attached to tissue culture plates. It is preferable to use cells grown on plates rather than in flasks, because the cell monolayer is more easily accessible.

Additional Materials (also see Basic Protocol 1)

- Unlabeled or labeled cells grown as a monolayer on a tissue culture plate (*UNIT 10.18*)
- Rubber policeman

NOTE: All solutions should be ice cold and procedures should be carried out at 4°C or on ice.

1. Rinse cells attached to a tissue culture plate twice with ice-cold PBS. Remove the PBS by aspiration with a Pasteur pipet attached to a vacuum trap.

CAUTION: Dispose of radioactive materials following applicable safety regulations.

2. Place the tissue culture plate on ice.
3. Add ice-cold nondenaturing lysis buffer to the tissue culture plate.

Use 1 ml lysis buffer for an 80% to 90% confluent 100-mm-diameter tissue culture plate. Depending on the cell type, a confluent 100-mm dish will contain $0.5\text{--}2 \times 10^7$ cells. For other plate sizes, adjust volume of lysis buffer according to the surface area of the plate.

4. Scrape the cells off the plate with a rubber policeman, and transfer the suspension to a 1.5-ml conical microcentrifuge tube using an adjustable pipettor fitted with a disposable tip. Vortex gently for 3 sec and keep tubes on ice for 15 to 30 min.

Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

5. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 27).

IMMUNOPRECIPITATION USING CELLS LYSED WITH DETERGENT UNDER DENATURING CONDITIONS

If epitopes of native proteins are not accessible to antibodies, or if the antigen cannot be extracted from the cell with nonionic detergents, cells should be solubilized under denaturing conditions. This protocol is based on that for nondenaturing conditions (see Basic Protocol 1, steps 1 to 7), with the following modifications. Denaturation is achieved by heating the cells in a denaturing lysis buffer that contains an ionic detergent such as SDS or Sarkosyl (*N*-lauroylsarcosine). The denaturing lysis buffer also contains DNase I to digest DNA released from the nucleus. Prior to immunoprecipitation, the denatured protein extract is diluted 10-fold with nondenaturing lysis buffer, which contains Triton X-100; this step protects the antigen-antibody interaction from interference by the ionic detergent. Immunoprecipitation is performed as described (see Basic Protocol 1).

The following protocol is described for cells in suspension culture, although it can be adapted for adherent cells (see Alternate Protocol 1). Only antibodies that react with denatured proteins can be used to immunoprecipitate proteins solubilized by this protocol.

Additional Materials (also see Basic Protocol 1)

Denaturing lysis buffer (see recipe)
Heating block set at 95°C (Eppendorf Thermomixer 5436 or equivalent)
25-G needle attached to 1-ml syringe

1. Collect cells in suspension culture (see Basic Protocol 1, steps 1 to 3). Place tubes on ice.
2. Add 100 µl denaturing lysis buffer per $\sim 0.5\text{--}2 \times 10^7$ cells in the pellet.
3. Resuspend the cells by vortexing vigorously 2 to 3 sec at maximum speed. Transfer suspension to a 1.5-ml conical microcentrifuge tube.

The suspension may be very viscous due to release of nuclear DNA.

Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

4. Heat samples 5 min at 95°C in a heating block.
5. Dilute the suspension with 0.9 ml nondenaturing lysis buffer. Mix gently.

The excess 1% Triton X-100 in the nondenaturing lysis buffer sequesters SDS into Triton X-100 micelles.

6. Shear DNA by passing the suspension five to ten times through a 25-G needle attached to a 1-ml syringe.

If the DNA is not digested by DNase I in the denaturing lysis buffer or thoroughly sheared mechanically, it will interfere with the separation of pellet and supernatant after centrifugation. Repeat mechanical disruption until the viscosity is reduced to manageable levels.

7. Incubate 5 min on ice.
8. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 27).

IMMUNOPRECIPITATION USING CELLS LYSED WITHOUT DETERGENT

Immunoprecipitation of proteins that are already soluble within cells (e.g., cytosolic or luminal organellar proteins) may not require the use of detergents. Instead, cells can be mechanically disrupted by repeated passage through a needle, and soluble proteins can be separated from insoluble material by centrifugation. The following protocol describes lysis of cells in a PBS-based detergent-free lysis buffer. Other buffer formulations may be used for specific proteins.

Additional Materials (also see Basic Protocol 1)

Detergent-free lysis buffer (see recipe)
25-G needle attached to 3-ml syringe

NOTE: All solutions should be ice-cold and procedures should be carried out at 4°C or on ice.

1. Collect and wash cells in suspension (see Basic Protocol 1, steps 1 to 3).
2. Add 1 ml of ice-cold detergent-free lysis buffer per $\sim 0.5\text{--}2 \times 10^7$ cells in a pellet.
3. Resuspend the cells by gentle agitation for 3 sec with a vortex mixer set at medium speed.

**ALTERNATE
PROTOCOL 3**

**Analysis of
Proteins**

10.16.9

4. Break cells by passing the suspension 15 to 20 times through a 25-G needle attached to a 3-ml syringe.

Extrusion of the cell suspension from the syringe should be rapid, although care should be exercised to prevent splashing and excessive foaming. Cell breakage can be checked under a bright-field or phase-contrast microscope. Repeat procedure until >90% cells are broken.

It is helpful to check ahead of time whether the cells can be broken in this way. If the cells are particularly resistant to mechanical breakage, they can be swollen for 10 min at 4°C with a hypotonic solution containing 10 mM Tris·Cl, pH 7.4 (APPENDIX 2) before mechanical disruption.

5. Clear the lysate and perform immunoprecipitation (Basic Protocol 1, steps 6 to 27).

ALTERNATE PROTOCOL 4

IMMUNOPRECIPITATION USING YEAST CELLS DISRUPTED WITH GLASS BEADS

Unlike animal cells, yeast cells have an extremely resistant, detergent-insoluble cell wall. To allow extraction of cellular antigens, the cell wall needs to be broken by mechanical, enzymatic, or chemical means. The most commonly used procedure consists of vigorous vortexing of the yeast suspension with glass beads. The breakage can be done in the presence or absence of detergent, as previously described for animal cells (see Basic Protocol 1, Alternate Protocol 2, and Alternate Protocol 3). The protocol described below is suitable for mechanical disruption of most yeast species, including *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. A protocol for metabolic labeling for yeast has been described by Franzusoff et al. (1991).

Additional Materials (also see Basic Protocol 1)

Unlabeled or radiolabeled yeast cells

Lysis buffer, ice cold: nondenaturing, denaturing, or detergent-free lysis buffer (see recipes)

Glass beads (acid-washed, 425- to 600- μ m diameter; Sigma)

NOTE: All solutions should be ice-cold and procedures should be carried out at 4°C or on ice.

1. Collect 10 ml of yeast culture at 1 OD₆₀₀ per immunoprecipitation sample, and centrifuge 5 min at 4000 \times g, 4°C. Place tube on ice.
2. Remove supernatant by aspiration with a Pasteur pipet attached to a vacuum trap.

CAUTION: *Dispose of radioactive materials following applicable safety regulations.*

3. Loosen pellet by vortexing vigorously for 10 sec. Rinse cells twice with ice-cold distilled water as in steps 1 and 2.

Radiolabeled yeast cells are likely to have been pelleted earlier as part of the labeling procedure. If the pellets are frozen, they should be thawed on ice prior to cell disruption.

4. Add 3 vol ice-cold lysis buffer and 3 vol glass beads per volume of pelleted yeast cells.

Use nondenaturing lysis buffer or detergent-free lysis buffer as required for the antigen under study. If the experiment requires denaturation of the antigen, the procedure can be adapted to include this (see Alternate Protocol 2 for higher eukaryotic cells); however, the yeast cells must be broken with glass beads before heating the sample at 95°C.

5. Shake cells by vortexing vigorously at maximum speed for four 30-sec periods, keeping the cells on ice for 30 sec between the periods.

Check cell breakage under a bright-field or phase-contrast microscope. It is helpful to check ahead of time if the cells can be broken in this way.

6. Remove the yeast cell lysate from the beads using a pipettor with a disposable tip. Transfer to a fresh tube.
7. Add 4 vol (see step 4) lysis buffer to the glass beads, vortex for 2 sec, and combine this supernatant with the lysate from step 6.
8. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 27).

IMMUNOPRECIPITATION WITH ANTIBODY-SEPHAROSE

This protocol, which follows the steps presented in Figure 10.16.2, relies on the formation of an insoluble immune complex between a protein antigen and an antigen-specific monoclonal (or polyclonal) antibody covalently bound to Sepharose.

Materials

Unlabeled cells, surface-labeled cells (e.g., with ^{125}I or biotin; *UNIT 3.18*) or biosynthetically ^{35}S -, ^3H -, or ^{14}C -labeled cells (*UNIT 10.18*)
Triton X-100 lysis buffer (see recipe)
Dilution buffer (see recipe)
Antibody (Ab)-Sepharose (see Support Protocol)
Activated, quenched (control) Sepharose, prepared as for Ab-Sepharose (see Support Protocol) but eliminating Ab or substituting irrelevant Ab during coupling
Tris/saline/azide (TSA) solution (see recipe)
0.05 M Tris-Cl, pH 6.8 (*APPENDIX 2*)
2× SDS sample buffer (*UNIT 10.2A*)

NOTE: Carry out all procedures in a 4°C cold room or on ice.

Lyse cells and preclear the lysate

1. Incubate cells in Triton X-100 lysis buffer (5×10^7 cells/ml) for 1 hr at 4°C.
2. Centrifuge the lysate 10 min at $3000 \times g$ to remove nuclei and save the supernatant.
3. Centrifuge the supernatant 1 hr at $100,000 \times g$ and save the supernatant.

Supernatants may also be prepared by microcentrifugation ($10,000 \times g$) for 30 min.

The supernatant must be used within several days or stored at -70°C . The length of storage is limited by autoradiolysis and the half-life of the isotope. ^3H - and ^{14}C -labeled samples can often be stored frozen for years. Storage of ^{125}I -labeled samples is usually limited to 1 to 2 months because of autoradiolysis, while the usefulness of ^{35}S -labeled samples is usually limited to 6 months because of half-life. Repeated freezing and thawing may disrupt antigenic determinants and dissociate some protein complexes, especially those that are noncovalently associated.

4. Preclear supernatant to be used in one batch by adding 10 μl activated, quenched (control) Sepharose per 200 μl supernatant. Shake on an orbital shaker 2 hr at room temperature or overnight at 4°C. Centrifuge 1 min at $200 \times g$ and save supernatant.

Preclearing removes nonspecifically absorbing material. Control Sepharose can be prepared without antibody or coupled with irrelevant (nonspecific) antibody. Irrelevant antibody is an antibody directed against an unrelated protein, and could also be whole IgG; it must not cross-react with the protein being immunoprecipitated.

ALTERNATE PROTOCOL 5

Analysis of Proteins

10.16.11

Immunoprecipitate the antigen

5. Precoat 1.5-ml microcentrifuge tubes by filling with Triton X-100 lysis buffer 10 min at room temperature. Remove the solution by aspiration.

Precoating minimizes antigen absorption to the tube.

6. Add 10^5 to 10^6 cpm of radiolabeled (^{125}I or ^{35}S) supernatant containing antigen (from step 4) to a precoated microcentrifuge tube and bring the volume to 200 μl with dilution buffer.

The recommended amount of radioactivity is appropriate for eukaryotic cells with >1000 molecules of antigen/cell. It is assumed that detection on slab gels of ^{125}I -labeled proteins will be carried out with enhancing screens and ^{35}S -labeled proteins with fluorography.

For nonradiolabeled samples, use 0.2 to 1 ml of precleared lysate.

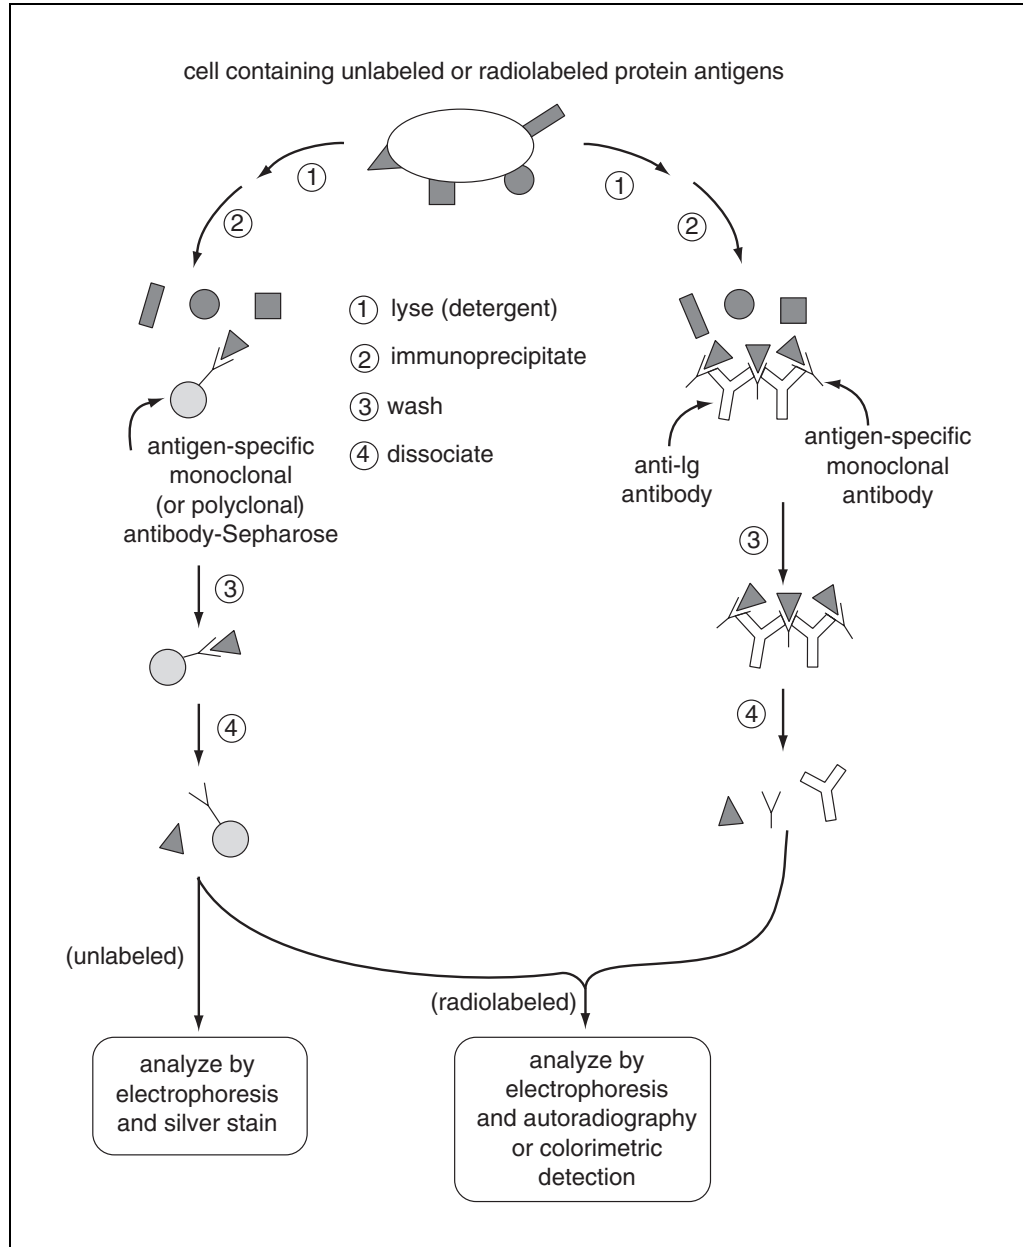

Figure 10.16.2 Schematic representation of the stages of the immunoprecipitation protocols using either antibody-Sepharose (left, see Alternate Protocol 5) or anti-Ig serum (right, see Alternate Protocol 6). (1) Cell lysis. (2) Immunoprecipitation using specific antibodies coupled covalently to Sepharose beads (left) or specific antibodies combined with anti-Ig serum (right). (3) Washing. (4) Dissociation of the antigen-antibody complex in sample buffer for electrophoresis.

7. Add ~10 μ l of a 1:1 slurry of Ab-Sepharose/dilution buffer and shake 1.5 hr at 4°C on an orbital shaker.

The antibody coupled to Sepharose is antigen specific. As described in the following support protocol, 5 mg/ml antibody per milliliter Sepharose is coupled, and the amount actually coupled can be estimated as described in step 10 of the support protocol. Shaking must be vigorous enough to suspend the Sepharose. Shaking may be extended to 3 hr; longer periods may increase background.

Wash, dissociate, and analyze the immunoprecipitate

8. Wash the Ab-Sepharose with 1 ml of the buffers listed below. After each wash, centrifuge 1 min at 200 \times g or microcentrifuge 5 sec. Then, carefully aspirate the supernatant with a fine-tipped Pasteur pipet and leave 10 μ l of fluid above the pellet. After the fourth wash, centrifuge again to bring down any residual drops on the side of the tube, aspirate, and leave 10 μ l over the pellet.

First wash: dilution buffer

Second wash: dilution buffer

Third wash: TSA solution

Fourth wash: 0.05 M Tris-Cl, pH 6.8.

Prepare a fine-tipped Pasteur pipet by pulling the pipet in a flame, scoring with a diamond pen, and breaking at the score.

9. Add 20 to 50 μ l of 2 \times SDS sample buffer. Because the sample buffer has a higher density than the wash solution, it will sink into the Sepharose; do not vortex, because Sepharose may stick to side of tube above buffer level. Cap the tube securely and incubate 5 min at 100°C.
10. Vortex and centrifuge 1 min at 200 \times g or microcentrifuge 5 sec. Load the supernatant, carefully avoiding the Sepharose, into a gel lane and analyze by SDS-PAGE (UNIT 10.2).
11. Detect labeled proteins by autoradiography (APPENDIX 3A) with an enhancing screen (125 I), by fluorography (35 S, 14 C, or 3 H), or by colorimetric or chemiluminescent detection (biotinylated proteins; UNIT 3.18).

PREPARATION OF ANTIBODY-SEPHAROSE

This protocol details the procedure for covalently linking an antibody to Sepharose (an insoluble, large-pore-size chromatographic matrix) using the cyanogen bromide activation method. It is necessary to first prepare the antibody and Sepharose separately. Next, the Sepharose is activated with cyanogen bromide (alternatively, CNBr-activated Sepharose can be purchased from Amersham Pharmacia Biotech and used according to the manufacturer's instructions). Finally, the CNBr-activated Sepharose is coupled to the antibody.

Materials

- 1 to 30 mg/ml antigen-specific monoclonal or polyclonal antibody
- 0.1 M NaHCO₃/0.5 M NaCl
- Sepharose CL-4B (or Sepharose CL-2B for high-molecular-weight antigens; Amersham Pharmacia Biotech)
- 0.2 M Na₂CO₃
- Cyanogen bromide (CNBr)/acetonitrile (see recipe)
- 1 mM and 0.1 mM HCl, ice-cold
- 0.05 M glycine (or ethanolamine), pH 8.0
- Tris/saline/azide (TSA) solution (see recipe)

SUPPORT PROTOCOL

Analysis of Proteins

10.16.13

Dialysis tubing (molecular weight cutoff >10,000)
Whatman no. 1 filter paper
Buchner funnel
Erlenmeyer filtration flask
Water aspirator

Prepare the antibody

1. Dialyze 1 to 30 mg/ml antibody against 0.1 M NaHCO₃/0.5 M NaCl at 4°C with three buffer changes during 24 hr. Use a volume of dialysis solution that is 500 times the volume of antibody solution.

Dialysis is performed to remove all small molecules containing free amino or sulfhydryl groups (see APPENDIX 3C).

2. Centrifuge 1 hr at 100,000 × g, 4°C, to remove aggregates. Save the supernatant.

Removal of aggregates is important. Because only some of the antibody molecules in an aggregate will be directly coupled to the Sepharose, the noncoupled antibody molecules may leach out during elution.

3. Measure the A₂₈₀ of an aliquot of the solution and determine the concentration of the antibody (mg/ml IgG = A₂₈₀/1.44). Dilute with 0.1 M NaHCO₃/0.5 M NaCl to 5 mg/ml (or to the same concentration as desired for Ab-Sepharose) and keep at 4°C. Measure the A₂₈₀ of this solution for later use in step 11.

Prepare the Sepharose

4. Allow the Sepharose slurry to settle in a beaker and decant and discard the supernatant. Weigh out the desired quantity of Sepharose (assume density = 1.0).

5. Set up a filter apparatus using Whatman no. 1 filter paper in a Buchner funnel and an Erlenmeyer filtration flask attached to a water aspirator. Wash the Sepharose on the filter apparatus with 10 vol water.

Sintered-glass funnels are traditionally recommended but rapidly become clogged unless coarse-porosity funnels are used.

Activate Sepharose with cyanogen bromide

6. Transfer Sepharose to 50-ml beaker and add an equal volume of 0.2 M Na₂CO₃.
7. Activate Sepharose at room temperature using 3.2 ml CNBr/acetonitrile per 100 ml Sepharose. Add CNBr/acetonitrile dropwise with a Pasteur pipet over 1 min, while slowly stirring the slurry with a magnetic stirrer. Continue stirring slowly for 5 min.

Excessive and vigorous stirring may fracture the Sepharose beads. The protocol uses 2 g CNBr/100 ml Sepharose. Two to four grams of CNBr/100 ml Sepharose can be used to couple 1 to 20 mg of antibody/ml Sepharose.

CAUTION: *Activation should be carried out in a fume hood.*

8. Rapidly filter the CNBr-activated Sepharose as in step 5. Aspirate to semidryness (i.e., until the Sepharose cake cracks and loses its sheen).
9. Wash with 10 vol ice-cold 1 mM HCl, then with 2 vol of ice-cold 0.1 mM HCl. Hydrate the cake with enough ice-cold 0.1 mM HCl so the cake regains its sheen, but so there is no excess liquid above the cake.

Washing is most efficient if the wash solution is added evenly over the surface of the cake at about the same rate as the solution is removed by filtration. CNBr-activated Sepharose is very unstable at the alkaline pH necessary for activation; it is much more stable in dilute HCl. CNBr-activated Sepharose can be purchased premade from Amersham Pharmacia Biotech, but the coupling capacity will be lower.

Couple antibody to CNBr-activated Sepharose

10. Immediately transfer a weighed amount of Sepharose (assume density = 1.0) to a beaker. Add an equal volume of a solution of antibody dissolved in 0.1 M NaHCO₃/0.5 M NaCl (from step 2). Stir gently with a magnetic stirrer or rotate end over end 2 hr at room temperature or overnight at 4°C.
11. Add 0.05 M glycine (or ethanolamine), pH 8.0, to saturate the remaining reactive groups on the Sepharose and allow the slurry to settle. Remove an aliquot of the supernatant, centrifuge to remove any residual Sepharose, and measure A_{280} . Compare absorbance to that of the A_{280} of the antibody solution from step 2 to determine the percentage coupling.
12. Store the Ab-Sepharose in TSA solution.

IMMUNOPRECIPITATION OF RADIOLABELED ANTIGEN WITH ANTI-Ig SERUM

This protocol relies on the formation of soluble immune complexes between a protein and an antigen-specific antibody, followed by immunoprecipitation of the immune complexes by antibodies contained in anti-immunoglobulin (Ig) serum. This procedure is usually only used with radiolabeled or biotinylated antigen, as the unlabeled antibody remains in the precipitate and greatly complicates the use of any other detection method.

Additional Materials (also see Alternate Protocol 5)

- Normal serum
- Anti-Ig serum (Zymed Laboratories)
- Antigen-specific antiserum *or* antigen-specific purified monoclonal antibody *or* antigen-specific hybridoma culture supernatant

Follow the procedures in Alternate Protocol 5, with the following modifications at the indicated steps:

- 4a. Preclarify by adding normal serum at a concentration of 2 µl/ml radiolabeled antigen. Add the proper amount of anti-Ig serum and let stand 12 to 18 hr at 4°C. Centrifuge 10 min at 1000 × g and reserve supernatant.

Normal serum is the source of carrier Ig. The proper amount of anti-Ig serum must be determined by titration with radiolabeled antigen or Ig. For high-titered anti-Ig serum, this amount would be 20× to 40× the volume of antigen-specific antiserum, 2 to 4 µl/µg purified MAb, or one-third the volume of hybridoma culture supernatant.

- 7a. Add 1 µl antigen-specific antiserum, 3 µg antigen-specific purified MAb, or antigen-specific hybridoma culture supernatant (30 µl cloned line or 100 µl uncloned line). Vortex and allow to stand 2 hr at 4°C. Then add the proper amount of anti-Ig serum, vortex, and allow to stand 12 to 18 hr at 4°C.
- 8a. Wash the immunoprecipitate (see Alternate Protocol 5, step 8), except centrifuge 7 min at 1000 × g.
- 9a. Add 20 to 50 µl of 2× SDS sample buffer. Do not vortex, as immunoprecipitates may stick to side of tube above buffer level. Cap the tube securely. For immunoprecipitates, incubate first 1 hr at 56°C and then 5 min at 100°C.

The initial 56°C incubation enhances the dissolution of the immunoprecipitates by reducing irreversible aggregation which occurs when precipitated protein is rapidly heated to 100°C. Proteolytic degradation has never been noted, probably because of the high IgG protein concentration.

ALTERNATE PROTOCOL 6

Analysis of Proteins

10.16.15

IMMUNOPRECIPITATION-RECAPTURE

Once an antigen has been isolated by immunoprecipitation, it can be dissociated from the beads and reimmunoprecipitated (“recaptured”) either with the same antibody used in the first immunoprecipitation or with a different antibody (Fig. 10.16.3). Immunoprecipitation-recapture with the same antibody allows identification of a specific antigen in cases where the first immunoprecipitation contains too many bands to allow unambiguous identification. By using a different antibody in the second immunoprecipitation, immunoprecipitation-recapture can be used to analyze the subunit composition of multi-protein complexes (Fig. 10.16.4). The feasibility of this approach depends on the ability of the second antibody to recognize denatured antigens.

Dissociation of the antigen from the beads is achieved by denaturation of antigen-antibody-bead complexes at high temperature in the presence of SDS and DTT. Prior to recapture, the SDS is diluted in a solution containing Triton X-100, and the DTT is neutralized with excess iodoacetamide. Recapture is then performed as in the first immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

Materials

- Elution buffer (see recipe)
- Beads containing bound antigen (see Basic Protocol 1, step 26)
- 10% (w/v) BSA
- Nondenaturing lysis buffer (see recipe)
- Heating block set at 95°C (Eppendorf Thermomixer 5436 or equivalent)

1. Add 50 μ l elution buffer to 15 μ l beads containing bound antigen. Mix by vortexing.
The DTT in the elution buffer reduces disulfide bonds in the antigen and the antibody, and the SDS contributes to the unfolding of polypeptide chains.
2. Incubate 5 min at room temperature and 5 min at 95°C in a heating block. Cool tubes to room temperature.
3. Add 10 μ l of 10% BSA. Mix by gentle vortexing.
BSA is added to prevent adsorption of antigen to the tube, and to quench nonspecific binding to antibody-conjugated beads.
4. Add 1 ml nondenaturing lysis buffer.
The iodoacetamide in the nondenaturing lysis buffer reacts with the DTT and prevents it from reducing the antibody used in the recapture steps. The presence of PMSF and leupeptin in the buffer is not necessary at this step.
5. Incubate 10 min at room temperature.
6. Clear the lysate and perform second immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

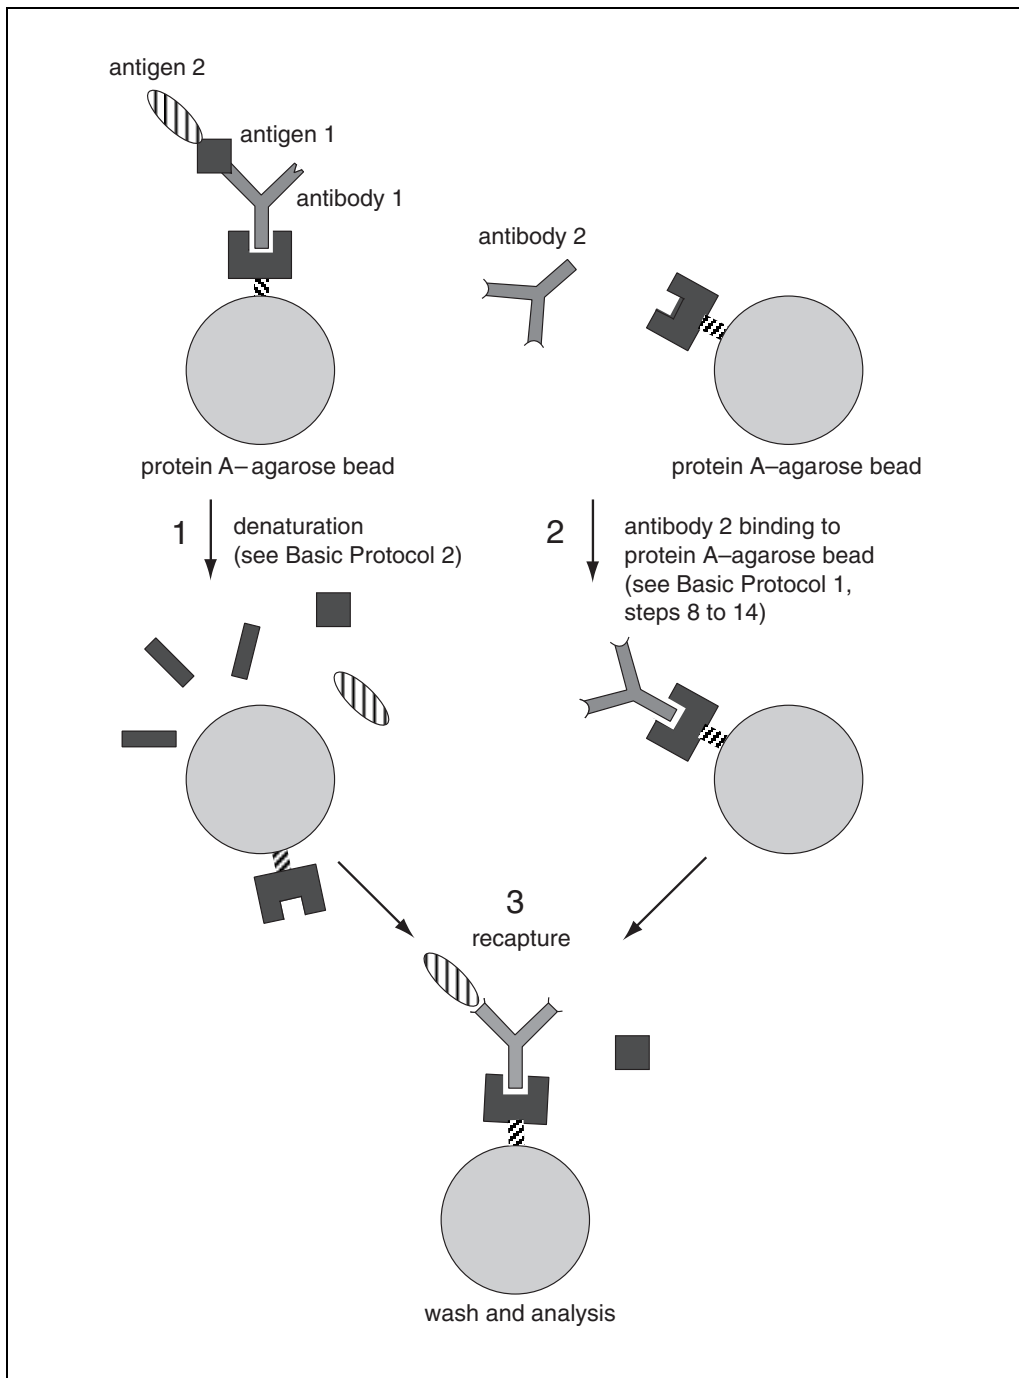

Figure 10.16.3 Scheme showing the stages of immunoprecipitation-recapture. (1) Dissociation and denaturation of the antigen: an antigen immunoprecipitated with antibody 1 bound to protein A-agarose beads is dissociated and denatured by heating in the presence of SDS and DTT. (2) Immobilization of the second antibody: antibody 2 is bound to protein A-agarose beads. (3) Recapture: the denatured antigen 2 (striped oval) is recaptured on antibody 2 bound to protein A-agarose beads. Alternatively, antibody 1 can be used again for further purification of the original antigen (square).

Figure 10.16.4 Example of an immunoprecipitation-recapture experiment. Human M1 fibroblasts were labeled overnight with [³⁵S]methionine (*UNIT 10.18*) and extracted with nondenaturing lysis buffer (see Basic Protocol 1). The cell extract was then subjected to immunoprecipitation with antibodies to BSA (irrelevant antibody control; lane 1) and to the AP-3 adaptor ($\sigma 3$; lane 2), a protein complex involved in protein sorting. Notice the presence of several specific bands in lane 2. The AP-3 immunoprecipitate was denatured as described in Basic Protocol 2 and individual components of the AP-3 complex were recaptured with antibodies to two of its subunits: $\sigma 3$ ($M_r \sim 22,000$; lane 3) and $\mu 3$ ($M_r \sim 47,000$; lane 4). An immunoprecipitation with an antibody to BSA was also performed as a nonspecific control (lane 5). The amount of immunoprecipitate loaded on lanes 1 and 2 is $\sim 1/10$ the amount loaded on lanes 3 to 5. Notice the presence of single bands in lanes 3 and 4. The positions of M_r standards (expressed as $10^{-3} \times M_r$) are shown at left. IP, immunoprecipitation.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.

CNBr/acetoneitrile

To 25 g of cyanogen bromide (*CNBr should be white, not yellow, crystals*), add 50 ml acetoneitrile to make a 62.5% (w/v) solution. This may be stored indefinitely at -20°C in a desiccator over silica. Allow to warm before opening.

CAUTION: *CNBr is a highly toxic lachrymator; handle in fume hood.*

Denaturing lysis buffer

1% (w/v) SDS

50 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)

5 mM EDTA (*APPENDIX 2*)

Store up to 1 week at room temperature (SDS precipitates at 4°C)

Add the following fresh before use:

10 mM dithiothreitol (DTT; from powder)

1 mM phenylmethylsulfonyl fluoride (PMSF; store 100 mM stock in 100% ethanol up to 6 months at –20°C)

2 µg/ml leupeptin (store 10 mg/ml stock in H₂O up to 6 months at –20°C)

15 U/ml DNase I (store 15,000 U/ml stock solution up to 2 years at –20°C)

1 mM 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF), added fresh from a 0.1 M stock solution in H₂O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at –20°C.

Detergent-free lysis buffer

PBS (*APPENDIX 2*) containing:

5 mM EDTA (*APPENDIX 2*)

0.02% (w/v) sodium azide

Store up to 6 months at 4°C

Immediately before use add:

10 mM iodoacetamide (from powder)

1 mM PMSF (store 100 mM stock in 100% ethanol up to 6 months at –20°C)

2 µg/ml leupeptin (store 10 mg/ml stock in H₂O up to 6 months at –20°C)

1 mM AEBSF, added fresh from a 0.1 M stock solution in H₂O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at –20°C.

Dilution buffer

TSA solution (see recipe) containing:

0.1% Triton X-100 (store at room temperature in dark)

0.1% bovine hemoglobin (store frozen)

Elution buffer

1% (w/v) SDS

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)

Store up to 1 week at room temperature

10 mM DTT (add fresh from powder before use)

Nondenaturing lysis buffer

1% (w/v) Triton X-100 (store at room temperature in dark)

50 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)

300 mM NaCl

5 mM EDTA (*APPENDIX 2*)

0.02% (w/v) sodium azide

Store up to 6 months at 4°C

Immediately before use add:

10 mM iodoacetamide (from powder)

1 mM PMSF (store 100 mM stock in 100% ethanol up to 6 months at –20°C)

2 µg/ml leupeptin (store 10 mg/ml stock in H₂O up to 6 months at –20°C)

1 mM AEBSF, added fresh from a 0.1 M stock solution in H₂O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at –20°C.

Tris/saline/azide (TSA) solution

10 mM Tris·Cl, pH 8.0 (APPENDIX 2)

140 mM NaCl

0.025% NaN₃

CAUTION: Sodium azide (NaN₃) is poisonous; wear gloves.

Triton X-100 lysis buffer

TSA solution (see recipe) containing:

1% Triton X-100 (store at room temperature in dark)

1% bovine hemoglobin (store frozen)

1 mM iodoacetamide (from powder)

Aprotinin (0.2 trypsin inhibitor U/ml)

1 mM PMSF (store 100 mM stock in 100% ethanol up to 6 months at -20°C)

Prepare fresh

1 mM AEBSF, added fresh from a 0.1 M stock solution in H₂O, can be used in place of PMSF.

AEBSF stock can be stored up to 1 year at -20°C.

Wash buffer

0.1% (w/v) Triton X-100 (store at room temperature in dark)

50 mM Tris·Cl, pH 7.4 (APPENDIX 2)

300 mM NaCl

5 mM EDTA (APPENDIX 2)

0.02% (w/v) sodium azide

Store up to 6 months at 4°C

COMMENTARY

Background Information

The use of antibodies for immunoprecipitation has its origin in the *precipitin* reaction (Nisonoff, 1984, and references therein). The term precipitin refers to the spontaneous precipitation of antigen-antibody complexes formed by interaction of certain polyclonal antibodies with their antigens. The precipitation arises from formation of large networks of antigen-antibody complexes, due to the bivalent or polyvalent nature of immunoglobulins and to the presence of two or more epitopes in some antigens. This phenomenon was quickly exploited to isolate antigens from protein mixtures; however, its use remained limited to antibodies and antigens that were capable of multivalent interaction. In addition, the efficiency of precipitate formation was highly dependent on the concentrations of antibody and antigen. Thus, the precipitin reaction was not generally applicable as a method for immunoprecipitation. A significant improvement was the use of secondary anti-immunoglobulin reagents (generally anti-immunoglobulin serum) to cross-link the primary antibodies, thus promoting the formation of a precipitating network.

In the 1970s, immunoprecipitation became widely applicable to the study of cellular antigens as a result of several technological advances. A critical development was the introduction of methods for the production of monoclonal antibodies (Köhler and Milstein, 1975). The ability to produce unlimited amounts of antibodies with specificity against virtually any cellular antigen had a profound impact in many areas of biology and medicine. The fact that preparation of monoclonal antibodies did not require prior purification of the antigens accelerated the characterization of cellular proteins and organelles, a process in which immunoprecipitation protocols played a major role. To this day, monoclonal antibodies produced in mice or rats continue to be among the most useful tools in biology.

Another important development was the discovery of bacterial Fc receptors, proteins found on the surface of bacteria that have the property of binding a wide range of immunoglobulins. Two of the most widely used bacterial Fc receptors are protein A from *Staphylococcus aureus* (Kessler, 1975) and protein G from group G streptococci. Protein A and protein G bind both polyclonal and monoclonal antibodies.

ies belonging to different subclasses and deriving from different animal species (Table 10.16.1). Protein A was initially used to adsorb immunoglobulins as part of fixed, killed *S. aureus* particles. Both protein A and protein G are now produced in large quantities by recombinant DNA procedures and are available coupled to solid-phase matrices such as agarose. In most cases, the binding of polyclonal or monoclonal antibodies to immobilized protein A (or G) avoids the need to use a secondary antibody to precipitate antigen-antibody complexes. Because of their broad specificity and ease of use, protein A-agarose and protein G-agarose (and related products) are the state-of-the-art reagents for the isolation of soluble antigen-antibody complexes in immunoprecipitation protocols.

Recent progress in the field of antibody engineering (reviewed by Rapley, 1995; Irving et al., 1996) promises to make antibody production a less time-consuming and haphazard process. Antibody fragments with high affinity for specific antigens can now be selected from phage display antibody libraries. Selected recombinant antibodies can then be produced in large quantities in *Escherichia coli*. Techniques have been developed for producing antibodies in soluble, secreted form. Affinity tags are added to the recombinant antibody molecules to facilitate purification, detection, and use in procedures such as immunoprecipitation. While attractive in principle, the production of recombinant antibodies has been plagued by technical difficulties that so far have limited their widespread use in biology. However, as technical problems are overcome, recombinant techniques will progressively replace immunization of animals as a way of producing antibodies for immunoprecipitation and for other applications.

Critical Parameters

Extraction of antigens

Isolation of cellular antigens by immunoprecipitation requires extraction of the cells so that the antigens are available for binding to specific antibodies, and are in a physical form that allows separation from other cellular components. Extraction with nondenaturing detergents such as Triton X-100 (see Basic Protocol 1, Alternate Protocol 1, and Alternate Protocol 5) or in the absence of detergent (see Alternate Protocol 3) allows immunoprecipitation with

antibodies to epitopes that are exposed on native proteins. Other nondenaturing detergents such as Nonidet P-40, CHAPS, digitonin, or octyl glucoside are also appropriate for extraction of native proteins (APPENDIX II). Some of these detergents (e.g., digitonin) preserve weak protein-protein interactions better than Triton X-100. If the antigen is part of a complex that is insoluble in nondenaturing detergents (e.g., cytoskeletal structures, chromatin, membrane “rafts”) or if the epitope is hidden within the folded structure of the protein, extraction under denaturing conditions is indicated (see Alternate Protocol 2). Alternate Protocol 2 may also be indicated for in vitro-translated products, which often tend to form aggregates (Anderson and Blobel, 1983).

The number of cells necessary to detect an immunoprecipitated antigen depends on the cellular abundance of the antigen and on the efficiency of radiolabeling. The protocols for radiolabeling (UNIT 10.18) and immunoprecipitation described in this book are appropriate for detection of antigens that are present at low to moderate levels (10,000 to 100,000 copies per cell), as is the case for most endogenous integral membrane proteins, signal transduction proteins, and transcription factors. For more abundant antigens, such as cytoskeletal and secretory proteins or proteins that are expressed by viral infection or transfection, the quantity of radiolabeled cells used in the immunoprecipitation can be reduced accordingly.

Production of antibodies

Immunoprecipitation can be carried out using either polyclonal or monoclonal antibodies (see discussion of selection below). Polyclonal antibodies are most often prepared by immunizing rabbits, although polyclonal antibodies produced in mice, guinea pigs, goats, sheep, and other animals are also suitable for immunoprecipitation. Antigens used for polyclonal antibody production can be whole proteins purified from cells or tissues, or whole or partial proteins produced in bacteria or insect cells by recombinant DNA procedures. Another useful procedure is to immunize animals with peptides conjugated to a carrier protein. Production of polyclonal antibodies to recombinant proteins and peptides has become the most commonly used approach to obtain specific probes for immunoprecipitation and other immunochemical techniques, because it does not require purification of protein antigens from their

native sources. The only requirement for making these antibodies is knowledge of the sequence of a protein, which is now relatively easy to obtain as a result of cDNA library production and genomic DNA sequencing projects. Polyclonal antibodies can be used for immunoprecipitation in the form of whole serum, ammonium sulfate-precipitated immunoglobulin fractions, or affinity-purified immunoglobulins. Although all of these are suitable for immunoprecipitation, affinity-purified antibodies often give lower backgrounds and are more specific.

Most monoclonal antibodies are produced in mice or rats. The sources of antigen for monoclonal antibody production are the same as those for production of polyclonal antibodies, namely proteins isolated from cells or tissues, recombinant proteins or protein fragments, and peptides. A significant advantage of using monoclonal antibodies is that antigens do not need to be purified to serve as immunogens, as long as the screening method is specific for the antigen. Another advantage is the unlimited supply of monoclonal antibodies afforded by the ability to grow hybridomas in culture or in ascitic fluid. Many monoclonal antibodies can now be produced from hybridomas deposited in cell banks or are directly available commercially. Ascitic fluid, cell culture supernatant, and purified antibodies are all suitable sources of monoclonal antibodies for immunoprecipitation. Ascitic fluid and purified antibodies should be used when a high antibody titer is important. Cell culture supernatants have lower antibody titers, but tend to give cleaner immunoprecipitations than ascitic fluids due to the lack of contaminating antibodies.

Selection of antibodies: Polyclonal versus monoclonal

What type of antibody is best for immunoprecipitation? There is no simple answer to this question, as the outcome of both polyclonal and monoclonal antibody production protocols is still difficult to predict. Polyclonal antibodies to whole proteins (native or recombinant) have the advantage that they frequently recognize multiple epitopes on the target antigen, enabling them to generate large, multivalent immune complexes. Formation of these antigen-antibody networks enhances the avidity of the interactions and increases the efficiency of immunoprecipitation. Because these antibodies recognize several epitopes, there is a better

chance that at least one epitope will be exposed on the surface of a solubilized protein and thus be available for interaction with antibodies. Thus, the likelihood of success is higher. These properties can be a disadvantage, though, as some polyvalent antibodies can cross-react with epitopes on other proteins, resulting in higher backgrounds and possible misidentification of antigens. Because they are directed to a short peptide sequence, anti-peptide polyclonal antibodies are less likely to cross-react with other proteins. However, their usefulness is dependent on whether the chosen sequence turns out to be a good immunogen in practice, as well as on whether this particular epitope is available for interaction with the antibody under the conditions used for immunoprecipitation.

Unfractionated antisera are often suitable for immunoprecipitation. However, there is a risk that serum proteins other than the antibody will bind nonspecifically to the immunoabsorbent, and in turn bind proteins in the lysate that are unrelated to the antigen. For instance, transferrin can bind nonspecifically to immunoabsorbents, potentially leading to the isolation of the transferrin receptor as a contaminant (Harford, 1984). Polyclonal antisera can also contain antibodies to other antigens (e.g., viruses, bacteria) to which the animal may have been exposed, and these antibodies can also cross-react with cellular proteins during immunoprecipitation. Affinity-purified antibodies are a better alternative when antisera do not yield clean immunoprecipitations. Affinity-purification can lead to loss of high-affinity or low-affinity antibodies; however, the higher specificity of affinity-purified antibodies generally makes them “cleaner” reagents for immunoprecipitation.

The specificity, high titer, and limitless supply of the best immunoprecipitating monoclonal antibodies are unmatched by those of polyclonal antibodies. However, not all monoclonal antibodies are useful for immunoprecipitation. Low-affinity monoclonal antibodies can perform acceptably in immunofluorescence microscopy protocols (UNIT 14.10) but may not be capable of holding on to the antigen during the repeated washes required in immunoprecipitation protocols. The use of ascitic fluid has the same potential pitfalls as the use of polyclonal antisera, as ascites may also contain endogenous antibodies to other antigens

and proteins such as transferrin that can bind to other proteins in the lysate.

In conclusion, an informed empirical approach is recommended in order to select the best antibody for immunoprecipitation. In general, it is advisable to generate and/or test several antibodies to a particular antigen in order to find at least one that will perform well in immunoprecipitation protocols.

Antibody titer

The importance of using the right amount of antibody for immunoprecipitation cannot be overemphasized. This is especially the case for quantitative immunoprecipitation studies, in which the antibody should be in excess of the specific antigen. For instance, in pulse-chase analyses of protein degradation or secretion (UNIT 10.18), it is critical to use sufficient antibody to deplete the antigen from the cell lysate. This is particularly important for antigens that are expressed at high levels, a common occurrence with the growing use of high-yield protein expression systems such as vaccinia virus (UNITS 16.15 - 16.19) or replicating plasmids in COS cells (UNIT 16.12). Consider, for example, a protein that is expressed at high levels inside the cell, and of which only a small fraction is secreted into the medium. If limiting amounts of antibody are used in a pulse-chase analysis of this protein, the proportion of protein secreted into the medium will be grossly overestimated, because the limiting antibody will bind only a small proportion of the cell-associated protein and a much higher proportion of the secreted protein. The same considerations apply to degradation studies. Thus, it is extremely important in quantitative studies to ensure that the antibody is in excess of the antigen in the cell samples. This can be ascertained by performing sequential immunoprecipitations of the samples (see Basic Protocol 1, annotation to step 21). If the second immunoprecipitation yields only a small amount of the antigen relative to that isolated in the first immunoprecipitation (<10%), then the antibody titer is appropriate. If, on the other hand, the amount of antigen isolated in the second immunoprecipitation is >10%, either more antibody or less antigen should be used.

Too much antibody can also be a problem, as nonspecific immunoprecipitation tends to increase with increasing amounts of immunoglobulins bound to the beads. Thus, titration of

the antibody used for immunoprecipitation is strongly advised.

Immunoabsorbent

If cost is not an overriding issue, the use of protein A- or protein G-agarose is recommended for routine immunoprecipitation (see Basic Protocol 1). Protein A- or protein G-agarose beads (or equivalent products) have a very high capacity for antibody binding (up to 10 to 20 mg of antibody per milliliter of gel). Both protein A and protein G bind a wide range of immunoglobulins (Table 10.16.1). Backgrounds from nonspecifically bound proteins are generally low. Protein A- and protein G-agarose beads are also stable and easy to sediment by low-speed centrifugation. A potential disadvantage, in addition to their cost, is that some polyclonal or monoclonal antibodies bind weakly or not at all to protein A or protein G (Table 10.16.1). This problem can be solved by using an intermediate rabbit antibody to the immunoglobulin of interest. For example, a goat polyclonal antibody can be indirectly bound to protein A-agarose by first incubating the protein A-agarose beads with a rabbit anti-goat immunoglobulin, and then incubating the beads with the goat polyclonal antibody. Anti-immunoglobulin antibodies (e.g., rabbit anti-goat immunoglobulins) coupled covalently to agarose can also be used for indirect immunoprecipitation in place of protein A- or protein G-agarose.

A less expensive alternative to protein A- or protein G-agarose is the use of anti-Ig serum to crosslink the primary antibody (see Alternate Protocol 6). This procedure can result in very low backgrounds, although it requires proper titration of the anti-Ig serum. Protein A-agarose can also be substituted by fixed *Staphylococcus aureus* particles (Pansorbin). They have a lower capacity, can give higher backgrounds, and take longer to sediment. However, they work quite well in many cases. In order to establish if they are appropriate for a particular experimental setup, conduct a preliminary comparison of the efficiency of protein A-agarose with *Staphylococcus aureus* particles as immunoabsorbent.

Specific antibodies coupled covalently to various affinity matrices can also be used for direct immunoprecipitation of antigens (see Alternate Protocol 5). After binding to protein A-agarose, antibodies can be cross-linked with dimethylpimelimidate (Gersten and Marchalo-

Figure 10.16.5 Lowering background by washing with SDS and sodium deoxycholate (DOC). In this experiment, BW5147 cells (mouse thymoma) labeled with [³⁵S]methionine for 1 hr were extracted with nondenaturing lysis buffer (see Basic Protocol 1). The extracts were subjected to immunoprecipitation with protein A–agarose beads incubated with either preimmune (PI) or immune (I) serum from a rabbit immunized with the ribosomal protein L17 (doublet at $M_r \sim 22,000$). Lanes 1 and 2 correspond to immunoprecipitates obtained using the protocols described in this unit. Notice the presence of nonspecific bands and/or associated proteins in lane 2. Lanes 3 and 4 correspond to beads that were washed an additional time with 0.1% (w/v) SDS and 0.1% (w/v) DOC. Notice the disappearance of most of the nonspecific bands and/or associated proteins. The positions of M_r standards (expressed as $10^{-3} \times M_r$) are shown at left.

nis, 1978). Purified antibodies can also be coupled directly to derivatized matrices such as CNBr-activated Sepharose (see Support Protocol). This latter approach avoids having to bind the antibody to protein A–agarose. Covalently bound antibodies should be used when elution of immunoglobulins from the beads complicates further analyses of the complexes. This is the case when proteins in immunoprecipitates

are analyzed by one- or two-dimensional gel electrophoresis (UNITS 10.2-10.4) followed by Coomassie blue or silver staining, or are used for microsequencing. Also, the released immunoglobulins could interfere with detection of some antigens by immunoblotting (UNIT 10.8) following immunoprecipitation.

The best results in terms of complete precipitation and lower backgrounds are obtained

when an antigen-specific antibody is coupled directly to Sepharose. Sepharose CL-4B appears to give a lower background than CL-2B, perhaps because aggregates are better excluded.

The support protocol for coupling protein antigens to CNBr-activated Sepharose is a modification of the methods of Cuatrecasas (1970) and March et al. (1974). As originally described, the washing was done at alkaline pH. Because activated Sepharose is very unstable at this pH, it was originally recommended that washing, adding the protein ligand, and mixing be done in <90 sec (Cuatrecasas, 1970). However, using an acid wash buffer (Gelb, 1973) as described in the support protocol causes activated groups to remain stable for ≥ 30 min. The 0.1 M NaHCO₃ buffer in which antibody is dissolved provides an optimal pH of ~ 8.4 , after mixing with activated-Sepharose. The low amount of CNBr recommended is sufficient to obtain a coupling yield of 80% to >99%. Higher amounts of CNBr may result in multipoint attachment of IgG molecules to the matrix, thereby reducing accessibility to antigen. Most investigators purchase CNBr-activated Sepharose, while others, to achieve a higher coupling efficacy or to avoid the expense of the commercial product, prefer to prepare it themselves.

Quantities and ratios recommended in these protocols have been found to work well with several hundred monoclonal antibodies and more than 40 different antigens. However, titration of Ab-Sepharose or sandwich reagents versus the protein antigen may further optimize a given immunoprecipitation.

Nonspecific controls

For correct interpretation of immunoprecipitation results, it is critical to include appropriate nonspecific controls along with the specific samples. One type of control consists of setting up an incubation with an irrelevant antibody in the same biochemical form as the experimental antibody (e.g., serum, ascites, affinity-purified immunoglobulin, antibody bound to protein A-agarose or directly conjugated to agarose), and belonging to the same species and immunoglobulin subclass as the experimental antibody (e.g., rabbit antiserum, mouse IgG2a). For an antiserum, the best control is preimmune serum (serum from the same animal obtained before immunization). Nonimmune serum from the same species is an acceptable substitute for preimmune serum in some

cases. “No-antibody” controls are not appropriate because they do not account for nonspecific binding of proteins to immunoglobulins. In immunoprecipitation-recapture experiments, control immunoprecipitations with irrelevant antibodies should be performed for both the first and second immunoprecipitation steps (Fig. 10.16.4). Another type of control is to perform an immunoprecipitation from cells that do not express a specific antigen in parallel with immunoprecipitation of the antigen-expressing cells. For instance, untransfected cells are a perfect control for transfected cells. In yeast cells, null mutants that do not express a specific antigen are an ideal control for wild-type cells.

Order of stages

In the immunoprecipitation procedure described in Basic Protocol 1, the antibody is prebound to protein A-agarose before addition to the cell lysate containing the antigen. This differs from other methods in which the free antibody is first added to the lysate and the antigen-antibody complexes are then collected by addition of the immunoadsorbent. Although both procedures can give good results, the authors prefer the protocol described here because this method allows better control of the amount of antibody bound to the immunoadsorbent. Prebinding antibodies to the immunoadsorbent beads allows removal of unbound antibodies. The presence of unbound antibodies in the incubation mixture could otherwise result in decreased recovery of the antigen on the immunoadsorbent beads. Another advantage of the prebinding procedure is that most proteins other than the immunoglobulin in the antibody sample (e.g., serum proteins) are removed from the beads and do not come in contact with the cell lysate. This eliminates potential adverse effects of these proteins on isolation of the antigen.

Washing

The five washes described in Basic Protocol 1 (four with wash buffer and one with PBS) are sufficient for maximal removal of unbound proteins; additional washes are unlikely to decrease the background any further. The last wash with PBS removes the Triton X-100 that can lead to decreased resolution on SDS-PAGE. It also removes other components of the wash buffer that could interfere with enzymatic treatment of immunoprecipitates. It is not advisable

Table 10.16.2 Troubleshooting Guide for Immunoprecipitation

Problem	Cause	Solution
<i>No specific radiolabeled antigen band</i>		
Gel is completely blank after prolonged autoradiographic exposure	Poorly labeled cells: too little radiolabeled precursor, too few cells labeled, lysis/loss of cells during labeling, too much cold amino acid in labeling mix, wrong labeling temperature	Check incorporation of label by TCA precipitation (<i>UNIT 10.18</i>); troubleshoot the labeling procedure
Only nonspecific bands present	Antigen does not contain the amino acid used for labeling	Label cells with another radiolabeled amino acid or, for glycoproteins, with tritiated sugar
	Antigen expressed at very low levels	Substitute cells known to express higher levels of antigens as detected by other methods; transfect cells for higher expression
	Protein has high turnover rate and is not well labeled by long-term labeling	Use pulse labeling
	Protein has a low turnover rate and is not well labeled by short-term labeling	Use long-term labeling
	Protein is not extracted by lysis buffer used to solubilize cells	Solublize with a different nondenaturing detergent or under denaturing conditions
	Antibody is nonprecipitating	Identify and use antibody that precipitates antigen
	Epitope is not exposed in native antigen	Extract cells under denaturing conditions
	Antibody does not recognize denatured antigen	Extract cells under nondenaturing conditions
	Antibody does not bind to immunoadsorbent	Use a different immunoadsorbent (<i>Table 10.16.2</i>); use intermediate antibody
	Antigen is degraded during immunoprecipitation	Ensure that fresh protease inhibitors are present
<i>High background of nonspecific bands</i>		
Isolated lanes on gel with high background	Random carryover of detergent-insoluble proteins	Remove supernatant immediately after centrifugation, leaving a small amount with pellet; if resuspension occurs, recentrifuge
High background in all lanes	Incomplete washing	Cap tubes and invert several times during washes
	Poorly radiolabeled protein	Optimize duration of labeling to maximize signal-to-noise ratio
	Incomplete removal of detergent-insoluble proteins	Centrifuge lysate 1 hr at $100,000 \times g$
	Insufficient unlabeled protein to quench nonspecific binding	Increase concentration of BSA

continued

Table 10.16.2 Troubleshooting Guide for Immunoprecipitation, continued

Problem	Cause	Solution
	Antibody contains aggregates	Microcentrifuge antibody 15 min at maximum speed before binding to beads
	Antibody solution contains nonspecific antibodies	Use affinity-purified antibodies; absorb antibody with acetone extract of cultured cells that do not express antigen; for yeast cells, absorb antibody with null mutant cells
	Too much antibody	Use less antibody
	Incomplete preclearing	Preclear with irrelevant antibody of same species of origin and immunoglobulin subclass bound to immunoadsorbent
	Nonspecifically immunoprecipitated proteins	Fractionate cell lysate (e.g., ammonium sulfate precipitation, lectin absorption, or gel filtration) prior to immunoprecipitation; after washes in wash buffer, wash beads once with 0.1% SDS in wash buffer or 0.1% SDS/0.1% sodium deoxycholate
<i>Immunoprecipitating antibody detected in immunoblots</i>		
Complete immunoglobulin or heavy and/or light chains visible in immunoblot	Protein A conjugate or secondary antibody recognizes immunoprecipitating antibody	Use antibody coupled covalently to solid-phase matrix for immunoprecipitation; probe blots with primary antibody from a different species and the appropriate secondary antibody specific for immunoblotting primary antibody

to complete all the washes quickly (e.g., in 5 min), because this may not allow enough time for included proteins to diffuse out of the gel matrix. Instead, beads should be washed over ~30 min, which may require keeping the samples on ice for periods of 3 to 5 min between washes. In order to reduce nonspecific bands, samples can be subjected to an additional wash with wash buffer containing 0.1% (w/v) SDS, or with a mixture of 0.1% (w/v) SDS and 0.1% (w/v) sodium deoxycholate (Fig. 10.16.5). This wash should be done before the last wash with PBS (in Basic Protocol 1) or before the wash with 0.05 M Tris-Cl, pH 6.8 (in Alternate Protocol 5).

Troubleshooting

Two of the most common problems encountered in immunoprecipitation of metabolically labeled proteins are failure to detect specific antigens in the immunoprecipitates, and high background of nonspecifically bound proteins for antigens that were radiolabeled *in vivo* and analyzed by SDS-PAGE (UNIT 10.2) followed by autoradiography or fluorography (APPENDIX 3A). When immunoprecipitates are analyzed by immunoblotting (UNIT 10.8), an additional problem may be the detection of immunoprecipitating antibody bands in the blots (Table 10.16.2).

Anticipated Results

For antigens that are present at >10,000 copies per cell, the radiolabeling and immunoprecipitation protocols described in this book

can be expected to result in the detection of one or more bands corresponding to the specific antigen and associated proteins in the electrophoretograms. Specific bands should not be present in control immunoprecipitations done with irrelevant antibodies. If antigens are labeled with [³⁵S]methionine (UNIT 10.18), specific bands should be visible within 2 hr to 2 months of exposure. Due to the relatively low yield of the immunoprecipitation-recapture procedure (<10% of that of a single immunoprecipitation step), detection of specific bands is likely to require longer exposure times. This may turn out to be problematic due to the radioactive decay of ³⁵S (half-life = 88 days). In immunoprecipitation-recapture experiments in which the antibodies used for the first and second immunoprecipitation steps recognize different antigens (e.g., for the study of protein-protein interactions; Fig. 10.16.3), it is advisable to include in the second immunoprecipitation step a positive control containing either the antibody used for the first immunoprecipitation (if the antibody recognizes both the native and denatured forms of the antigen) or a different antibody with specificity for the same antigen (Fig. 10.16.4, lane 3).

Time Considerations

Preparation of cell extracts (Basic Protocol 1 and Alternate Protocols 1 to 4) takes 1 to 3 hr to complete, and isolation of the antigen on antibody-conjugated beads takes 2 to 3 hr. Binding antibodies to immunoadsorbent beads can be done prior to or simultaneously with preparation of the cell extracts and also takes 1 to 3 hr. Therefore, the whole immunoprecipitation procedure can be completed in 1 day. Similar time requirements apply for Alternate Protocols 5 and 6. Reaction between antibody and antigen can be extended overnight, but this may increase the background when using Ab-Sepharose. Antigen-antibody complexes should not be left overnight in the midst of washing, as significant dissociation may occur.

Immunoprecipitation-recapture experiments (Basic Protocol 2) require an additional 1 to 2 hr to denature and prepare the antigen for immunoprecipitation, and 2 to 3 hr to isolate the antigen. Completion of an entire immunoprecipitation-recapture experiment requires a very long workday. Alternatively, samples can be frozen after the first immunoprecipitation, and the elution and recapture can be carried out another day. Immunoprecipitates can be ana-

lyzed immediately (e.g., resolved by SDS-PAGE) or frozen and analyzed another day.

Synthesizing Proteins In Vitro by Transcription and Translation of Cloned Genes

BASIC PROTOCOL

The availability of a cloned gene makes it possible to synthesize the encoded protein by in vitro transcription and translation. Such in vitro synthesized proteins are extremely useful for a wide variety of purposes including the analysis of DNA-protein interactions (UNIT 12.9). The basis of the method is to clone the protein-coding sequences into a vector containing a promoter for SP6 or T7 RNA polymerase (UNIT 1.5), to produce messenger RNA by transcribing the DNA template with this enzyme (UNIT 3.8), and to synthesize the desired protein (often as a ³⁵S-labeled species) by translation of this mRNA in vitro. A major advantage of this method is that any desired mutant protein can be generated simply by altering the DNA template.

Materials

Plasmid DNA containing SP6 or T7 promoter
 DNA containing cloned gene *or* cDNA encoding protein of interest
 Appropriate restriction endonucleases (UNIT 3.1)
 TE buffer (APPENDIX 2)
 5× ribonucleoside triphosphate mix
 10× SP6/T7 RNA polymerase buffer (UNIT 3.4)
 10 mM spermidine (for SP6 RNA polymerase only)
 Pancreatic ribonuclease inhibitor (e.g., RNasin from Promega Biotec)
 SP6 or T7 RNA polymerase (UNIT 3.8)
 Buffered phenol (UNIT 2.1)
 Isobutanol
 10 M ammonium acetate
 100% ethanol
 In vitro translation kit (wheat germ extract or reticulocyte lysate)
³⁵S-labeled methionine (1400 Ci/mmol)
 0.1 M NaOH
 10% trichloroacetic acid (TCA)
 EN³HANCE (Du Pont NEN)

Additional materials for subcloning DNA fragments (UNIT 3.16), preparing highly purified plasmid DNA (UNIT 1.7), digesting DNA with restriction endonucleases (UNIT 3.1), phenol extraction and ethanol precipitation (UNIT 2.1), agarose and nondenaturing polyacrylamide gel electrophoresis (UNITS 2.5, 2.7, & 12.2), quantitating radioactivity by acid precipitation on glass-fiber filters (UNIT 3.4), one-dimensional SDS-PAGE (UNIT 10.2), and autoradiography (APPENDIX 3).

Prepare the DNA template

1. Subclone protein-coding DNA sequences of interest into a plasmid vector that contains a promoter for SP6 or T7 RNA polymerase (e.g., pSP64) at a site downstream of the promoter.

The protein-coding sequences must be contiguous—i.e., uninterrupted by introns. It is also crucial that the protein-coding sequences be cloned in the correct orientation downstream of the bacteriophage promoter such that the correct initiation codon is the first AUG in the RNA to be synthesized. It is best if the AUG initiation codon is relatively close (25 to 100 bases) to the 5'-end of the RNA; this may require additional DNA manipulations of the protein-coding sequences such as nested deletions (UNIT 7.2) or oligonucleotide-directed mutagenesis (UNIT 8.1). See critical parameters.

2. Prepare plasmid DNA containing protein-coding sequences downstream of the bacteriophage promoter (step 1) by CsCl/ethidium bromide centrifugation or PEG precipitation (UNIT 1.7).

It is important that the DNA be of high quality; DNA produced by standard miniprep procedures (UNIT 1.6) is generally not adequate. It is important that the DNA preparations be devoid of ribonuclease activity.

3. Cleave 10 μg DNA with a restriction endonuclease that cuts just downstream of termination codon (ideally 50 to 200 bp) and does not cut within the protein-coding region. Remove a small aliquot, and check the efficiency of cleavage by agarose gel electrophoresis.

Although not essential, this step will ultimately result in the synthesis of higher molar amounts of the desired mRNA because it minimizes the length of the transcript. However, mRNAs containing less than 50 bases beyond the termination codon may be translated less efficiently.

4. Purify the DNA by phenol extraction and ethanol precipitation. Resuspend in 50 μl TE buffer.

This amount of DNA is enough for ten separate in vitro transcription and translation reactions.

Prepare the mRNA by in vitro transcription

5. Set up the following 25- μl reaction mixture at room temperature (to avoid precipitation of the DNA template by spermidine):

8 μl H₂O
5 μl DNA (total 1 μg)
5 μl 5 \times ribonucleoside triphosphate mix
2.5 μl 10 \times SP6/T7 RNA polymerase buffer
2.5 μl 10 mM spermidine (for SP6 RNA polymerase only)
1 μl RNasin (30 to 60 U)
1 μl SP6 or T7 RNA polymerase (5 to 20 U).

Incubate 60 min at 40°C. For reactions with T7 RNA polymerase, omit the spermidine and add an additional 2.5 μl water.

If desired, the transcription reaction can be monitored by electrophoresis in formaldehyde gels (UNIT 4.9) or by including a small amount of labeled ribonucleotides in the reaction mixture.

6. Add 25 μl buffered phenol, vortex, and extract immediately. Transfer the aqueous phase to a new microcentrifuge tube, extract twice with isobutanol, and add 6 μl of 10 M ammonium acetate and 70 μl ethanol. Ethanol precipitate with RNA and wash once with ethanol.
7. Resuspend the RNA in 24 μl TE buffer, add 6 μl of 10 M ammonium acetate and 70 μl ethanol, reprecipitate, and wash once with ethanol. Resuspend RNA in 10 μl TE buffer.

The RNA should be translated immediately or quick frozen and stored at -70°C.

Prepare the protein by in vitro translation

8. Add 1 to 10 μl RNA to the appropriate reagents in an in vitro translation kit and follow the directions of the manufacturer. Add 15 μCi of [³⁵S]methionine (1400 Ci/mmol) to radioactively label the protein. Reactions are typically performed in 30- μl volumes at room temperature for 30 to 60 min. After the reaction is complete, store at 0° to 4°C.

The amount of RNA to be added depends on the efficiency of the in vitro transcription reaction. In general, 1 to 2 μ l should be enough, but if necessary, up to 10 μ l can be used.

Translation reactions are generally carried out with commercially available kits that use either wheat germ extracts or reticulocyte lysates (see commentary). Although commercial kits are relatively expensive, they are highly recommended as active translation extracts can be difficult and tedious to prepare. For each new preparation of translation extract, it is useful to perform a control reaction that lacks added RNA.

For some applications, unlabeled methionine is used to synthesize proteins that are unlabeled or of lower specific activity. Proteins should be used as soon as possible, although they are generally stable at 0° to 4°C for a week.

9. Remove 1 μ l of the translation products and add to 50 μ l of 0.1 M NaOH; incubate 15 min at 37°C. Add 1 ml of 10% TCA and incubate an additional 15 min on ice.
10. Collect the precipitated protein on glass fiber filters and quantitate the incorporated [³⁵S]methionine by scintillation counting (UNIT 3.4).

By comparing the amount of incorporated [³⁵S]methionine in the sample to the control lacking added RNA, it is possible to estimate the amount of protein synthesized. Wheat germ extracts lack any endogenous methionine, hence making the calculation straightforward; reticulocyte lysates contain variable amounts of endogenous methionine.

11. Remove 3 μ l of the translation reaction and analyze the products by one-dimensional SDS–polyacrylamide gel electrophoresis, including lanes for molecular weight standards. Visualize the [³⁵S]proteins by fluorography with EN³HANCE and autoradiography.

Ideally, the synthesis should yield a single species of predicted molecular weight. The band should be visible in 1 to 4 hr.

REAGENTS AND SOLUTIONS

5× ribonucleoside triphosphate mix

5 mM each ATP, UTP, CTP

5 mM diguanosine triphosphate (G-5'ppp5'-G)TP

0.5 mM GTP

COMMENTARY

Background Information

The procedure for synthesizing proteins in vitro from cloned genes can be divided into several steps. First, protein-coding sequences are cloned into a vector containing a promoter for SP6 or T7 RNA polymerase (UNIT 1.5). The protein-coding sequence can be obtained from a cDNA clone, or for genes lacking introns, it can be generated from cloned genomic DNA. In some cases, it is necessary to modify the initial cDNA or genomic clone to optimize the lengths of the 5' or 3' untranslated sequences adjacent to the protein-coding region (see critical parameters).

Second, messenger RNA encoding the pro-

tein is generated by transcribing the DNA template with the appropriate bacteriophage RNA polymerase. This step is carried out essentially as described in UNIT 3.8, except that 90% of the GTP in the reaction mixture is replaced by diguanosine GTP. In this way, 90% of the RNA synthesized contains a 5'-capped structure that is normally found in eukaryotic mRNAs; this is important for efficient translation in vitro (Melton et al., 1984). Given the very high specificity of SP6 and T7 RNA polymerases for transcriptional initiation from their cognate promoters, the RNA synthesized is a single species that encodes the desired protein.

Third, the essentially pure mRNA is translated *in vitro* using wheat germ extracts or reticulocyte lysates. By using [³⁵S]methionine during the translation reaction, the protein is synthesized as a radiolabeled species. Moreover, because the translation reaction is programmed with a pure mRNA species, the protein generated should be radiochemically pure; i.e., analysis by SDS-PAGE should yield a single band of expected molecular weight assessed by autoradiography. Of course, the protein synthesized *in vitro* will not be biochemically pure, because of the vast excess of other proteins present in the translation extract. For most applications, *in vitro* synthesized proteins can be used directly without any further purification.

A significant advantage of this approach is that any desired mutant protein can be created simply by altering the DNA template, and then tested for the property of interest. For example, by creating a set of N- or C-terminal deletions of the protein, a DNA-binding domain can be localized (Hope and Struhl, 1986; *UNIT 12.9*). The availability of truncated but functional proteins can be useful for determining the subunit structure of a protein (Hope and Struhl, 1987). [³⁵S]proteins are also useful for structural studies involving proteases (Hope et al., 1988) and for examining protein-protein interactions. In addition, they can be used as substrates to assay for factors that modify the structure and/or activity of the protein.

Critical Parameters

In order to synthesize the desired protein, the uninterrupted protein-coding sequence must be cloned in the correct orientation downstream of the bacteriophage promoter. For efficient translation, it is essential that the correct initiation codon is the 5'-proximal AUG in the mRNA to be synthesized; initiation from internal AUG codons is generally very inefficient. It is best if the AUG initiation codon is relatively close (25 to 100 bases) to the 5'-end of the RNA; this may require additional DNA manipulations of the protein-coding sequences. Occasionally, synthesis of a desired protein may be inefficient because the AUG initiation codon resides in a poor sequence context or is inaccessible due to secondary structure of the mRNA. To circumvent either of these problems, the best approach is use the appropriate mutagenesis procedure(s) to replace the normal 5'-untranslated sequences (and possibly the first few translated codons) with the equivalent region from an efficiently translated protein.

For synthesizing mRNA, the most important consideration is the quality of the DNA preparation. In particular, RNA synthesis reactions can be inhibited by high concentrations of RNA, and the transcription products are easily destroyed by contaminating ribonucleases. DNA prepared by standard miniprep procedures (*UNIT 1.6*) is generally not suitable; preparation by CsCl gradient centrifugation or PEG precipitation (*UNIT 1.7*) is highly recommended. With high-quality DNA, the transcription of full-length mRNA is rarely a problem. However, if necessary, the amount and quality of the RNA synthesized can be examined by electrophoresis in formaldehyde gels (*UNIT 4.9*).

Although many mRNAs can be translated efficiently in wheat germ extracts or in reticulocyte lysates, synthesis of individual proteins may be more efficient in one of these systems. In general, it is thought that wheat germ extracts initiate translation somewhat better than reticulocyte lysates but are more prone to premature termination (or degradation of the mRNA template). Thus, wheat germ extracts may be preferred for shorter proteins, whereas reticulocyte lysates may be the best choice for longer proteins. However, many other factors can influence the translation efficiency for any particular protein. Wheat germ extracts contain no exogenous methionine, and hence generate proteins with somewhat higher specific activity than those produced in reticulocyte lysates, which contain variable amounts of exogenous methionine. For all experiments involving *in vitro* synthesized proteins, it is essential to determine the quality of the translation product by SDS-PAGE (*UNIT 10.2*).

Finally, a general consideration is that the protein synthesized *in vitro* may not be active either because its structure is different from the native protein or because a critical cofactor is missing. For such reasons, it is possible that proteins synthesized in wheat germ extracts or reticulocyte lysates might have different properties.

Anticipated Results

The *in vitro* transcription and translation reactions should yield a single band on an SDS-polyacrylamide gel whose molecular weight corresponds to that expected for the protein of interest. For some proteins, the mobility of the *in vitro* synthesized product is much slower than expected and the apparent molecular weight can be strongly influenced by the gel conditions (Hope and Struhl, 1985). Further confirmation that the correct protein is

being synthesized can be obtained by cleaving the template DNA at various positions within or just beyond the protein-coding sequences, and examining the proteins synthesized. Even in successful syntheses, minor bands are often observed. The most common reasons for bands corresponding to lower-molecular-weight products are premature termination of translation, aberrant initiation at internal AUG codons, and proteolysis. Bands corresponding to higher-molecular-weight species are less common and may be due to failure to terminate at the correct stop codon and post-translational modification. Protein modification may account for why certain in vitro synthesis reactions yield a set of distinct products of similar molecular weight.

A standard reaction should generate 1 to 10 ng of radiochemically pure protein at a specific activity between 10^8 and 10^9 cpm/ μ g. Because the materials necessary for in vitro protein synthesis are essentially unlimited, it should be possible to make at least 1 μ g of protein.

Time Considerations

The time necessary to generate a DNA template suitable for efficient synthesis of protein in vitro is highly variable; it can be as short as a few days. Assuming a high-quality preparation of such a DNA template, it is possible in a single day to cleave the DNA, transcribe the template into mRNA, synthesize the protein, and analyze the products by SDS-PAGE and autoradiography. More typically, these steps

are carried out over 2 days. The procedure can be stopped at essentially any point; however, mRNA should be stored at -70°C . Once synthesized, protein can be stored at 0° to 4°C without loss of stability for ~ 1 week. If a given protein is to be synthesized on multiple occasions, it is useful to prepare excess amounts of cleaved DNA template and/or mRNA.

Metabolic Labeling with Amino Acids

Metabolic labeling techniques are used to study biosynthesis, processing, intracellular transport, secretion, degradation, and physical-chemical properties of proteins. In this unit, protocols are described for metabolically labeling mammalian cells with radiolabeled amino acids (Table 10.18.1). Cells labeled using these procedures are suitable for analysis by immunoprecipitation (UNIT 10.16), characterization of cellular proteins, analysis of protein trafficking, and one- and two-dimensional gel electrophoresis (UNITS 10.2-10.4). The first protocols describe pulse-labeling (10 to 30 min) of mammalian cells in suspension with [³⁵S]methionine (see Basic Protocol), and necessary modifications for adherent mammalian cells (see Alternate Protocol 1). Alternate protocols are also presented for pulse-chase analysis (see Alternate Protocol 2) and long-term labeling (“steady state,” 6 to 32 hr; see Alternate Protocol 3). This is followed by conditions for metabolic labeling of cells with radiolabeled amino acids other than [³⁵S]methionine (see Alternate Protocol 4). The degree of label incorporation can be determined by precipitation with trichloroacetic acid (TCA; see Support Protocol).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% CO₂ incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO₂ to maintain pH 7.4.

Table 10.18.1 Radiolabeled Amino Acids Used in Metabolic Labeling of Proteins

Amino acid ^a	Frequency (%) ^b	Radioisotope	Specific activity (Ci/mmol)	Comments ^c
Leucine	10.4	³ H	5-190	E
Serine	8.1	³ H	5-40	T, I

Supplement 44

SAFETY PRECAUTIONS FOR WORKING WITH ³⁵S-LABELED COMPOUNDS

When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1F*).

Solutions containing ³⁵S-labeled compounds have been found to release volatile radioactive substances (Meisenhelder and Hunter, 1988). In addition to the usual safety practices followed when handling radioactive materials (see *APPENDIX 1F*), some extra precautions should be taken when using ³⁵S-labeled amino acids:

1. Vials containing ³⁵S-labeled compounds should always be handled in a designated fume hood equipped with an activated charcoal filter. This includes thawing the solution, opening the vial, and adding the radiolabeled amino acid to the labeling medium. Before opening, vials should be vented with a needle attached to a syringe packed with activated charcoal. Avoid using tissue culture hoods for this purpose as they are likely to become contaminated.
2. Minimize exposure of ³⁵S-containing solutions to the air.
3. Use baths, incubators, and centrifuges designated for work with radioactive materials. Place a tray containing a layer of activated charcoal in the CO₂ incubator to reduce the amount of ³⁵S-labeled compounds released to the air during cell labeling. Alternatively, filters impregnated with activated carbon (β-Safe, Schleicher & Schuell) can be attached to the covers of tissue culture dishes.
4. Monitor areas used during labeling by conducting wipe tests.
5. Dispose of solid and liquid ³⁵S waste quickly and with appropriate precautions.

BASIC PROTOCOL

PULSE-LABELING OF CELLS IN SUSPENSION WITH [³⁵S]METHIONINE

Pulse-labeling of proteins is performed by incubating cells for short periods (≤30 min) in culture medium containing a radiolabeled amino acid. The conditions described below are optimized for labeling times of 10 to 30 min. The same protocol is used for labeling cells for up to 6 hr, although a smaller number of cells and/or a larger amount of labeling medium should be used for optimal results. Very short pulses (<10 min) may require special conditions that are discussed elsewhere (see Critical Parameters). For labeling times >6 hr, see Alternate Protocol 3. [³⁵S]methionine is the radiolabeled amino acid of choice for metabolic labeling of proteins because of its high specific activity (>800 Ci/mmol) and ease of detection. A potential disadvantage of [³⁵S]methionine is its low abundance in proteins (~1.8% of the average amino acid composition; see Table 10.18.1). For proteins that contain little (e.g., only one) or no methionine, other radiolabeled amino acids should be used (see Alternate Protocol 4).

Materials

[³⁵S]L-Methionine (>800 Ci/mmol) or [³⁵S]-labeled protein hydrolyzate (>1000 Ci/mmol)

Pulse-labeling medium (see recipe), warmed to 37°C

Cell suspension (e.g., Jurkat, RBL, K562, BW5147, T and B cell hybridomas), grown in a humidified, 37°C, 5% CO₂ incubator or prepared from tissues (e.g., lymphocytes)

PBS (*APPENDIX 2*), ice cold

Vacuum aspirator with trap for liquid radioactive waste

Additional reagents and equipment for TCA precipitation (optional; see Support Protocol)

Metabolic Labeling with Amino Acids

10.18.2

1. Thaw [³⁵S]methionine at room temperature and prepare a 0.1 to 0.2 mCi/ml working solution in prewarmed (37°C) pulse-labeling medium.

CAUTION: Volatile ³⁵S-containing compounds can be released during the labeling procedure (refer to Safety Precautions and APPENDIX 1F). Keep [³⁵S]methionine-containing medium in a tightly capped tube in a 37°C water bath until use. Do not let it sit >60 min at 37°C.

2. Harvest $0.5\text{--}2 \times 10^7$ cells in suspension by centrifuging 5 min at $300 \times g$, room temperature.
3. Wash cells with ~10 ml prewarmed pulse-labeling medium. Centrifuge 5 min at $300 \times g$, room temperature, and aspirate supernatant. Resuspend cells by gently tapping the bottom of the tubes and repeat wash.
4. Resuspend cells at 5×10^6 cells/ml in prewarmed pulse-labeling medium and incubate 15 min in a 37°C water bath to deplete intracellular pools of methionine. Invert tubes periodically to resuspend cells.
5. Centrifuge cells 5 min at $300 \times g$, room temperature, and aspirate supernatant.
6. Resuspend cells in a fresh 15-ml centrifuge tube, using 2 ml [³⁵S]methionine working solution (step 1). Cap tubes tightly. Incubate cells 10 to 30 min (see Critical Parameters) in a 37°C water bath, resuspending frequently by gentle inversion of the tubes.

Alternatively, use a rotator placed in a 37°C incubator.

7. Centrifuge cells 5 min at $300 \times g$, 4°C, and aspirate supernatant. Resuspend with gentle swirling in 10 ml ice-cold PBS and repeat centrifugation.

CAUTION: The medium and wash are radioactive—follow applicable safety regulations for disposal.

Because of the short times and high concentrations of radiolabeled amino acids employed, pulse-labeling may not result in complete depletion of label from the medium. If this is the case, the labeling mixture can be reused. Collect the labeling medium containing [³⁵S]methionine or ³⁵S-labeled protein hydrolyzate and filter carefully through a 0.45- μ m filter unit. Estimate the percentage of unincorporated radioactivity by scintillation counting aliquots of the labeling mixture before and after labeling the cells. Store the labeling mixture up to 2 months frozen at -20°C .

8. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

Labeled cells are now ready for the desired processing and analysis. If cell pellets cannot be processed immediately, they can be kept on ice for a few hours or frozen at -80°C for several days. Thaw frozen cell pellets on ice before analysis. In most cases, freezing cells will not affect the biochemical properties of the proteins, but freezing and thawing cell extracts after solubilization with detergents can cause dissociation of multisubunit complexes or proteolysis of labeled proteins.

PULSE-LABELING OF ADHERENT CELLS WITH [³⁵S]METHIONINE

Labeling adherent cells is essentially the same as described for cells in suspension except that cells are labeled while attached to a dish. As with suspended cells, adherent cells are pulse-labeled 10 to 30 min (see Basic Protocol introduction). Alternatively, some adherent cells can be detached from plates by incubation for 10 min at 37°C with 10 mM EDTA in PBS (*APPENDIX 2*) and labeled as a suspension (see Basic Protocol). This is particularly advantageous when labeling cells for pulse-chase experiments, because it simplifies handling of multiple samples and allows more uniform labeling of the cells.

Additional Materials (also see Basic Protocol)

Adherent cells (e.g., HeLa, NRK, M1, COS-1, CV-1, or fibroblasts or endothelial cells in primary culture)
100-mm tissue culture dishes

1. Grow adherent cells to 80% to 90% confluency in 100-mm tissue culture dishes.

Depending on the cell type, a confluent 100-mm dish will contain $0.5\text{--}2 \times 10^7$ cells.

2. Prepare [³⁵S]methionine working solution as described (see Basic Protocol, step 1).
3. Aspirate culture medium from the dishes and wash twice by gently swirling with 10 ml prewarmed (37°C) pulse-labeling medium, aspirating medium after each wash.
4. Add 5 ml prewarmed pulse-labeling medium and incubate 15 min in a humidified, 37°C, 5% CO₂ incubator to deplete intracellular pools of methionine.
5. Remove medium from cells, add 2 ml [³⁵S]methionine working solution (from step 2), and incubate 10 to 30 min in a CO₂ incubator.

If necessary, as little as 1 ml of labeling medium per plate can be used. It is critical, however, that the plates sit on a perfectly horizontal surface during incubation to avoid drying of the cell monolayer.

6. Remove medium from cells. Wash once with 10 ml ice-cold PBS and remove PBS.

CAUTION: *The medium and wash are radioactive—follow applicable safety regulations for disposal.*

If significant detachment of cells occurs during labeling, it may be necessary to scrape the cells carefully in the [³⁵S]methionine-containing medium and transfer the suspension to a 15-ml centrifuge tube before centrifuging and washing with PBS.

7. Add 10 ml ice-cold PBS and scrape cells carefully with either a disposable plastic scraper or a rubber policeman.
8. Transfer the suspension to a 15-ml centrifuge tube, centrifuge 5 min at $300 \times g$, 4°C, and discard supernatant.
9. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

Labeled cells are now ready for the desired processing and analysis (see Basic Protocol, step 8 annotation, if cells are not to be used immediately).

PULSE-CHASE LABELING OF CELLS WITH [³⁵S]METHIONINE

Pulse-chase protocols are used to analyze time-dependent processes, such as posttranslational modification, transport, secretion, or degradation of newly synthesized proteins. Cells in suspension or adherent cells are pulse-labeled with [³⁵S]methionine (see Basic Protocol and Alternate Protocol 1), after which they are incubated (chased) in complete medium containing excess unlabeled methionine, as described below.

Additional Materials (also see *Basic Protocol* and *Alternate Protocol 1*)

Chase medium (see recipe), 37°C

1. Prepare $0.5\text{--}2 \times 10^7$ cells per sample per time point, and pulse-label 10 to 30 min with 2 ml of 0.1 to 0.2 mCi/ml [³⁵S]methionine per $0.5\text{--}2 \times 10^7$ cells (see Basic Protocol, steps 1 to 6, or see Alternate Protocol 1, steps 1 to 5).
2. Remove the [³⁵S]methionine working solution, wash once with 10 ml 37°C chase medium, and add 10 ml 37°C chase medium.

Rapid termination of the labeling reaction can be achieved by adding two times the volume of chase medium containing excess unlabeled methionine (15 mg/liter) directly to the labeling mixture.

Final concentration of cells in suspension should be 2×10^6 cells/ml for chases ≤ 2 hr, or 0.5×10^6 cells/ml for chases > 2 hr. For adherent cells, add 10 ml/100-mm dish.

3. Incubate for the desired time at 37°C. Incubate cell suspensions with rotation in tightly capped tubes. Incubate adherent cells in a CO₂ incubator.
- 4a. *For cells in suspension:* Collect cells by centrifuging 5 min at $300 \times g$, 4°C.

The supernatant can be discarded or can be collected for analysis of proteins that are secreted or shed into the medium.

- 4b. *For adherent cells:* Scrape off adherent cells and transfer to 15-ml centrifuge tubes. Centrifuge 5 min at $300 \times g$, 4°C, and either save or discard the supernatant as in step 4a.

5. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

Labeled cells are now ready for the desired processing and analysis (see Basic Protocol, step 8 annotation, if cells are not to be used immediately).

LONG-TERM LABELING OF CELLS WITH [³⁵S]METHIONINE

Long-term labeling refers to continuous metabolic labeling of cells for periods of 6 to 32 hr. Long-term labeling is particularly advantageous when studying proteins that are synthesized at low rates. It is also used to accumulate mature labeled proteins, rather than biosynthetic precursors, for characterization of their properties. Steady-state labeling is a form of long-term labeling in which cells are incubated with the radiolabeled amino acid until the rates of synthesis and degradation of the radiolabeled proteins are equal. Steady-state labeling allows calculation of the stoichiometry of subunits within a protein complex, provided that the primary structure of the subunits is known. In these procedures, unlabeled methionine is added to the medium to maintain cell viability and to sustain incorporation of label for the duration of the experiment. The amount of unlabeled methionine added depends on factors such as the length of the labeling period and the cell density. Media containing between 5% and 20% the normal amount of unlabeled methionine are generally used. The conditions described below are suitable for overnight (~16 hr) labeling of cells in suspension or adherent cells.

**ALTERNATE
PROTOCOL 2**

**ALTERNATE
PROTOCOL 3**

**Analysis of
Proteins**

10.18.5

Additional Materials (also see *Basic Protocol and Alternate Protocol 1*)

Long-term labeling medium (see recipe), warmed to 37°C
75-cm² tissue culture flask

1. Prepare a 0.02 to 0.1 mCi/ml [³⁵S]methionine working solution in prewarmed (37°C) long-term labeling medium (see *Basic Protocol*, step 1).

For cell suspensions

- 2a. Prepare and wash cells once with prewarmed long-term labeling medium (see *Basic Protocol*, steps 2 and 3).
- 3a. Resuspend 0.5–2 × 10⁷ cells in 25 ml of 0.02 to 0.1 mCi/ml [³⁵S]methionine working solution and transfer to a 75-cm² tissue culture flask.

For adherent cells

- 2b. Grow 0.5–2 × 10⁷ adherent cells in a 75-cm² tissue culture flask (80% to 90% confluency) in a CO₂ incubator. Wash once with prewarmed long-term labeling medium (see *Alternate Protocol 1*, step 3).
- 3b. Add 25 ml of 0.02 to 0.1 mCi/ml [³⁵S]methionine working solution to each 75-cm² flask.
4. Tighten caps to prevent release of volatile ³⁵S-labeled compounds. Incubate 16 hr in a CO₂ incubator.
5. Wash cells and determine incorporation (see *Basic Protocol*, steps 7 and 8, or *Alternate Protocol 1*, steps 6 to 9).

*Labeled cells are now ready for the desired processing and analysis (see *Basic Protocol*, step 8 annotation, if cells are not to be used immediately).*

**ALTERNATE
PROTOCOL 4**

METABOLIC LABELING WITH OTHER RADIOLABELED AMINO ACIDS

In some instances, it may be necessary to label proteins with radiolabeled amino acids other than [³⁵S]methionine—e.g., when the proteins have a low methionine content or have no methionine residues at all. In these cases, the best choices are [³⁵S]cysteine or [³H]leucine.

Cysteine residues are more abundant in proteins than are methionine residues (3.4% versus 1.8%; Table 10.18.1), although cysteine is less stable. Formulations of [³⁵S]cysteine that have high specific activity (>800 Ci/mmol) can be obtained from several companies. Leucine has the advantage of being the most frequent amino acid in proteins (10.4%; Table 10.18.1) and specific activities of [³H]leucine are the highest among ³H-labeled amino acids (up to 190 Ci/mmol). If proteins are known to be rich in a particular amino acid or if special methods are to be performed (e.g., radiochemical sequencing or multiple labeling), ³H-labeled amino acids other than [³H]leucine can be used.

Label cells with these amino acids as described for [³⁵S]methionine in the previous protocols. Substitute [³⁵S]cysteine or ³H-labeled amino acids in the labeling medium. Use labeling media lacking cysteine or any other respective amino acid.

CAUTION: Solutions containing [³⁵S]cysteine release volatile ³⁵S-labeled compounds (refer to Safety Precautions).

TCA PRECIPITATION TO DETERMINE LABEL INCORPORATION

In metabolic labeling experiments, it is often useful to monitor the incorporation of radioactivity into total cellular proteins. This can easily be achieved by precipitation with trichloroacetic acid (TCA) using BSA as a carrier protein. This protocol can be used at the end of the labeling procedures in each protocol.

Materials

Labeled cell suspension (see Basic Protocol or Alternate Protocols 1 to 4)
BSA/ NaN_3 : 1 mg/ml BSA containing 0.02% (w/v) sodium azide (NaN_3)
10% (w/v) TCA solution (see recipe), ice cold
Ethanol

Filtration apparatus attached to a vacuum line
2.5-cm glass microfiber filter disks (Whatman GF/C)

CAUTION: TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions.

1. Add 10 to 20 μl of a labeled cell suspension to 0.1 ml BSA/ NaN_3 . Place on ice.
2. Add 1 ml ice-cold 10% (w/v) TCA solution. Vortex vigorously and incubate 30 min on ice.
3. Filter the suspension onto 2.5-cm glass microfiber filter disks in a filtration apparatus under vacuum.
4. Wash the disks twice with 5 ml ice-cold 10% (w/v) TCA solution and twice with ethanol. Air dry 30 min.

CAUTION: *The wash fluids should be handled as mixed chemical/radioactive waste—follow applicable safety regulations for disposal (see APPENDIX 1F).*

5. Spot the same volume of the radiolabeled cell suspension used in step 1 (10 to 20 μl) on a glass microfiber disk. Air dry.
This disk will be used to measure the total amount of radiolabeled amino acid in the cell suspension.
6. Transfer disks from steps 4 and 5 to 20-ml scintillation vials, add 5 ml scintillation fluid, and measure the radioactivity in a scintillation counter.
7. Calculate the ratio of TCA-precipitable label to total radioactivity (i.e., the ratio of sample radioactivity in step 4 to the total radioactivity in step 5).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

NOTE: Use sterile tissue culture technique to prepare these reagents.

Chase medium

Pulse-labeling medium (see recipe) containing 15 mg/liter unlabeled methionine or equivalent excess amount of other amino acid used for radiolabeling. Store up to 2 weeks at 4°C.

Long-term labeling medium (90% methionine-free medium)

Mix 9 vol pulse-labeling medium (see recipe), lacking methionine or other appropriate amino acid, with 1 vol chase medium (see recipe) containing the same amino acid. Store up to 2 weeks at 4°C.

Pulse-labeling medium

Use supplemented Dulbecco's modified Eagle medium (DMEM; see APPENDIX 3F but omit nonessential amino acids) or RPMI, each lacking methionine or other specific amino acid, but containing 10% (v/v) FBS (dialyzed overnight against saline solution to remove unlabeled amino acids). Add 25 mM HEPES (with pH adjusted to 7.4 with NaOH). Store up to 2 weeks at 4°C.

The amino acid used to label cells is omitted from this medium (e.g., if [³⁵S]methionine is employed, methionine-free DMEM or RPMI 1640 must be used). Specific amino acid-free media can be obtained from several tissue culture media suppliers, or can be prepared (see APPENDIX 3F) from amino acid-free medium by adding individual amino acid components, omitting the one that will be used to label. A kit for the preparation of such media is available (Select-Amine from Life Technologies).

Trichloroacetic acid (TCA) solution, 10% (w/v)

Prepare a 100% (w/v) TCA stock solution by dissolving the entire contents of a newly opened TCA bottle in water (e.g., dissolve the contents of a 500-g bottle of TCA in sufficient water to yield a final volume of 500 ml). Store up to 1 year at 4°C. Prepare 10% (w/v) TCA by dilution and store up to 3 months at 4°C.

CAUTION: TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions.

COMMENTARY

Background Information

Metabolic labeling of cellular proteins is achieved by placing cells in a nutritional medium containing all components necessary for growth of cells in culture, except for one amino acid that is substituted by its radiolabeled form. The radiolabeled amino acids are transported across the plasma membrane by carrier-mediated systems and, once in the cytosol, are loaded onto tRNA molecules before being incorporated into newly synthesized proteins.

Because metabolic labeling techniques use the metabolic machinery of the cell to incorporate radiolabeled amino acids, there are limitations on the type of radiolabeled amino acids that can be employed. The list of potential precursors is restricted to L-amino acids normally found in proteins, in which one or more atoms are substituted by a radioisotope (Table 10.18.1). Sulfuric amino acids, such as methionine and cysteine, are conveniently labeled with ³⁵S. Most other amino acids can be obtained labeled with ³H.

Critical Parameters

The protocols in this unit should be considered as models from which more specific methods can be designed. The conditions described here have been optimized for radiolabeling proteins that are expressed at low to moderate levels (10⁴ to 10⁵ copies per cell) and assume that the labeled cells will be used for immunoprecipitation (UNIT 10.16). This level of expres-

sion is characteristic of most endogenous membrane proteins, luminal organellar proteins, signal transduction proteins, and transcription factors. More abundant proteins, such as cytoskeletal proteins or proteins expressed by infection or transfection, can be labeled with less radiolabeled amino acid and/or fewer cells. The choice of a particular labeling protocol and its modification will be aided by careful consideration of a number of parameters that influence the incorporation of radiolabeled amino acids into proteins, as discussed below.

Selection of amino acid label

Purified [³⁵S]methionine of high specific activity (>800 Ci/mmol) can be obtained from several suppliers of radiolabeled amino acids. Protein hydrolyzates of *Escherichia coli* grown in the presence of [³⁵SO₄]²⁻ (e.g., Tran³⁵S-label from ICN Biomedicals or Expre³⁵S³⁵S from NEN Life Sciences) can be used as substitutes for [³⁵S]methionine in metabolic labeling techniques. These preparations contain ³⁵S distributed among several different compounds. In a typical batch, ~70% of the radioactivity will be present as [³⁵S]methionine and ~15% as [³⁵S]cysteine; the remainder are other ³⁵S-labeled compounds. Labeling with these radioactive protein hydrolyzates in methionine-free medium will result in incorporation of label only in methionine residues; use of methionine- and cysteine-free medium will result in labeling of both methionine and cysteine residues.

Purified [³⁵S]methionine should be used whenever certainty of labeling with only [³⁵S]methionine is required. Another reason for using purified [³⁵S]methionine is that it tends to be more stable and emit less volatile decomposition products than ³⁵S-labeled protein hydrolyzates. In most cases, however, the relatively inexpensive radioactive protein hydrolyzates (~1/3 the cost of [³⁵S]methionine) can be used instead of purified [³⁵S]methionine. [³⁵S]methionine preparations should be stored frozen at -80°C. Under these conditions, they are stable for at least 1 month; the half-life of ³⁵S is 88 days.

For proteins with one or no methionine residues but several cysteine residues, labeling with [³⁵S]cysteine (available with specific activities >800 Ci/mmol) is a good option. ³⁵S-labeled protein hydrolyzates are not good sources of [³⁵S]cysteine for radiolabeling because only ~15% of the ³⁵S-labeled compounds are [³⁵S]cysteine.

Purified [³H]leucine (available with specific activities of up to 190 Ci/mmol) is a good alternative to ³⁵S-labeled amino acids. The half-life of ³H is ~12 years. The specific activities of other ³H-labeled amino acids range between 5 and 140 Ci/mmol (Table 10.18.1). Several problems can arise when using certain ³H-labeled amino acids due to their participation in metabolic pathways. The following problems must be considered when using tritiated amino acids for metabolic labeling of proteins.

Nonessential versus essential amino acids. Cells are able to synthesize nonessential amino acids from other compounds. If the radiolabeled amino acids used are nonessential, their specific activity will be reduced by dilution with the endogenously synthesized amino acids. Therefore, essential amino acids (E in Table 10.18.1) should be favored for metabolic labeling.

Transamination. The α -amino groups of many amino acids can be removed in reactions catalyzed by transaminases (T in Table 10.18.1). Deamination of the radiolabeled amino acids can be prevented by addition of the transaminase inhibitor (aminoxy)acetic acid during starvation and labeling of the cells (Coligan et al., 1983).

Interconversion. Certain radiolabeled amino acids can be converted by cells into other amino acids (I in Table 10.18.1). This problem is of particular importance in methods used to determine the amino acid composition or sequence of radiolabeled proteins.

Labeling time

The experimental purpose, the turnover rate of the protein of interest, and the viability of the cells should all be considered when determining the length of time for labeling. If the purpose of the experiment is to identify or characterize a protein precursor, pulse-labeling (10 to 30 min) must be used (see Basic Protocol and Alternate Protocol 1). If the protein of interest has a low turnover rate or if it is necessary to accumulate a labeled mature product, a protocol for long-term labeling (6 to 32 hr) is more appropriate (see Alternate Protocol 3). If the biosynthesis, posttranslational modification, intracellular transport, or fate of newly synthesized proteins is being analyzed, a pulse-chase protocol should be used (see Alternate Protocol 2).

The turnover rate of the protein of interest is an important parameter to be considered when determining the labeling time. Proteins with a high turnover rate are optimally labeled for short times. Longer times will result in increased labeling of other cellular proteins, causing a decrease in the relative abundance of the labeled protein of interest in the cell lysate. This could result in increased detection of non-specific proteins in immunoprecipitates (see UNIT 10.16). Conversely, proteins that turn over slowly should be labeled for longer times.

Incorporation of radiolabeled amino acids into proteins is directly proportional to their length of labeling time for a certain period, after which it tends to plateau. When all the limiting amino acid is consumed, protein synthesis ceases. The length of the initial phase of linear incorporation will vary with the concentration of the labeling amino acid and the density and metabolic activity of the cells.

Concentration and specific activity of the radiolabeled amino acid

Because radiolabeled amino acids are used in limiting amounts, their incorporation into proteins is directly proportional to their concentration in the labeling medium. If very short pulses are required, the concentration of labeled amino acid can be increased to compensate for the shorter labeling time. The incorporation of radiolabeled amino acids is also directly proportional to their specific activity. Addition of unlabeled amino acids, as is required in long-term labeling protocols, will result in reduced incorporation over short periods.

Cell density

At low cell densities, the amount of labeled protein synthesized is directly proportional to the cell concentration. At high densities, however, incorporation will increase nonlinearly. Very concentrated cell samples ($>5 \times 10^7$ cells/ml) can only be labeled for short periods (≤ 5 min) as rapid loss of metabolic activity and cell viability will occur due to acidification of the medium and accumulation of toxic metabolites.

Conditions for very short pulses

Very short pulses (2 to 10 min) are required to study posttranslational modifications that occur shortly after synthesis. This includes folding, disulfide bond formation, and early carbohydrate modifications of newly synthesized proteins. Proteins that are rapidly degraded after synthesis are also best studied with very short pulses. The protocol for very short pulses is similar to the Basic Protocol for pulse-labeling, with the following modifications: (1) the pulse-labeling medium contains higher concentration of radiolabeled amino acid (up to 1 mCi/ml), (2) labeling is stopped by addition of ice-cold PBS containing 20 mM freshly prepared *N*-ethylmaleimide (NEM) to prevent oxidation of free sulfhydryls, and (3) if a chase is necessary, 1 mM cycloheximide is added to the chase medium to quickly stop the elongation of nascent polypeptide chains. For additional details on very short pulses, see Braakman et al. (1991).

Temperature and pH

Unless otherwise required for special conditions (e.g., heat shock, temperature-sensitive mutants), metabolic labeling should be performed at 37°C. For this reason, it is important that the labeling medium be warmed to 37°C before adding it to the cells. A dramatic reduction in incorporation occurs at room temperature. It is also important that the pH of the labeling medium be ~ 7.4 .

Anticipated Results

A typical incorporation of labeled amino acid precursor after a 30-min pulse under the conditions described in this unit (see Basic Protocol and Alternate Protocols 1 and 2) is 5% to 20%. In the case of long-term labeling, the incorporation typically reaches 30% to 60%. If the labeled cells are used for immunoprecipitation (UNIT 10.16), followed by SDS-PAGE (UNIT 10.2) and autoradiography (APPENDIX 3A), specific bands should be visible within two hours to two months of exposure.

Time Considerations

It takes 1 to 2 hr to prepare cells and materials for labeling. The actual labeling time depends upon the protocol chosen—pulse-labeling takes 10 to 30 min and long-term labeling takes 6 to 32 hr. Washing and processing cells may take an additional 1.5 hr.

Isolation of Proteins for Microsequence Analysis

UNIT 10.19

The first basic protocol can be used to determine the amino-terminal sequence of polypeptides or proteins. It is particularly appropriate for large fragments of insoluble or hydrophobic proteins or proteins that cannot be purified to >90% molar purity without electrophoresis. Although the efficacy of this technique varies with the protein, it is possible to obtain useful sequence information starting with ≤ 50 pmol of the protein of interest.

If the protein is blocked at the amino terminus, chemical cleavage or partial enzymatic digestion must be performed prior to electrophoresis. Upon isolation, the internal amino acid sequence is analyzed as described in the second basic protocol. This method requires ~ 200 pmol of protein for analysis. It is understood that both of the analyses will be done in association with an expert operator of an automated protein sequencer. In addition, the second basic protocol requires expertise with reversed-phase HPLC to separate peptides.

DETERMINATION OF AMINO ACID SEQUENCE BY SDS-PAGE AND TRANSFER TO PVDF MEMBRANES

**BASIC
PROTOCOL**

A minigel is prepared and preelectrophoresed. A sample containing the desired protein is loaded onto the minigel and fractionated by SDS-PAGE at neutral pH. The proteins are then electrophoretically transferred to a sheet of polyvinylidene difluoride (PVDF) and stained with Coomassie blue. The separated bands are excised, then analyzed in an automated protein sequencer.

Materials

- Separating and stacking gel solutions (Table 10.19.1)
- 4 \times gel buffer
- Glutathione, reduced powder (Sigma #G4251)
- 10 \times lower reservoir buffer
- 10 \times upper reservoir buffer
- Mercaptoacetic acid, sodium salt
- Protein sample in sample buffer (see support protocol)
- Methanol
- Transfer buffer
- 0.1% Coomassie blue in 50% methanol (v/v)
- 10% acetic acid in 50% methanol (v/v)
- Vertical minigel unit (e.g., Bio-Rad Mini-Protean II; Hoefer Mighty Small SE 250/280 is not recommended for this procedure)
- Power supply (constant voltage and constant current)
- Microvolume syringe or gel-loading pipet tip
- Powder-free plastic gloves
- PVDF membranes (e.g., Immobilon-P or -PSQ, Millipore; ProBlott, Applied Biosystems)
- Small-format transfer apparatus (Midget MultiBlot, Hoefer or Pharmacia LKB; Mini Trans-Blot, Bio-Rad)
- Automated protein sequencer (Applied Biosystems)
- Additional reagents and equipment for minigel preparation (UNIT 10.2)

**Analysis of
Proteins**

Supplement 21

Table 10.19.1 Recipes for Polyacrylamide Separating and Stacking Gels

SEPARATING GEL											
Stock solutions	Final acrylamide concentration in the separating gels (%)										
	5	6	7	8	9	10	11	12	13	14	15
30% acrylamide monomer ^a	3.33	4.00	4.67	5.33	6.00	6.67	7.33	8.00	8.67	9.33	10.00
H ₂ O	11.49	10.83	10.16	9.50	8.84	8.17	7.51	6.84	6.18	5.51	4.85
TEMED ^b	0.040	0.033	0.029	0.025	0.025	0.020	0.018	0.017	0.015	0.014	0.013

Mix the above ingredients (listed in milliliters of stock solution) with 5 ml of 4× gel buffer and 0.14 ml of 5% potassium persulfate or 70 μl of 10% ammonium persulfate.

STACKING GEL

0.666 ml 30% acrylamide monomer^a
 3.033 ml H₂O
 0.025 ml 10% ammonium persulfate *or* 0.05 ml 5% potassium persulfate
 0.025 ml TEMED^b

^aGas-stabilized monomer solution (containing 37.5:1 acrylamide/*N,N*-methylene-bisacrylamide) from which acrylic acid and carbonyl-containing compounds have been removed (Protogel, National Diagnostics; or PAGE1 protein gel mix, Boehringer Mannheim)

^bTEMED may have to be altered to facilitate proper polymerization. Values given are reasonable approximations.

Pour and preelectrophorese the minigels

1. Pour denaturing minigels as in UNIT 10.2, substituting the separating and stacking gel solutions listed in Table 10.19.1.

Deaerate the gel polymerization mixtures prior to adding persulfate and TEMED and be careful not to draw in air through the polymerization mixtures when transferring or pipetting the solutions.

After removal of combs, the wells should be rectangular and firm. If they are not, prepare a fresh gel; poorly polymerized stacking gels are the most common cause of low sequencing yields.

2. Assemble vertical minigel unit.
3. Dilute 80 ml of 4× gel buffer to 320 ml (to 1× gel buffer). Pour 200 ml of 1× gel buffer into lower buffer reservoir. Add reduced glutathione (powder) to remaining 1× gel buffer to 1.0 mM final. Pour this into upper buffer reservoir. Attach gel to a constant voltage/constant current power supply (see UNIT 10.2 introduction for a discussion of electricity and electrophoresis).

Glutathione acts as a scavenger to eliminate the by-products of acrylamide polymerization.

4. Preelectrophorese by applying 10 mA per minigel for 45 min.

Voltage applied for >45 min may impair resolution.

5. Turn off power supply. Allow gel to stand overnight.

Gels may be stored this way for several days.

Load and electrophorese the sample

6. Pour off gel buffer and blot wells with tissue or filter paper.
7. Dilute 10× lower and upper reservoir buffers to 1×. Pour 200 ml of 1× lower reservoir buffer into lower reservoir. Add 0.1 g mercaptoacetic acid (sodium salt) to 150 ml of 1× upper reservoir buffer and pour into upper reservoir.

Mercaptoacetic acid is used as a substitute for glutathione at this step because it is less likely to interfere with sequence analysis.

8. Load protein sample dissolved in sample buffer with a microvolume syringe or gel-loading pipet tip.

When using 5-well combs and 0.75-mm gels, results are best with sample volumes <30 μ l/well.

It is advisable to run a known protein such as β -lactoglobulin (Applied Biosystems or Sigma) as a control for the procedure.

9. Electrophorese sample by applying 10 mA until pink tracking dye (pyronin Y; see support protocol) reaches bottom of gel. Turn off power supply.

The tracking dye should focus to sharp zones within 5 to 10 min. Pyronin Y is used instead of bromphenol blue because it binds tightly to transfer membranes, thereby identifying the bottom of the blot. Electrophoresis should be complete in 60 to 80 min.

Transfer the minigel samples to PVDF membranes

NOTE: Wear powder-free plastic gloves for all subsequent steps; one fingerprint contains many times more amino acids than the sample.

10. Wet two PVDF membranes with methanol and immerse them in transfer buffer.
11. Disassemble minigel unit and gently separate glass plates.
12. Assemble blotting sandwich supplied with the small-format transfer apparatus in the following sequence: plastic frame, sponge, filter paper, gel, two PVDF membranes, filter paper, sponge, plastic frame (see UNIT 10.8, Fig. 10.8.1; substitute PVDF membrane for nitrocellulose).

As with other blotting procedures, it is crucial to exclude air bubbles from the sandwich. The easiest way to do this is to assemble the sandwich in a tray filled with the transfer buffer. PVDF membranes may be placed on both sides of the gel to guard against inadvertent reversal of the electrode connections if desired.

13. Insert sandwich into transfer apparatus, placing membranes closest to the anode (red or positive electrode). Fill apparatus with transfer buffer.
14. Apply ~6 V/cm (e.g., 50 V in the LKB Midget MultiBlot apparatus) across electrodes of transfer apparatus for a period of time appropriate to protein of interest and gel concentration. Turn off power supply.

The efficiency with which a particular protein will transfer to the PVDF membrane depends on several variables. Transfer shows a rough inverse correlation with molecular weight, but there are many marked exceptions. Isoelectric point, hydrophobicity, and tertiary structure following partial renaturation of the protein are all important. Many smaller, highly charged proteins will travel through conventional PVDF membranes before others have migrated out of the gel, so a particular transfer should be optimized for the protein of interest. This means that some trial and error may be necessary. Duplicate PVDF sheets allow material migrating through the first membrane to be recovered and, in conjunction with staining of the gel following transfer, help optimize subsequent experiments.

PVDF-based membranes have been developed (e.g., ProBlott from Applied Biosystems and Immobilon-PSQ from Millipore) which adsorb blotted proteins much more avidly than others. These membranes make the transfer less critical for most samples and also permits analysis of low-molecular-weight peptides. With these membranes, one can err on the side of prolonged transfer without adverse effects.

At the specified voltage, transfer takes 30 to 40 min for 20- to 50-kDa proteins in a 15% gel, 60 to 70 min for 50- to 100-kDa proteins in a 10% to 12% gel, and 90 min for 150- to

200-kDa proteins in a 7% gel. For proteins >60 kDa, reduce the amount of methanol in transfer buffer to 1%.

Stain the blots and excise the bands

15. Disassemble transfer apparatus. Immerse PVDF membrane blots in 0.1% Coomassie blue in 50% methanol and agitate 5 min.
16. Destain blots in 10% acetic acid prepared in 50% methanol by agitating until bands become clearly visible (5 to 10 min).
17. Transfer to water and photograph (optional; *UNIT 10.6*).
18. Excise band of interest with a razor blade (use a new razor blade for each band). Place each band in a microcentrifuge tube and allow to air dry at room temperature (do not heat). Store excised bands at -20°C .

Sequence the proteins

19. Insert excised band into sequencer reaction cartridge, protein side facing the solvent delivery (see manufacturer's instructions).

All pieces of PVDF must fit in a single layer in the reaction cartridge; they may be cut or trimmed to fit as required. When using conventional chemistry ("NORMAL" program on Applied Biosystems instruments), two alternate configurations have proven optimal, depending on the sequencer. For many gas-phase instruments, placing the PVDF pieces between the upper-cartridge block and the TFA-etched glass-fiber filter gives the best results. For some gas-phase and most pulsed-liquid instruments, placement between the glass-fiber disk and the cartridge seal is better. The results of the cartridge leak test should be normal. The Blott cartridge should be used on Applied Biosystems instruments, if available.

20. Sequence the sample on an automated protein sequencer.

The "Blott-2 reaction cycle" should be used if a Blott reaction cartridge is installed. The conversion cycle described by Tempst and Riviere (1989) is recommended.

SUPPORT PROTOCOL

PREPARATION OF PROTEIN SAMPLES FOR SDS-PAGE

Samples are concentrated and freed of contaminants that interfere with electrophoresis by precipitation. They are then solubilized in a sample buffer containing SDS.

Additional Materials

Protein samples
1 M NaHCO_3 (optional)
100% ethanol, ice-cold (containing no denaturants; USP grade)
Sample buffer
0.1% (w/v) pyronin Y
Ultrafiltration concentrator (Amicon) or Speedvac evaporator (Savant)
Drawn-out Pasteur pipet *or* gel-loading pipet tip
Boiling water bath

1. Adjust the salt concentration of the protein sample to >100 mmol/liter with 1 M NaHCO_3 , if necessary.
2. Concentrate samples to 50 to 100 μl by ultrafiltration (follow manufacturer's instructions explicitly) or vacuum centrifugation (it is crucial to avoid introduction of airborne debris when vacuum is released). Transfer to 1.5-ml microcentrifuge tubes.

3. Add 9 vol ice-cold 100% ethanol to the samples. Incubate 1 hr on dry ice or overnight at -20°C .

Most samples may be kept indefinitely at this stage.

4. Microcentrifuge 15 min at maximum speed. Aspirate the supernatant with a drawn-out Pasteur pipet or a gel-loading pipet tip and save the pellet.

A drum rotor, which holds the microcentrifuge tubes at a 90° angle, is more likely to give compact, easily visualized pellets than the commonly used fixed-angle rotor.

5. Dissolve the pellet in 10 μl sample buffer by drawing the sample buffer up and down with a pipettor. Boil 3 min in a boiling water bath.
6. Add 1 μl of 0.1% pyronin Y (tracking dye) to the sample. Load on the minigel in the basic protocol.

DETERMINATION OF INTERNAL AMINO ACID SEQUENCE FROM ELECTROPHORETICALLY-SEPARATED PROTEINS

BASIC PROTOCOL

As many as 50% of all eukaryotic proteins are blocked at the amino terminus, making sequence determination of the intact protein impossible. The method presented here allows multiple stretches of internal amino acid sequence to be obtained from most proteins that can be isolated by any one- or two-dimensional gel electrophoresis and transfer method. About 200 pmol of protein is an adequate sample size; smaller amounts have sufficed in several cases.

The protein(s) of interest is separated by electrophoresis and transferred to nitrocellulose. Protein bands or spots are visualized with Ponceau S and excised. After destaining, the nitrocellulose is treated with polyvinylpyrrolidone (PVP) to prevent adsorption and inactivation of proteolytic enzyme, which is added to cleave the protein. The resulting peptides, which elute from the membrane, are separated by reversed-phase HPLC. Each peptide is analyzed individually in an automated microsequencer.

Materials

- Protein sample
- 0.1% (w/v) Ponceau S (Sigma) in 1% (v/v) acetic acid
- 1% acetic acid (v/v)
- 0.2 mM NaOH
- 0.5% (w/v) polyvinylpyrrolidone (Sigma # PVP-40) in 0.1 M acetic acid
- Digestion buffer
- 1 mg/ml sequencing-grade trypsin (Promega #V511A)
- Chromatography solvent A: 5% (v/v) acetonitrile in 0.1% (v/v) trifluoroacetic acid (TFA)
- Chromatography solvent B: 70% (v/v) acetonitrile in 0.085% (v/v) TFA
- 0.22- μm nitrocellulose membrane (e.g., Schleicher & Schuell #BA83)
- Acid-washed glass plate or petri dish
- Powder-free gloves
- Fine-tipped forceps
- 0.5-ml microcentrifuge tube
- Bath sonicator (e.g., Branson 12)
- Centrifugal filter device, 0.22- μm membrane, low-protein-binding (e.g., Millipore #UFC3-OGV-00)
- Reversed-phase HPLC column (e.g., Vydac #214TP52), UV column monitor, and chart recorder
- Column oven (optional)

Analysis of Proteins

10.19.5

Electrophoresis and transfer the proteins

1. Resolve protein(s) of interest by electrophoresis and transfer to nitrocellulose membrane as described in *UNIT 10.8*.

It is important to end up with as much protein as possible bound to the smallest possible area of nitrocellulose. Apart from this constraint, there are few limitations on the design of the separation, as chemical modification of the amino terminus will not interfere with subsequent analyses.

Although PVDF membranes may be used, nitrocellulose seems to give better yields (see commentary).

The membrane must never be allowed to dry from this point on.

Stain and excise the separated proteins

2. Place nitrocellulose membrane in an acid-washed glass petri dish (or similar vessel) containing 50 ml (for an 8 × 10-cm minigel) of 0.1% Ponceau S prepared in 1% aqueous acetic acid. Agitate gently 1 min.

For larger blots, increase the volume of stain in proportion to the area.

3. Transfer to 1% acetic acid for 1 min, changing the solution as necessary to allow easy visualization of band(s).

Use enough 1% acetic acid to cover the membrane generously.

4. Using a new razor blade and wearing powder-free gloves, cut out the band(s) of interest. Place in 1.5-ml microcentrifuge tube(s).

It is important to remove all areas of blank nitrocellulose to minimize subsequent adsorption of the protease used for digestion. Meticulous technique is crucial at this step to eliminate contamination of the sample by adventitious proteins. A clean work area, scrupulously clean glassware and instruments, and powder-free gloves are minimum precautions; tryptic fragments of human keratin have been identified in some samples!

To distinguish UV-absorbing peaks corresponding to the protein from those derived from the proteolytic enzyme or other reaction constituents, cut a piece of nitrocellulose from a blank area of the blot to use as a control.

The bands may be transferred to microcentrifuge tubes containing 0.5 ml water and stored at -20°C at this step.

Destain the membrane pieces

5. Transfer membrane pieces to 1 ml of 0.2 mM NaOH and vortex 1 min. Aspirate the NaOH and immediately proceed to step 6.

Proteins are more apt to be lost from the nitrocellulose under alkaline than acidic conditions. Because release of the peptides is desired at a later stage, the length of time for destaining should be minimized. Residual stain on the blot will not adversely affect the final results.

Block the membrane

6. Add 1 ml of 0.5% PVP-40 in 0.1 M acetic acid and agitate tube gently 30 min at room temperature.
7. Aspirate the PVP-40 and wash membrane five times with 1 ml water. Be sure to remove any liquid droplets caught under tube cap.

- Using clean fine-tipped forceps, transfer excised band to a clean glass surface (e.g., acid-washed glass plate or petri dish) and cut it into 1- to 2-mm pieces. Use forceps to collect the pieces and squeeze out excess liquid. Immediately proceed to step 9.

Digest the protein with protease

- Transfer pieces to a 0.5-ml microcentrifuge containing 25 μ l digestion buffer. Add 1 μ l 1 mg/ml trypsin. Mix so that membrane pieces are evenly coated with solution.
- Incubate overnight at room temperature.

Elute the peptides

- Microcentrifuge sample 1 sec at high speed, room temperature, to recover liquid that may have condensed on tube walls and cap.
- Sonicate sample 5 min at room temperature.
- Microcentrifuge 1 min at top speed, room temperature.
- Transfer supernatant to a centrifugal filter device. Rinse membrane pieces with 100 μ l digestion buffer and add to supernatant. Microcentrifuge sample 20 to 30 sec at top speed.

Filtration removes nitrocellulose particles that might clog the HPLC column. Samples should be stored frozen unless they will be fractionated immediately.

Chromatograph and process the samples

- Equilibrate a 2.1-mm-i.d. \times 250-mm reversed-phase HPLC column with 95% chromatography solvent A/5% solvent B at a flow rate of 0.15 ml/min. For optimal resolution, perform the separation at 60°C if a column oven is available.
- Inject the sample. Wash column 10 to 15 min with 95% solvent A/5% solvent B.
- Elute the peptides with a gradient between chromatography solvents A and B as follows: 5% to 40% solvent B over 1 hr; 40% to 75% solvent B over 30 min; and 75% to 100% solvent B over 15 min. Monitor elution of the peptides at 215 nm.

Elution gradient guidelines are described in Stone and Williams (1986).

The TFA concentration should be adjusted to equalize the UV absorbance (215 nm) of the eluants. Alternatives to TFA, such as phosphoric acid or hydrochloric acid, are compatible with the procedure. Buffers containing ammonia or UV-containing impurities should not be used.

Trypsin elutes at 60% solvent B and can be used as an internal standard. Characteristically, it elutes in a broader peak than the majority of peptides.

- Monitor the appearance of peptide peaks with a chart recorder adjusted so that 0.05 to 0.1 AUFS corresponds to a full-scale deflection.

Minimize the length and capacity of the capillary tubing between the column and the point of collection as much as possible. Polyethylether ketone (PEEK) tubing (0.005-in. i.d.) is helpful for this purpose.

- When chart-recorder pen begins a deflection indicative of a peak, wipe tip of capillary tubing against a clean surface (e.g., a Kimwipe or the previous collection tube) and collect this fraction in a microcentrifuge tube.

Clean gloves should be worn at this point. Commercial microcentrifuge tubes are sufficiently clean as supplied by the manufacturer if they are stored in the original container and handled with clean gloves.

20. Immediately cap tube and place it on dry ice.

Rapid freezing prevents adsorption of separated peptides to the walls of the microcentrifuge tube. The samples can be stored at -80°C indefinitely.

21. Sequence samples using glass support disks precycled with polybrene as prescribed by Applied Biosystems.

Improved reaction (Speicher, 1989) and conversion (Tempst and Riviere, 1989) cycles will reduce background and improve sensitivity.

It is very useful to compare chromatograms obtained from the sample and from the blank nitrocellulose to identify peaks corresponding to peptides derived from the protein of interest. UV-absorbing impurities may originate from several sources, including residual PVP-40, contaminated glassware, and the proteolytic enzyme (autolysis of the protease). These can be eliminated easily by inspecting the control chromatogram. Peaks as small as 0.002 AUFS have often been sequenced successfully.

REAGENTS AND SOLUTIONS

Digestion buffer

0.1 M Tris-Cl, pH 8
1 mM CaCl_2
10% (v/v) acetonitrile
Store frozen

4× gel buffer

41.24 g *bis*-Tris (0.493 M)
7.08 ml 37.5% HCl (reagent grade)
 H_2O to 400 ml
Final pH should be 6.61; do not adjust the pH with acid or base. This buffer may be stored indefinitely at -20°C or ≤ 2 months at 4°C .

10× lower reservoir buffer

52.4 g *bis*-Tris (0.626M)
12.2 ml 37.5% HCl
 H_2O to 400 ml
Final pH should be 5.90; do not adjust the pH with acid or base. This buffer may be stored indefinitely at -20°C or ≤ 2 months at 4°C .

10× upper reservoir buffer

40.28 g *N*-tris-(hydroxymethyl)-methyl-2-aminoethanesulfonic acid (TES; 0.439 M)
94.64 g *bis*-Tris (1.131 M)
4.0 g sodium dodecyl sulfate (SDS)
 H_2O to 400 ml
Final pH should be 7.25; do not adjust the pH with acid or base. This buffer may be stored indefinitely at -20°C or ≤ 2 months at 4°C .

Sample buffer

50 mM Tris-Cl, pH 6.8
5% (v/v) 2-mercaptoethanol
10% (v/v) glycerol
1% (w/v) SDS
Store frozen in small aliquots for ≤ 2 months

(continued)

Transfer buffer

2.21 g cyclohexylaminopropane sulfonic acid (CAPS), free acid
0.5 g dithiothreitol
150 ml methanol
H₂O to 1 liter
Adjust pH to 10.5 with NaOH and chill to 4°C
Prepare just before use

For proteins >60 kDa, reduce amount of methanol to 1%.

COMMENTARY

Background Information

The most difficult part of any protein sequencing project is to obtain a sample that is sufficiently free of both protein and nonprotein contaminants. SDS-PAGE is used because of its resolving power and its ability to maintain solubility of almost any protein. Many proteins of interest are identified only by migration on an analytical gel or by immunoreactivity in immunoblot experiments. The sequencing procedures outlined here allow the direct comparison of primary structures.

Following the demonstration that blotting procedures could be used to prepare samples for microsequencing (Aebersold et al., 1986; Vandekerckhove et al., 1986; Matsudaira, 1987), acceptance of these techniques was slow due to the inability of many investigators to obtain adequate sequencing signals. Evaluation of several parameters has indicated that preelectrophoresis with a scavenger such as glutathione or mercaptoacetic acid to eliminate reactive by-products of acrylamide polymerization, and lowering the separation pH to reduce the reactivity of the N-terminal amine, can dramatically improve the signals (Moos et al., 1988).

Recently, Tris-Tricine gels have become popular, especially for low-molecular-weight proteins and peptides (Schägger and von Jagow, 1987). These gels address the concerns of pH-dependent N-terminal blockage and give good results in sequencing experiments. Their commercial availability in precast format makes them an attractive choice for the novice.

The ability to sequence proteins blocked at the amino terminus following electrophoretic separation on gels (second basic protocol; Aebersold et al., 1987; Tempst et al., 1990) is an important improvement in protein analysis. Although meticulous cleanliness and exacting technique are required, the protocol is straightforward and highly reliable. Its particular strength is that it can be used following any type of gel electrophoresis or electrophoretic trans-

fer. It is even possible to combine small spots obtained from several gels (e.g., minor components detected by two-dimensional analysis). Its principal limitation is the relatively low yield of material for sequencing from a given amount of blotted protein; a dark band of Ponceau S-staining material corresponding to 100 to 250 pmol (or more for some proteins) is often required. This problem is obviated somewhat by the extremely high quality of sequence data that can be obtained from minute (e.g., 2 mAUFs) HPLC peaks.

Modifications to enhance the sensitivity of the microsequencer 5- to 8-fold have been developed (Tempst and Riviere, 1989); these have proven extremely useful for all microsequencing procedures. A new automated chemistry cycle specifically optimized for PVDF significantly improves results (Speicher, 1989). Applied Biosystems has developed a reaction cartridge designed for PVDF blots that simplifies sample placement and substantially improves sequencing results (Sheer et al., 1990). Finally, a procedure for covalently entrapping blotted proteins in a polymer network may prove beneficial (information available from Milligen/Biosearch; see APPENDIX 4).

Critical Parameters and Troubleshooting

Determination of amino acid sequence by SDS-PAGE and transfer to PVDF membranes

In practice, the electrophoresis conditions described in the first basic protocol improve the initial sequencing yield by 2- to 3-fold over those obtained with earlier procedures. Because many proteins are available in very small quantities, this consideration is often crucial. If the sample is *not* in short supply, it may be reasonable to attempt sequencing with electrophoresis conditions commonly in use (UNIT 10.2; Matsudaira, 1987), especially if the reagents are available in the laboratory. Samples already

transferred to PVDF by other procedures may also be tried; these should be rewet with methanol and washed with water (3 times, 5 min each) before sequencing to remove dust and materials such as glycine that may have been used in the transfer.

Efficient acrylamide polymerization is crucial to obtain good sequencing signals. Even the most efficiently polymerized gels contain 50 to 60 mM acrylamide monomer and possibly other compounds that react in a pH-dependent manner with the N terminus during electrophoresis. Therefore, fresh, high-quality reagents, ultrapure water, and thorough deaeration of the polymerization mixtures are necessary. TEMED is the most likely reagent to deteriorate and a fresh bottle should be opened each month.

The buffer system used in this protocol operates at a lower ionic strength than others in common use and therefore is more sensitive to the presence of ionic impurities in the sample. The most efficient way to remove these is by precipitation with organic solvent. Ethanol was chosen for this application (support protocol) because it is least likely to contain impurities that could react with amino termini of proteins (Yuan et al., 1987). Precipitation is most efficient with concentrated samples, so centrifugal ultrafiltration can be useful. Too much SDS in the sample will impair stacking. This is why only 1% SDS, which is sufficient to saturate almost all proteins, is used in the sample buffer. Pyronin Y is used as a tracking dye because it binds to PVDF tightly and unambiguously locates the dye front.

The gel buffers and polymerization mixtures should be prepared exactly as specified. No adjustments in pH should be necessary. SDS is not included in the gel polymerization mixtures as this could impair stacking. The same buffer is used in both the stacking and resolving gel. If efficient stacking and good resolution are not observed, the buffers are incorrect, the sample contains too much salt (see support protocol), or the gel is overloaded (10 to 20 $\mu\text{g}/\text{band}$ is about right).

If poor sequencing yields are obtained with a standard protein known to be unblocked, there are problems with gel polymerization, transfer, or placement of the blots in the reaction cartridge of the sequencer. Optimization of transfer is straightforward, and samples that have been applied directly to PVDF pieces without prior electrophoresis can be used to assess the transfer. It is strongly recommended that β -lac-

toglobulin, which has worked well in many laboratories and is widely available, be used on a test run before using valuable experimental samples. In addition, it is a good idea to use β -lactoglobulin as a positive control in every experiment. This will distinguish between existing N-terminal blockage and blockage that may occur during the procedure. Exposure of the blots to high pH and high temperature should be minimized.

When preparing the sample for electrophoresis, the supernatant should be aspirated very carefully—a magnifying lens may be helpful to avoid aspirating the pellet. A 10- μg pellet is usually visible to the naked eye.

Determination of internal amino acid sequence from electrophoretically-separated proteins

Once a sufficiently pure protein has been obtained, the most troublesome aspect of sequencing is chemical modification of the N terminus of the protein, either *in vivo* or *in vitro*. Approximately 50% of eukaryotic cellular proteins are thought to have naturally occurring N-terminal blockage. For these proteins, enzymatic or chemical cleavage procedures are required in order to obtain sequence information by automated Edman degradation (Hewick et al., 1981; Tempst and Riviere, 1989). In addition, many reagents commonly encountered in protein isolation procedures can irreversibly modify unblocked N-terminal amino groups and prevent Edman degradation. Because of this, a standard protein, such as β -lactoglobulin, should be analyzed as a control. Failure to obtain any sequence or a low-yield sequence for the standard protein suggests problems with the reagents.

The success of this method depends on a number of factors. (1) A reasonably homogeneous band or spot must be obtained. If two or more proteins are overlapping, it will be difficult to resolve individual peptides and impossible to assign sequence data to specific proteins. (2) It is important to maintain meticulous cleanliness throughout the procedure. Keratins from the skin are particularly problematic. (3) UV-absorbing contaminants in polyvinylpyrrolidone (PVP) can obscure the peptide peaks, which are often very small. Therefore, careful washing after the PVP blocking step is necessary. (4) The digestion should be performed in a minimum volume, as proteases are less active when dilute. The high concentrations used (compared to traditional

solution digestion procedures) are not a problem because proteases are generally separated from most of the peptides by HPLC. If an autolysis product should be isolated, this will be apparent when its sequence is compared with databases. (5) Careful manual collection of the HPLC fractions can improve the results; a bit of practice, and paying special attention to changes in the *rate of change* of the recorder pen's movement will be helpful. In general, quite closely spaced peaks will give unique amino acid sequences.

In the author's experience, trypsin is the most reliable enzyme for this procedure. Other enzymes—including Lys-C, Asp-N, and Glu-C—may also be tried to provide overlapping sequences or in case the tryptic pattern does not provide the desired information. In this event, the digestion buffer recommended by the supplier of the protease, supplemented as above with 10% acetonitrile, should be substituted.

The most common problems are spurious peaks, no peaks, and only a trypsin peak in the HPLC analysis. Spurious peaks arise from UV-absorbing contaminants, as discussed above. If a trypsin peak is absent, a control reaction containing the buffer and protease but no protein or nitrocellulose should be injected. If there is still nothing, the trypsin concentration should be checked. If a trypsin peak is present in the control samples, blocking was inadequate or the amount of nitrocellulose without adsorbed protein was too high. If only a trypsin peak is detected, either not enough protein was present or the trypsin was inactive. The latter possibility can be assessed by digesting some standard protein with the same lot of protease.

Anticipated Results

In the first basic protocol, if 100 pmol β -lactoglobulin are loaded onto a 12% gel prepared as described, the initial sequencing signal should indicate a yield of 50 to 80 pmol with gas-phase instruments (e.g., Applied Biosystems 470A). In some cases, usable sequence may be obtained from as little as 10 pmol. In general, if a band is easy to see with Coomassie blue staining, there is enough to sequence, but if it is so faint that excision is difficult, it is doubtful that there is enough protein. However, very faint bands, particularly of low-molecular-weight proteins, have yielded sequence.

For N-terminally blocked proteins, if enough material is present in a band or spot, usable sequence from 2 to 3 peptides can be obtained for most proteins. In several cases, two dozen or more HPLC peaks from a single band

have yielded high-quality sequence data, allowing determination of as many as two hundred residues from a single experiment.

Though the efficiency of the precipitation procedure (support protocol) varies with the sample, it is usual to recover 70% to 100% of samples >1 μg from a volume of 50 μl .

Time Considerations

Time required for the SDS-PAGE and transfer procedure: casting the gels—20 min hands-on time and ~2 hr total, including deaeration and polymerization; preelectrophoresis—just a few minutes hands-on time and 45 min total; electrophoreses—60 to 80 min; setting up the transfer—15 min; transfer—30 to 90 min; staining—15 min; band excision—5 to 30 min; sample preparation—15 min hands-on time and 1 hr for incubation on dry ice. The entire procedure can be completed in a single day, though it is preferable to cast the gels a day in advance.

Time required for determination of internal amino acid sequences following electrophoretic separation and transfer of proteins: destaining and PVP blocking—30 min; washing—5 min/sample; mincing the nitrocellulose—2 to 3 min/sample; digestions—overnight 12 to 24 hr; sample recovery and filtration—10 min; reversed-phase HPLC separations—2 hr/sample. A set of samples may be separated on a gel, transferred, and processed for digestion in ~5 hr. If several proteins from a given gel are of interest, a few days of HPLC will be required; at 2 hr per run, only 3 samples per day can be analyzed.

Capillary Electrophoresis of Proteins and Peptides

Capillary electrophoresis (CE) is a high-resolution technique for the separation of a wide variety of molecules of biological interest such as metabolites, drugs, amino acids, nucleic acids, and carbohydrates. This unit focuses on the use of CE to separate proteins and peptides. As with polyacrylamide gel electrophoresis (PAGE; UNIT 10.2), CE separations of proteins and peptides are based on charge-to-mass ratios. While PAGE separations are restricted to polyacrylamide matrices and a relatively small number of buffer systems, CE separations can be achieved in a variety of different matrices using a wide range of electrophoresis buffers. Consequently, there is a much greater flexibility in the design of optimal separation protocols.

CE employs a fused-silica capillary column, which may or may not be derivatized, either in free solution or in the presence of a fluid matrix. In contrast to PAGE, the resulting protein or peptide bands cannot be fixed or stained. The CE separation is, in essence, a dynamic one and is more analogous to high-performance liquid chromatography (HPLC) than PAGE. However, CE separation is based on electrophoretic parameters, so it can be viewed as orthogonal to HPLC, which is based predominantly on solvent partitioning parameters. The combination of these two techniques is very powerful for analyzing and characterizing proteins and peptides. The initial expectation that CE would play a major role in protein separations has not been realized. However, CE is particularly useful for determining the purity of a sample and for rapid, efficient, and quantitative evaluation of protein purification.

For best separation results, it is necessary to optimize the procedure. If some properties of the protein are known—e.g., its isoelectric point (pI)—the selection of a suitable running buffer is relatively straightforward. In fact, CE itself can be used to determine the isoelectric point of a protein, either in purified form or in a mixture, by focusing the sample in a pH gradient that is generated within the capillary during electrophoresis (Basic Protocol 1). After refocusing, the sample is mobilized either by changing the anode buffer, or by applying a hydrodynamic force to the column to move the separated components past the detector. However, there is little information available that will predict the potential of a protein to interact with the capillary wall. Underivatized silica capillaries have a strong tendency to adsorb proteins, thereby immobilizing them and making protein separations impractical. If such interactions occur, then an additive or a coated capillary column is required. A certain amount of trial and error is involved, and it may be necessary to perform several CE runs to optimize the separation conditions for a given protein. One approach to optimization is described in Basic Protocol 2.

CE is most useful for separations of peptides (Basic Protocol 3), because it offers great flexibility in separation parameters. It can be used to monitor proteolytic digestions and optimize digestion conditions for the production of a representative peptide fingerprint of a protein. This profile can subsequently be used to provide structural information about the protein, especially when used in conjunction with reversed-phase HPLC (RP-HPLC; UNIT 10.14). It can be used to screen peptide fractions that are obtained from a preparative RP-HPLC separation of a protease digestion. Fractions that contain single or major components are suitable candidates for protein sequence analysis. Similarly, CE can be used to assess the purity of synthetic peptides. In the presence of an internal standard, it can provide quantitative information about the various components that are present in a peptide mixture. CE can also be used as a micropreparative technique—with either multiple separations that are pooled (Basic Protocol 4) or a single, larger-scale separation

Figure 10.20.1 Schematic of a CE instrument.

(Alternate Protocol)—for the isolation of peptides from a protease digestion (in much the same way that RP-HPLC is currently used). In most of these examples the same capillary column can be used for all the separations. Only changes in buffer composition, ionic strength, and the presence or absence of additives are required for each specific application.

INSTRUMENTATION

CE separation in its simplest form can be achieved by passing a high voltage between two buffer reservoirs that are joined by a liquid-filled fused-silica capillary (Fig. 10.20.1). This results in the generation of electroosmotic flow (EOF; see Separation Theory), which allows the molecules of interest to be carried from one end of the capillary to the other. The capillaries are generally 30 to 50 cm long with 50 to 75 μm i.d. The net total volume of these capillaries is in the low microliter range. For comparison, the volume of a slab gel lane is ~ 1000 μl . The capillaries are thin-walled; this allows rapid and efficient exchange of the Joule heating that results from the high voltages (20 to 25 kV) that are necessary for electrophoretic separations. This heat dissipation minimizes the negative convective effects that could result in band-broadening during electrophoresis. The fused-silica capillary is coated on the outside with a polyimide layer that confers excellent tensile strength to the otherwise fragile capillary. The polyimide sheathing is carefully burned from a small portion of the capillary to expose a section of the silica. This clear section of the capillary is inserted into the light path of a UV detector and becomes the flow cell. As the protein and peptide molecules are swept through the capillary by EOF, they pass through the detector light path and are registered on the UV monitor. In effect the capillary becomes a very-low-volume flow cell.

IMPORTANT NOTE: The removal of the polyimide coating makes the capillaries susceptible to breakage. Capillaries that are not provided in cartridges by the manufacturer should be handled with care to avoid breakage.

The combination of high field strength and large surface-to-volume ratios results in rapid and very efficient separations of both proteins and peptides. Sample loading volumes are routinely in the nanoliter range, with starting sample concentrations of ~ 0.1 $\mu\text{g}/\mu\text{l}$ for UV detection. On-capillary preconcentration protocols are available when starting concentra-

Table 10.20.1 Commercially Available CE Instruments

Manufacturer	Model	Detection method	Reversal of polarity	Capillary heating	Cooling of sample/buffer	Capillary format	Software available
Applied Biosystems	270-HT	UV: 190-700 nm	Controlled by software	FAC	Sample	Free-hanging	DA
Beckman	P/ACE 5000 P/ACE 5510 P/ACE 5510	UV: filter; Diode-array: 190-600 nm; Fluorescence: argon laser; MS interface	Manual	Liquid (Peltier)	Sample/buffer	Cartridge	C, DA
Bio-Rad	Biofocus 3000	UV: 190-800 nm	Controlled by software	Liquid	Sample/buffer	Cartridge	C, DA
Hewlett-Packard	HP 3D CE	Diode-array: 190-600 nm	Controlled by software	FAC (Peltier)	Sample/buffer	Cartridge	C, DA

^aAll instruments have hydrostatic/electrokinetic sample loading and fraction collecting.

^bAbbreviations: C, CE system control software; DA, data acquisition; FAC, forced-air convection; MS, mass spectrometry.

tions are below these levels. Sample loading can be achieved either hydrodynamically or electrokinetically. Hydrodynamic loading can be performed by pressure injection, vacuum injection, or gravity injection, e.g., pressure loading at 0.5 lb/in² for 5 sec. Any of these methods will deliver a small aliquot of sample into the capillary column. Hydrodynamic sample loading has limitations where the capillary contains a viscous matrix or the sample itself has a high viscosity. Electrokinetic loading is performed by applying a low voltage across the capillary column for a fixed time, e.g., 7.5 kV for 4 sec. Sample buffer conductivity, run buffer conductivity, and EOF all play a part in determining the amount of material loaded into the capillary column. In general, samples in high salt buffers should be avoided because buffer ions will carry the charge rather than the sample ions. There are several methods for concentrating the sample onto the capillary column (Burgi and Chien, 1992). All instruments listed in Table 10.20.1 have both sample loading capabilities. Clearly, with respect to sensitivity, speed, and versatility, CE can offer some significant advantages over gel electrophoresis for the separation of proteins and peptides.

As shown in Figure 10.20.1, CE can require minimal instrumentation. However, in reality, due to the high voltages that are utilized, safety issues require that the capillary column be incorporated into a dedicated CE instrument. These instruments can provide efficient capillary cooling and online detection of analytes. Table 10.20.1 lists a number of commercially available instruments and some of their characteristics. For the purpose of this discussion, it is assumed that a generic CE system possessing the following capabilities is used: an active capillary cooling system, a UV detector capable of monitoring at 200 nm, a thermostatted autosampler, and a chromatographic data package. Given this basic unit a variety of separations can be performed, depending upon the nature of the proteins or peptides that are being separated.

SEPARATION THEORY

CE is part of the family of electrophoretic techniques that separate species based upon their sizes and ionic properties. An ion (*i*) placed into an electric field will move in the direction parallel to the field with a velocity (v_i) as follows:

$$v_i = \mu_i E$$

Here μ_i is the electrophoretic mobility of species i , and E is the electric field, as defined by the following equation, where V is the voltage and L is the total length from electrode to electrode:

$$E = \frac{V}{L}$$

The electrophoretic mobility of an ion (μ_i) is:

$$\mu_i = \frac{q}{6 \pi \eta a_i}$$

where q is the charge on the ion, η is the viscosity of the solution, and a_i is the radius of the ion.

As seen from these three equations, the movement of the molecule in the column is dependent on the applied voltage, the length of the column, the charge on the molecule, and the size of the molecule.

In CE, buffer flow is generated inside the column when the electric field is applied. This flow is from the cathode electrode to the anode electrode in a fused-silica capillary column (from left to right in Fig. 10.20.1); this movement of the buffer is called the electroosmotic flow (EOF). In addition, normal electrophoretic separation occurs whereby a positively charged molecule moves in the same direction as the EOF, a negatively charged molecule moves in a direction opposite to the flow, and a neutral molecule is carried along by the flow. Thus, the total velocity of the molecule (μ_t) is given by the following equation, where μ_{eo} is the EOF in the column.

$$\mu_t = (\mu_{eo} + \mu_i) E$$

The magnitude of the EOF will vary as a function of the pH of the carrier buffer. In uncoated fused-silica columns, a low pH generates a slow EOF, whereas a high pH generates a fast flow. The flow can be suppressed or completely reversed depending on the coating on the column or organic modifier added to the carrier buffer (Landers et al., 1992; Tsuiji and Little, 1992). Thus, EOF is another parameter that can be optimized to aid in difficult separations. Neutral molecules, because they are all carried along by the flow, can be difficult to separate. Addition of a micelle to the carrier buffer results in the partitioning of molecules between the micelle and carrier buffer and can effectively resolve neutral molecules (Khaledi, 1994).

STRATEGIC PLANNING

Proteins can be separated on coated or uncoated capillary columns, and the choice of separation protocol depends on the specific properties of the target protein. The most important property is the pI, which can be determined by either conventional gel electrophoresis or CE. The use of a buffer ~2 pH units above the pI is optimal for CE separations. Table 10.20.2 lists a number of buffers and their pH ranges. The presence of high salt concentrations in the sample can interfere with the separation process, and dialysis or dilution may be required. Protein concentrations of microgram per microliter are optimal for CE separations; however, on-capillary concentration protocols exist that allow the separation of proteins with concentrations 1 to 2 orders of magnitude lower.

Peptides can be effectively separated in open-tube fused-silica capillary columns. The EOF generated within the capillary causes separation of both charged and neutral peptides. The respective migration times are dependent upon both the pH of the electrophoretic separation and the charge-to-mass ratios of the peptides. For example, at low pH, peptides with net positive charge migrate towards the anode faster than neutral or negatively charged peptides. Even negatively charged peptides are swept towards the anode by EOF.

Table 10.20.2 Useful Electrolytes for CE of Peptides

Electrolyte	Useful pH range	Minimum useful wavelength (nm)
Phosphate	1.14-3.14	195
Citrate	3.06-5.40	260
Acetate	3.76-5.76	220
MES ^a	5.15-7.15	230
Phosphate	6.20-8.20	195
Tris	7.30-9.30	220
Borate	8.14-10.14	180

^aAbbreviation: MES, 2-(*N*-morpholino)ethanesulfonic acid.

In practice this migration order is further modified by the mass of the peptides, with small positively charged peptides having faster migration rates.

The choice of buffer for CE is of primary importance. The use of buffer systems that separate at high pH significantly alters the migration positions of peptides relative to those of low-pH separations. The selection of a specific buffer is dictated both by its buffering capacity at a selected pH and by its minimum usable UV absorbance wavelength. Characteristics of some useful buffer systems are shown in Table 10.20.2. Small differences in the pH or composition of the buffer can have a significant impact on the absolute mobilities of the peptides, so it is advisable to adjust the pH of buffers accurately and reproducibly. Alternatively, a suitable internal standard can be incorporated into the separation in order to obtain relative mobilities. The protein can be solubilized in water or 40 mM buffer in the presence or absence of urea. The sample buffer does not need to be the same composition as the running buffer, however, use of ionic detergents is not recommended. For the separation of peptides from a tryptic digest of a protein, where almost every peptide carries at least two positive charges, a phosphate buffer of pH 2.0 to 3.0 is commonly used. Likewise, for V8 protease digestions (which cleaves C-terminal to glutamic acid residues), the preferred separation conditions use a borate buffer with a pH range of 8.0 to 9.0.

SEPARATION OF PROTEINS BY ISOELECTRIC FOCUSING

Isoelectric focusing (IEF) separations can be performed readily by CE; this can be a useful first step in selecting subsequent buffer systems for protein separations. Proteins and peptides are amphoteric in nature, so their charge is dictated by the surrounding carrier buffer. When a protein or peptide is placed in an electric field, it moves to a region where the surrounding pH equals its isoelectric point (pI); at this point the molecule stops moving. A pH gradient is generated in a coated capillary column by filling the column with a sample solution that contains ampholytes. A high-pH solution (sodium hydroxide) is placed in the cathode reservoir and a low-pH solution (phosphoric acid) is placed in the anode reservoir. An electric field is then applied across the column, and the ampholytes and the sample move to a location in the column corresponding to their respective pIs. If the molecule drifts out of the isoelectric region, a charge is induced by the surrounding pH solution, and the molecule moves back to the region of zero charge. Narrow regions are formed with pI resolutions on the order of 0.01 pH units. To determine the pI of a particular protein in the column, markers of known pIs are added to the sample mixture, and extrapolation between markers yields the pI of the protein of interest.

After separation of the sample in the absence of EOF, mobilization of the proteins past the detector is necessary. A simple replacement of the anode reservoir with the buffer in

BASIC PROTOCOL 1

Analysis of Proteins

10.20.5

the cathode reservoir establishes EOF and causes the sample zone to migrate past the detector. The separation discussed here assumes there is no EOF in the column during focusing. However, separations may also be done in the presence of EOF (Mazzeo and Krull, 1992).

Materials

Ampholyte mixture, pH 3 to 10 (Bio-Rad)
Sample containing 0.5 to 1.0 mg protein/ml in water
IEF markers (Bio-Rad; optional)
20 mM sodium hydroxide (NaOH; store at 4°C)
10 mM phosphoric acid (store at 4°C)
50- μ m-i.d. coated silica capillary column
CE instrument (see Table 10.20.1)

1. Add ampholyte mixture to 0.5 ml protein sample to give a final concentration of 2.5% (v/v) ampholytes.

If desired, add IEF markers to a final concentration of 0.1 mg/ml to calibrate the column.

2. Add the solution to the sample reservoir. Fill the capillary by pressurizing the reservoir (0.5 lb/in²).
3. Place 10 mM phosphoric acid in the anode reservoir (negative end). Place 20 mM NaOH in the cathode reservoir (positive end).
4. Focus the sample 4 to 6 min at 8 to 10 kV constant voltage. Monitor the current until it reaches steady state.

The instrument should be operated in accordance with the manufacturer's instructions.

5. Mobilize the sample by placing 20 mM NaOH in the anode reservoir and setting the voltage to 10 kV. Monitor the mobilization of the proteins past the detector 15 to 20 min.

Another method for mobilizing the proteins past the detector is to apply a hydrodynamic force to one end of the column and push the zones past the detector. Commercially available CE instruments have this capacity as an option. To minimize distortion of the pI regions, a constant electric field (10 kV) must be applied at the same time. The pressure applied is small (0.5 lb/in²) and is maintained for the entire time of mobilization.

6. Wash the column after each run with 10 mM phosphoric acid for 1 min at 0.5 lb/in². Store the column at room temperature in running buffer (short-term) or water (long-term).

BASIC PROTOCOL 2

SEPARATION OF PROTEINS

To use CE for protein analyses, the more that is known about the particular protein, the higher the success rate for developing a separation method. Knowing the pI of a protein permits selection of the appropriate run buffer to maximize differences in the charge-to-size ratio. IEF separation performed using CE (Basic Protocol 1) can be a useful first step in selecting subsequent buffer systems for protein separations on an underivatized capillary column. If no protein is detected, it has probably adsorbed to the silica surface of the column. Repeating the separation in the presence of an ionic detergent such as SDS will coat the protein with negative charge and prevent adsorption. However, this means that proteins will separate on the basis of size alone. Alternatively, if the pI of the protein is unknown, the separation can often be achieved by using a coated capillary column in the presence of high-pH, high-ionic-strength buffer.

Materials

- Sample containing 10 mg protein/ml in water
- 50 mM and 500 mM sodium borate, pH 8.0 to 9.5 (for separation of proteins with unknown pI)
- 5 mM and 50 mM buffer at pH >pI (for separation of proteins with known pI; see Table 10.20.2)
- 50- μ m-i.d. coated (unknown pI) or uncoated (known pI) fused-silica capillary column
- CE instrument (see Table 10.20.1)

For separations of proteins with unknown pI

- 1a. Dilute protein sample 1/10 (v/v) with 50 mM sodium borate buffer to give a final concentration of 1.0 mg/ml.

Alternatively, dialyze sample (at a concentration of 1 mg/ml) in 50 mM sodium borate buffer.

- 2a. Fill a coated column with 500 mM sodium borate buffer.
- 3a. Inject the sample hydrodynamically, e.g., 3 sec at 1 lb/in².

Consult the manufacturer's instruction manual for the proper procedure.

- 4a. Separate using the following conditions:

- Detector wavelength: 200 nm
- Temperature: 25°C
- Run voltage: 10 kV
- Run time: 30 min.

For separations of proteins with known pI

- 1b. Dilute protein sample 1/10 (v/v) with a 5 mM buffer that has a pH above the pI of the protein to induce a charge on the protein (final protein concentration = 1.0 mg/ml).

Alternatively, dialyze sample (at a concentration of 1 mg/ml) in 5 mM buffer.

- 2b. Fill an uncoated capillary column with the same buffer at 50 mM.
- 3b. Inject the sample hydrodynamically, e.g., 3 sec at 1 lb/in².

Consult the manufacturer's instruction manual for the proper procedure.

- 4b. Separate using the following conditions:

- Detector wavelength: 200 nm
- Temperature: 25°C
- Run voltage: 25 kV
- Run time: 30 min.

If the protein of interest is not detected, add 10 mM SDS to the run buffer to induce a charge on the molecule. If the peaks are too broad, add 0.1% (w/v) methylcellulose to coat the column and reduce adsorption of the molecule onto the wall of the column. The addition of SDS and/or methylcellulose will increase the run time of the separation.

ANALYTICAL PEPTIDE SEPARATIONS

CE is particularly useful for separating specific peptides from complex mixtures such as the products of proteolytic digestion. In this procedure, the peptide mixture to be analyzed is placed in a sample vial at the cathode end of the capillary column. The anode reservoir contains running buffer. The sample is loaded into the capillary either electrokinetically or hydrodynamically by pressure or vacuum, then the sample vial is replaced by a vial containing running buffer and electrophoresis begins. The following protocol describes the use of a P/ACE 5000 CE instrument (Beckman) using low-pressure sample injection. However, other instruments (see Table 10.20.1) are capable of similar separations when operated according to the manufacturer's instructions.

Materials

Peptide mixture: e.g., tryptic digest of β -lactoglobulin (Applied Biosystems)
0.05 M and 0.25 M sodium phosphate buffer, pH 2.30 (store at 4°C)
0.1 M sodium hydroxide (NaOH)
75- μ m-i.d. fused-silica capillary column (Beckman)
CE instrument (e.g., P/ACE 5000, Beckman, or equivalent; see Table 10.20.1)

1. Precondition the capillary by flushing with the following solutions:

10 column volumes of 0.1 M NaOH at low pressure (0.5 lb/in²)
10 column volumes water
4 column volumes of 0.25 M sodium phosphate buffer, pH 2.30.

Store the column in 0.25 M sodium phosphate buffer, pH 2.30, at 25°C.

When changing to a different separation buffer, equilibrate the column 4 hr with the new buffer (Strickland and Strickland, 1990).

If a new capillary is being used, it is essential that this preconditioning step be performed prior to attempting separations.

2. Prepare the peptide mixture by dissolving 10 nmol (~300 μ g) in 10 ml of 0.05 M sodium phosphate buffer, pH 2.30. Freeze unused mixture in 100- μ l aliquots.
3. Apply 10 to 20 nl sample using low-pressure injection for 10 sec at 0.5 lb/in².

Consult the manufacturer's manual for the proper procedure.

4. Separate the peptide mixture using the following conditions:

Electrolyte: 0.05 M sodium phosphate buffer, pH 2.3
Detector wavelength: 200 nm
Temperature: 25°C
Voltage: 25 kV.

Consult the manufacturer's manual for proper operating conditions.

5. Rinse the column with the following solutions:

0.5 min with water
1.0 min with 0.1 N NaOH
1.5 min with water
1 min with 0.25 M sodium phosphate buffer, pH 2.30.

Store the column in running buffer or water at room temperature.

An example of a separation protocol for a Beckman P/ACE 5000 instrument with a 37-min run time is described in Table 10.20.3.

MICROPREPARATIVE CAPILLARY ELECTROPHORESIS: MULTIPLE SEPARATIONS

BASIC PROTOCOL 4

Although CE has been most commonly used for analytical separations, considerable interest has developed in using its high resolving power in micropreparative applications. Two basic approaches have evolved, one utilizing multiple separations and collections from an analytical capillary (Bergman and Jörnval, 1992) and the other utilizing a single separation and collection on a much larger-diameter (150- μm -i.d.) capillary (see Alternate Protocol). For the multiple collection approach to be effective, the elution times of the peptides must be reproducible. The following method uses the P/ACE 5000 capillary electrophoresis instrument to separate a mixture of peptides.

Materials

Peptides: ACTH 4-10, angiotensin I, and angiotensin II (Sigma)
 0.05 mM and 0.25 mM sodium phosphate buffer, pH 2.30 (store at 4°C)
 0.1 M sodium hydroxide (NaOH)
 75- μm -i.d. fused-silica capillary column (Beckman)
 CE instrument (e.g., P/ACE 5000, Beckman, or equivalent; see Table 10.20.1)
 Conical microvials (Beckman)

1. Precondition the capillary column by flushing with the following solutions at low pressure (0.5 lb/in²):

10 column volumes of 0.1 M NaOH
 10 column volumes of water
 4 column volumes of 0.25 M sodium phosphate buffer, pH 2.30.

Store in 0.25 M sodium phosphate, pH 2.30.

When changing to a different separation buffer, equilibrate the column 4 hr with the new buffer (Strickland and Strickland, 1990).

2. Prepare a peptide mixture by dissolving 0.2 mg each of ACTH 4-10, angiotensin I, and angiotensin II in 1 ml of 0.05 M sodium phosphate buffer, pH 2.30 (final concentration = 0.6 mg peptide/ml). Store 100- μl aliquots at -20°C.
3. Load 10 to 20 nl peptide mixture by low-pressure injection for 10 sec at 0.5 lb/in².

Analysis of Proteins

10.20.9

Consult the manufacturer's manual for the proper procedure.

4. Separate the mixture using the following conditions:

Electrolyte: 0.05 M sodium phosphate, pH 2.30

Detector wavelength: 200 nm

Temperature: 25°C

Run voltage: 25 kV

Fraction size: 3-min per collection vial.

Consult the manufacturer's manual for proper operating conditions.

5. Replace the standard outlet reservoir (anode) with a series of conical microvials, each containing 10 μ l of 0.05 M sodium phosphate buffer, pH 2.30. Collect 3-min fractions into each of the vials for the length of the separation.
6. Repeat the injection and separation (steps 3 to 5) four times and combine the contents from the corresponding fraction numbers.

It will take 2 to 3 hr to complete the fractionation.

7. Screen fractions for peptide content using the analytical separation previously described (see Basic Protocol 3).

ALTERNATE PROTOCOL

MICROPREPARATIVE CAPILLARY ELECTROPHORESIS: SINGLE SEPARATION

In this micropreparative protocol, a larger quantity of the peptide mixture is loaded onto a 150- μ m-i.d. capillary column and the fractions are collected from a single separation (Kenny et al., 1993). For the single-collection approach the CE instrument must be able to effectively control the capillary temperature at the elevated power levels that are required for electrophoresis. Forced air cooling is generally inadequate for this purpose.

Additional Materials (also see Basic Protocol 4)

4:1 (v/v) 0.5 M sodium phosphate buffer (pH 2.50)/ethylene glycol

150- μ m-i.d. fused-silica capillary column (Polymicro)

1. Prepare peptide mixture and precondition the column (see Basic Protocol 4, steps 1 and 2).
2. Load 0.1 μ l peptide mixture by low-pressure injection for 10 sec at 0.5 lb/in².

Consult the manufacturer's manual for the proper procedure.

3. Separate the peptide mixture using the following conditions:

Electrolyte: 0.05 M sodium phosphate buffer, pH 2.30

Detector wavelength: 200 nm

Temperature: 25°C

Run voltage: 7.5 kV

Fraction size: 3-min per collection vial.

Consult the manufacturer's manual for proper operating conditions.

4. Replace the standard outlet reservoir (anode) by a series of conical microvials each containing 10 μ l of 4:1 (v/v) 0.5 M sodium phosphate buffer/ethylene glycol. Collect 3-min fractions into each vial for the length of the separation.

It will take ~2 hr to fractionate the sample.

5. Screen fractions for peptide content using the analytical separation protocol (see Basic Protocol 3).

COMMENTARY

Background Information

Protein separation is one of the more difficult types of separation to perform by capillary electrophoresis (CE; Novotny et al., 1990). Each protein has its own set of optimal separation conditions, and one optimized protocol will not necessarily transfer well to the separation of a different protein. The more that is known about the properties of the molecule, the easier it will be to optimize the separation conditions. The most important property is probably the pI, because it will dictate the selection of pH and ionic strength conditions for the initial separation attempt. However, a variety of other properties must also be taken into account when optimizing a separation protocol: shape (globular or fibrous), aggregation tendencies, solubility in dilute solutions, salt requirements, thermal stability, and hydrophobic nature. Several parameters can be varied within CE separations in order to utilize this knowledge—e.g., temperature, buffer/salt selection, ionic and nonionic detergents, and matrix additives (polyacrylamide, methylcellulose). Several protocols have been developed that can serve as useful starting points for most protein separations. Table 10.20.4 lists references for some groups of proteins. Furthermore, many of the manufacturers listed in Table 10.20.1 have developed additional protocols for protein separations.

Ultimately, the selection of an appropriate separation protocol for a protein depends on the specific properties of that protein. However, there are separation approaches that utilize specific properties of proteins. IEF-CE separates on the basis of charge alone; CE in the presence of ionic detergents such as SDS separates on the basis of size alone; and CE using underivatized capillaries at low pH or derivatized capillaries at high salt and high pH separates on the basis of both size and charge. Successful CE separations also depend on the behavior of

other contaminants that are present in the mixture. It may also be possible to take advantage of the knowledge gained from previous purification steps, e.g., ion-exchange or size-exclusion chromatography, to select CE separation conditions.

Analytical-scale separation of peptides by CE has found application in a variety of areas. Proteolytic digestions can be monitored by placing the digestion mixture in a sample vial on the sample table that is equilibrated to 37°C. The instrument can then be programmed to analyze an aliquot at desired intervals, such as every 4 hr. Digestion is complete when a stable CE profile is obtained. Also, fractions collected from an HPLC separation of a protease digest can readily be screened orthogonally by CE to determine the homogeneity of any given peak. Fractions with a single major component can then be subjected to protein sequence analysis.

The sensitivity of UV detection at 200 nm is such that digest levels of ≥ 100 pmol can be effectively screened by this method. Below these load levels the fractions have to be reduced in volume or concentrated on the capillary to achieve a sufficiently high concentration for visualization with UV detection (Dolnik et al., 1990; Burgi and Chien, 1992).

Selection of an appropriate micropreparative protocol will depend on the type of instrumentation that is available. The single-separation micropreparative protocol will only work with a CE instrument that has adequate cooling capabilities. The multiple-separation micropreparative protocol will work on any CE instrument that has reproducible and stable electrophoretic mobilities.

Critical Parameters

For protein analysis, the charge on the protein is the most important parameter for separation. However, the charge-to-shape ratio also plays a role in effective separation of proteins.

Table 10.20.4 References for Separations of Different Protein Types

Protein type	Reference
Basic proteins	Wiktorowicz and Colburn (1990); Bullock and Yuan (1991)
Glycoproteins	Tran et al. (1991); Tsuiji and Little (1992)
Antibody-antigen complexes	Nielsen et al. (1991)
Milk proteins	Chen et al. (1992)

The charge on the protein is controlled by the buffer and the additives used for the run. The shape is determined by the denaturing conditions of the solutions. The surface charge on a protein may ultimately dictate the extent of wall interactions in addition to electrophoretic mobility, whereas shape has its greatest effect upon mobility alone.

The recovery of peptides from underivatized silica capillary columns appears to be very good—even at subpicomole levels. However, proteins are frequently irreversibly bound to these same capillaries. Clearly, at some point a “peptide” must become a “protein” in the context of CE. There is little published data available to clarify this issue, although good recoveries of peptides with 30–40 amino acid residues in length have been obtained from underivatized capillary columns. If the recoveries of higher molecular weight peptides are poor, then the separation should be repeated using a coated capillary column. During peptide synthesis, single-amino-acid-deletion products are frequently produced. The properties of these deletion products are very similar to those of the expected species, so the deletion products may not be readily resolved by reversed-phase HPLC. In this case, CE has proven to be a very useful orthogonal technique because of its high resolution power and separation based on charge-to-mass ratios. However, it must be emphasized that the effective separation and detection of proteins and peptides requires relatively high solute starting concentrations.

When using uncoated columns, a sodium hydroxide rinse is required to maintain the capillary surface. However, this rinse is never used with coated capillaries because it will remove the coating. Commercially available coated columns are satisfactory, but linear polymers (e.g., methylcellulose) have been used with more success (Palmieri and Nolan, 1994). If a protocol can be worked out for the molecule of interest, rapid CE analysis with little loss of starting material can augment the tools used now for protein analysis (e.g., HPLC).

Troubleshooting

Mechanical and electrical problems that might be encountered during instrument use are addressed in the troubleshooting sections of the manufacturers’ manuals. One of the common difficulties is the loss of electrical contact during a run. This loss of current can be caused if a small bubble forms in the column during

injection or if the power generated by the run is so great that the solution boils or outgasses. Purging the column after a failed run removes any bubbles in the column. The sample vial must contain enough sample to cover the end of the column during injection to prevent injection of air into the column. The sample vial can dry out during a long run, so sample temperature control or the use of the proper cap on the vial is required to slow evaporation. Reducing the buffer concentration or the run voltage can eliminate bubble formation during a run. Degassing the run buffer is also useful if the outgassing problems continue.

The instrument sometimes arcs during a run; this is caused by salt deposits or moisture on the high-voltage electrode stations. Particular attention should be given to keeping the electrode stations salt free. Moisture buildup can be minimized by reducing the separation voltage by 5 kV. Frequent visual inspection is also advised.

The column can plug up because of salt deposition if the column dries out. Washing the column with water dissolves the plug; storing the column in water, if it is not going to be used for a long period of time, prevents plugging. Proteins can precipitate during a run and plug the column. Using lower protein concentrations prevents this type of plugging.

Anticipated Results

Electrophoretic profiles for both protein and peptide separations should be highly reproducible. However, absolute migration times may vary from run to run, especially if the separation temperature is not adequately controlled. For this reason, the use of an appropriate internal standard is highly recommended (see the manufacturer’s instructions).

At load levels <50 pmol of digest, the recovery of peptides from a narrow-bore (1-mm) HPLC separation is poor. A convenient upper separation range for micropreparative CE is ~50 pmol of digest. The use of CE as a preparative separation technique therefore complements conventional HPLC capabilities. Recoveries from micropreparative CE separations are essentially quantitative down to the low picomole level, although postseparation handling losses can be significant. To use the multiple-separation micropreparative approach (see Basic Protocol 4), the CE instrument must be capable of maintaining very stable migration times. Not all instruments have this capability, so it is advisable that the method be used for simple mixtures of peptides. The single-sepa-

ration micropreparative approach is recommended for more complex mixtures. Because the fractions are collected "blind," they should be screened by matrix-assisted laser desorption/ionization (MALDI; Henzel and Stults, 1995) mass spectrometry prior to sequencing.

Time Considerations

Complete analysis times for IEF are ~30 min. Analysis times for protein separations are ~30 min for each step in method development. Peptide separations are normally completed in 40 min and frequently in as little as 20 min. Micropreparative peptide separations using either the multiple or single-separation approach are normally achievable within 90 min, but may take 2 hr or longer. It should be noted that these times are approximate, and sufficient time should be allowed to electrophorese all the components completely from the capillary.

Overview of Peptide and Protein Analysis by Mass Spectrometry

UNIT 10.21

WHY IS MS AN ESSENTIAL TOOL IN PROTEIN STRUCTURE ANALYSIS?

Mass spectrometry (MS) is now regarded as an indispensable tool for peptide and protein primary structure analysis. The increasingly widespread use of this technique is due in large part to its ability to solve structural problems not easily handled by conventional protein chemistry techniques. MS can provide accurate molecular weights for peptides and proteins with masses up to 500,000 Da using only a few picomoles (tens of femtomoles in favorable cases) of material. The accuracy achieved by MS is frequently better than 0.01% of the calculated mass (see Table 10.21.1). This means, for example, that the experimentally determined M_r of a 25-kDa protein will be ± 2.5 Da of the actual mass. In contrast, molecular weight estimates obtained by SDS-PAGE have accuracies of 5% to 10%; moreover, the mobility of the protein in the gel can be grossly affected (up to 50%) by the presence of covalent modifications such as lipids and carbohydrates. The accuracy of protein molecular weight estimates obtained by other methods, such as sedimentation velocity and gel permeation, can also be affected by the presence of lipid or carbohydrate. For correction and interpretation of this data, a molecular weight derived by mass spectrometry is needed (Hensley et al., 1994).

Unlike these other techniques, mass spectrometry provides molecular mass information independent of any modifications to the structure (such as glycosylation and phosphorylation). A mass difference between the observed and the expected mass of the protein or a peptide suggests the presence of post-translational modification or proteolytic processing, and the mass difference will be the starting point for defining the structure of the modification. A difference of +42 Da, for example, together with the lack of a free NH_2 -terminus, is indicative of the presence of an α -*N*-acetyl group. Similarly, a difference of +80 Da suggests the presence of a phosphate or sulfate moiety, and a cluster of molecular ion peaks separated by 162, 203, 291, or 146 Da indicates glycoforms differing by the presence of hexose, *N*-acetylhexosamine, *N*-acetylneuraminic acid, or deoxyhexose (see Table A.1C.4 in APPENDIX 1C). Thus molecular weight information provides a

useful measure of the integrity, purity, and overall state of modification of a peptide or protein. When evaluated in the context of other available structural data, the molecular mass information alone can be used to solve a variety of peptide and protein structural problems.

The ability of MS to determine the molecular weights of peptides in mixtures (such as result from a proteolytic digest of a protein) with better than 0.01% accuracy forms the basis of the mass spectrometric peptide mapping strategy, a rapid and highly efficient method to verify the fidelity of translation of protein sequences deduced from DNA or cDNA sequencing. This can be done either by direct analysis of unfractionated mixtures (Billeci and Stults, 1993) or on-line with liquid chromatography (Hess et al., 1993; Carr et al., 1993; Kassel et al., 1994) or capillary electrophoresis (Wahl et al., 1992; Foret et al., 1994; Smith et al., 1996).

Mass spectrometry also has the ability to provide amino acid sequence information on peptides using methodology generically referred to as tandem mass spectrometry (MS/MS). Using MS/MS, complete or partial sequence information may be obtained at the femtomole to picomole level for peptides containing up to 25 amino acid residues. In favorable cases some internal sequence data can often be obtained for peptides up to 30 or 40 residues. Unlike Edman sequencing, MS can provide this type of sequence information even if the peptides are present in complex mixtures, and, more importantly, even if they are modified. Methodologies such as Edman degradation and amino acid analysis have serious limitations with regard to characterizing structurally modified proteins and peptides, because many commonly occurring modifications are lost or destroyed by the harsh cleavage and derivatization conditions employed (Uy and Wold, 1977; Wold, 1981; Wold and Moldave, 1984; Carr et al., 1991). Furthermore, the sensitivity and speed of MS-based sequencing now exceeds that of Edman-based sequence analysis (Hunt et al., 1992; Wilm et al., 1996).

Vast amounts of cDNA sequence data, obtained by grand-scale sequencing of the human and other genomes, are presently flooding into databases. However, little is known about the functions of most of the proteins the various genes encode, nor is much known about the

Analysis of
Proteins

10.21.1

Supplement 38

Table 10.21.1 Key Ionization Methods for Biomolecule Analysis

Ionization method	Tolerance for buffers, salts, and detergents	MW range	Mass assignment accuracy	Compatible with on-line LC/CE-MS
Electrospray ionization (ESI)	Low tolerance (≤ 20 mM) for nonvolatile buffers, alkali metal salts, detergents; on-line LC-MS used for contaminant removal	≤ 150 kDA	$\pm 0.005\%$ – 0.01% to 50 kDA $\pm 0.02\%$ – 0.03% to 150 kDA	Yes
Matrix-assisted laser desorption/ionization (MALDI)	High tolerance (≥ 50 mM) for alkali metal salts, phosphate, urea, etc.; tolerant of some nonionic detergents; intolerant of SDS	≥ 350 kDA	$\pm 0.01\%$ – 0.05% to 25 kDA $\pm 0.05\%$ – 0.3% to 300 kDA	No

processed states of the expressed, mature forms of the proteins. In contrast, the protein content of a cell, referred to as the proteome (Kahn, 1995; Wilkins et al., 1995), can be studied by protein differential display using two-dimensional gel electrophoresis (UNIT 10.4), immunoprecipitation, and related procedures, allowing physiologically relevant proteins to be recognized by changes in their expression levels in response to stimuli. Because of its speed and sensitivity, mass spectrometry, through the use of strategies that employ molecular weight and/or partial sequence information to search protein databases, has emerged as the primary technology for identifying these proteins (Henzel et al., 1993; Mann et al., 1993; Pappin et al., 1993; Wilm and Mann, 1994; Eng et al., 1994).

This introductory overview has been designed with several goals in mind. The first and perhaps the most important one is to try and dispel the still widely held, but now mistaken, belief that mass spectrometry is beyond the technical resources of the typical laboratory or facility engaged in the structural characterization or synthesis of peptides and proteins. Over the last five years, mass spectrometers and associated data systems have become available that can be operated by anyone capable of running a modern amino acid analyzer or Edman sequencer, yet are powerful enough to handle the most demanding analyses that the peptide or protein investigator might require. As a result, it is no longer necessary to be a “card-carrying” mass spectroscopist to use the instruments and techniques of MS effectively and to apply it successfully to one’s own research program. The remaining goals of this article are to familiarize peptide and protein chemists with the types of mass spectrometers that are appropriate for the majority of their

analytical needs, to describe the kinds of experiments that can be performed with these instruments on a routine basis, and to discuss the kinds of information that these experiments provide. The emphasis here is on established tools and techniques that can realistically be used for problem solving. As a result, many useful instruments and techniques employed by the trained mass spectroscopist are not discussed here, because they do not satisfy these criteria or are not yet widely available. A few of these are briefly mentioned at the end of this introductory overview. The units that follow this overview will further discuss many of the principles introduced here and provide detailed protocols and applications of the methods. The overview concludes with a tutorial discussion on the meaning and practical importance of a number of fundamental experimental and performance-related issues that have important implications for interpretation and use of mass spectral data, such as mass accuracy and resolution.

More comprehensive discussion of mass spectrometry of biological molecules may be found in Chapter 16 of *Current Protocols in Protein Science* (Coligan et al., 1997). Additional information is available in several recently published books (Burlingame and McCloskey, 1990; McCloskey, 1990; Burlingame and Carr, 1996) and review articles (Carr et al., 1991; Biemann, 1992; Chait and Kent, 1992; Aebersold, 1993; Wang and Chait, 1994; Mann and Wilm, 1995; Williams and Carr, 1995; Mann and Talbo, 1996). The biannual review of mass spectrometry in *Analytical Chemistry* by Burlingame and colleagues provides a particularly good annotated bibliography of the recent literature on techniques and application of MS in the biological sciences

(Burlingame et al., 1994). Mass spectrometry information is also rapidly proliferating on the World Wide Web.

WHAT IS MS?

Mass spectrometry is a powerful analytical technique for forming gas-phase ions from intact, neutral molecules and subsequently determining their molecular masses. All mass spectrometers have three essential components: an ion source, a mass analyzer, and a detector. Ions are produced from the sample in the ion source using a specific ionization method (see discussion of Key Ionization Methods and Related Ancillary Techniques). The ions are separated in the mass analyzer based on their mass-to-charge (m/z) ratios and then detected, usually by an electron multiplier. The data system produces a mass spectrum, which is a plot of ion abundance versus m/z . Except in the case of electrospray mass spectrometry (where the ion source is at atmospheric pressure), the ion source, mass analyzer, and detector are usually situated inside a high-vacuum chamber (pressure between 10^{-8} and 10^{-4} Torr).

KEY IONIZATION METHODS AND RELATED ANCILLARY TECHNIQUES

The decade of the 1980s marked a revolutionary period in the development of "soft ionization" techniques for the analysis by mass spectrometry of large, polar, nonvolatile molecules (Carr et al., 1991). These ionization techniques produced primarily intact protonated molecular ions of peptides and proteins. In the early 1980s, fast atom bombardment (FAB) and, to a lesser extent, plasma desorption (PD) mass spectrometry were used extensively for structural characterization of peptides and small proteins. In 1988, electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry were first shown to be useful for the analysis of peptides, proteins, carbohydrates, and oligonucleotides. Within a few years of their introduction, ESI and MALDI techniques became the MS methods of choice for biopolymers analysis, largely supplanting FAB-MS and PD-MS. For this reason these techniques will be the focus of this overview. The capabilities and sample requirements of these two MS techniques are compared in Table 10.21.1. The performance specifications in the table are those that can be routinely achieved by trained operators and do not represent the ultimate performance of each technique.

Several factors account for the widespread acceptance of ESI-MS and MALDI-MS. Both ionization methods (see detailed descriptions below) are optimally combined with relatively low-cost, simple-to-operate mass analyzers. A quadrupole mass filter is typically used for ESI-MS, whereas a time-of-flight (TOF) analyzer is commonly employed for MALDI-MS. The sensitivity of both methods is in the low-to subpicomole range, and both are capable of analyzing molecules with a wide range of molecular weights (Table 10.21.1). The methods have many analytical capabilities in common, but do differ in a number of respects that are of practical significance. Both techniques work best with clean (salt- and detergent-free) samples, but MALDI is capable of providing information directly on relatively dirty samples. Both methods can provide molecular weight information for large proteins, but the information is invariably easier to obtain and more sensitive with MALDI-MS. In the molecular weight range from 5 to 50 kDa, however, analysis by ESI-MS usually provides much more accurate molecular weight measurements. ESI-MS in this molecular weight range also typically exhibits better mass resolution than MALDI, which permits detection of protein variants that differ only slightly in mass. These practical differences between the techniques, and their impact on the information that can be obtained about a protein structure, are discussed below.

In addition to the development of the ionization approaches described above, a number of key enabling technologies that have significantly improved the performance and sensitivity of ESI-MS and MALDI-MS have been introduced in the last few years. These technologies have moved MS onto the center stage of protein discovery and characterization. The first such advance has been the development and refinement of microscale desalting procedures such as efficient liquid-liquid extraction for peptides produced by in-gel digestion (Shevchenko et al., 1996), micropacked glass capillaries for cleanup of 1 to 5 μ l of sample (Houthaeve, et al., 1995), and microscale high-performance liquid chromatography (HPLC) employing columns with internal diameters ≤ 1 mm (Zhang et al., 1995). Second has been the development of ultra-low-flow (< 50 nl/min) electrospray sources that enable 1 to 2 μ l of a dilute sample containing femtomole per microliter concentrations of peptides to be analyzed for periods of > 60 min (Wilm and Mann, 1996). The long duration of analysis permits

many experiments, including conventional MS experiments and MS/MS, to be carried out on a single sample loading. A third development has been the introduction of novel scanning methods whereby MS can be used to selectively detect specific protein modifications (Carr et al., 1993; Huddleston et al., 1993a,b). Fourth is the development of the so-called post-source decay (PSD) experiment (Kaufmann et al., 1994), which provides the ability to mass select particular peptide molecular ions and to analyze the metastable fragment ions from this precursor that are formed during the MALDI process. Like the ESI tandem MS experiment, PSD can provide a substantial amount of peptide sequence information (see section entitled What Is Tandem MS?). Finally, a variety of computer-based searching strategies have been developed whereby known proteins can be identified from protein and DNA databases by searching MS-derived molecular weights with and without partial sequence information (Henzel et al., 1993; Mann et al., 1993; Pappin et al., 1993; Eng et al., 1994; Wilm and Mann, 1994; Hall et al., 1996).

WHAT IS TANDEM MS?

In tandem mass spectrometry (commonly referred to as MS/MS), two consecutive stages of mass analysis are used to detect secondary fragment ions that are formed from a particular precursor ion. The first stage serves to isolate a peptide precursor ion of interest based on its m/z , and the second stage to mass analyze the product ions formed by spontaneous or induced fragmentation of the selected precursor ion. Interpretation of the product-ion spectrum provides sequence information for the peptide selected. The manner in which product ions are produced and detected is different in MALDI and ESI mass spectrometry, and therefore is described in the following sections that are devoted to these specific techniques.

MS/MS provides information that is highly complementary to that provided by Edman degradation; in addition, MS/MS has several advantages relative to Edman degradation for determining peptide sequence. First, MS/MS can produce sequence information for blocked or otherwise modified peptides that are either difficult or impossible to sequence by Edman degradation (for example, see the MS/MS spectrum of the phosphopeptide in Fig. 10.21.6). Second, the ability to individually select and fragment peptides in mixtures eliminates the need for extensive purification of peptides prior to sequence analysis. Third, MS-based peptide

sequencing is faster than Edman sequencing because it is not a stepwise process. All of the structural information, in the form of fragment ions, is presented in a single mass spectrum acquired in a single experiment. Finally, MS-based approaches are now at least as sensitive as Edman degradation (e.g., 1 to 5 pmol of peptide or protein is required), and state-of-the-art MS-based sequencing by either ESI-MS or MALDI-MS is capable of providing sequence information at the 50- to 250-fmol level (Hunt et al., 1992; Wilm et al., 1996).

Peptide fragment ions are produced in the mass spectrometer primarily by cleavage of the amide bonds (—CO—NH—) that join pairs of amino acid residues. The most commonly observed fragment ions and their nomenclature are shown in Figure 10.21.1, and a list of commonly observed low-mass fragment ions indicative of the presence of particular amino acid residues is presented in Table 10.21.2. The fragmentation of peptides in MS has been well described (Hunt et al., 1986; Biemann, 1988, 1990; Falick et al., 1993). The interested reader is referred to these studies and references therein for more detailed discussions of fragmentation and its possible mechanisms. The difference in mass between adjacent sequence ions of the same type defines an amino acid. Of the twenty commonly occurring amino acids, sixteen have unique masses, Leu and Ile have exactly the same mass, and Lys and Gln have nearly the same mass (Table A.1C.3 in APPENDIX 1C). A mass difference between two adjacent sequence ions of the same fragment type that does not correspond to the mass of an amino acid residue may represent the presence of a post-translational modification. A list of common post-translational modifications and their masses is given in Table A.1C.4 in APPENDIX 1C.

Two caveats to the above discussion on MS/MS should be noted. First, although it is generally very easy to obtain the internal sequence of a peptide by this procedure, it is often difficult to determine the order of the first two and sometimes the last few residues in the peptide without additional experiments. Several methods involving reanalysis by MS/MS after chemical derivatization have been developed to help sort out the sequence at the ends of the peptide when required (Sherman et al., 1995; Gulden et al., 1996). Alternatively, there are several sequence ladder approaches, using either chemical derivatives or peptidases, that can be useful for identifying the N- and C-terminal residues (Chait et al., 1993; Bartlett-Jones et al., 1994; Thiede et al., 1995; Patterson et al.,

sequence-specific ions

non-sequence-specific ions

Figure 10.21.1 Nomenclature for peptide fragment ions. R represents the variable amino acid side chain (see APPENDIX 1C). The non-sequence-specific ions are designated by the single-letter amino acid codes (Table A.1C.1) for the R groups they include.

Table 10.21.2 Common Low-Mass Ions Characteristic of Amino Acids^a

m/z	Amino acid present
<u>70</u> , 87, 100, <u>112</u> , 129	Arginine
<u>70</u> (w/o 87, 100, and 112)	Proline
<u>72</u>	Valine
84 (w/o 101)	Lysine
<u>86</u>	Leucine or isoleucine
101 (w/o 84)	Glutamine
102	Glutamic acid
104	Methionine
106	Pyridylethyl cysteine
<u>110</u>	Histidine
120	Phenylalanine
133	Carbamidomethylated cysteine
134	Carboxymethylated cysteine
<u>136</u>	Tyrosine
<u>147</u>	Acrylamide-modified cysteine
159	Tryptophan
<u>216</u>	Phosphotyrosine

^aUnderlining indicates more abundant ions; w/o, without.

1995). The second caveat is that, unlike Edman degradation, MS cannot at present be used reliably to determine the NH₂-terminal sequence of proteins directly, although several successful attempts have been made (Speir et al., 1995).

MALDI-MS

Matrix-assisted laser desorption/ionization (MALDI)-MS as commonly practiced today was first described by Karas and Hillenkamp (1988). They demonstrated that by cocrystallizing analyte molecules with a large molar excess of a small, UV-absorbing organic acid, large proteins such as serum albumin could be desorbed and ionized by short, intense pulses from a UV laser and detected using a TOF mass spectrometer. Refinement of the technique was rapid. New laser wavelengths and correspondingly optimized matrices were introduced (Beavis et al., 1992). In less than 2 years, proteins >100 kDa were being routinely analyzed with subpicomole sensitivity (Hillenkamp et al., 1991) and molecular weights could be assigned with an accuracy of ~0.1%. Beavis and Chait (1990) demonstrated that for small proteins (<30 kDa) mass accuracies on the order of 0.01% to 0.02% could be achieved by coadding peptides or proteins of known mass to the sample to serve as internal mass reference standards (Beavis and Chait, 1990). This is 2 to 3 orders of magnitude more accurate than SDS-PAGE.

MALDI-MS has also been shown to be extremely useful for the analysis of peptides (Billeci and Stults, 1993). Unlike ESI, MALDI produces predominately singly charged molecular ions from peptides and proteins (although larger proteins can produce multiply charged ions as well; see Fig. 10.21.8), making the analysis of mixtures very much more straightforward. The ease of spectral interpretation combined with femtomole sensitivity and a tolerance for many of the common biological buffers makes MALDI an obvious choice for the analysis of unfractionated enzyme digests. Recent developments in the use of MALDI-MS for the analysis of peptides and proteins have been reviewed (Wang and Chait, 1994; Mann and Talbo, 1996).

The MALDI process can result in extensive fragmentation of the sample. Decomposition that occurs in the ion source, upstream from the field-free region of the flight tube, is referred to as "prompt fragmentation" and can be observed in a linear spectrum. Ions formed by prompt fragmentation are usually of low abun-

dance, and are formed when very high laser irradiance is used. For example, disulfide bonds have been demonstrated to undergo prompt fragmentation to yield the free peptides (Zhou et al., 1993; Patterson and Katta, 1994). Fragmentation that occurs after the source, in the flight tube, is referred to as metastable decay or post-source decay (Kaufmann et al., 1994). These fragment ions, which are often abundant, cannot be observed in a linear TOF instrument but can be observed with the use of a reflectron. As described below, they can be very useful for peptide sequencing.

The mechanism by which MALDI operates is still a matter of some debate (Dreisewerd et al., 1995). The one point upon which everyone agrees, however, is that the matrix is critical to the success of the experiment. In its simplest form, sample preparation for MALDI involves mixing the sample with a large (10⁴) molar excess of matrix and applying 0.5 to 2.0 μl of this solution to the target, where it air dries. Once in the mass spectrometer, the sample is bombarded with photons of UV light. The matrices, all compounds that are strongly UV-absorbing at the designated wavelength, serve three major functions in the experiment. First, the large excess of matrix separates the analyte molecules from one another, thereby reducing intramolecular interactions. Second, the matrix rapidly absorbs large amounts of energy from the incoming photons, resulting in an explosive breakdown of the matrix-analyte lattice. This explosion sends both matrix and analyte molecules into the gas phase. Third, the matrix is necessary for ionization of the analyte molecules. Transfer of protons from the matrix to the peptide and protein molecules is believed to occur via gas-phase reactions in the dense cloud that forms above the target during laser irradiance. The choice of matrix depends on the irradiance wavelength and the type of sample to be analyzed. A N₂ laser operating in the UV at 337 nm is the most typical laser in use on commercial MALDI instruments. Matrices that have been shown to be routinely useful at 337 nm are 3,5-dimethoxy-4-hydroxy-*trans*-cinnamic acid (sinapinic acid), 2,5-dihydroxybenzoic acid, and α-cyano-4-hydroxy-*trans*-cinnamic acid (Hillenkamp et al., 1991; Beavis et al., 1992). Lasers that operate in the infrared at 2.94 μm have also been shown to be useful in MALDI applications, particularly for the analysis of proteins directly from gels or blots (Strupat et al., 1994). MALDI has been demonstrated on magnetic-sector (Annan et al., 1992; Medzihradzky et al., 1996), ion-trap

Figure 10.21.2 Schematic diagrams of linear (**A**) and reflectron (**B**) MALDI-TOF mass spectrometers. The flight paths of precursor and fragment ions in each instrument are shown.

(Qin and Chait, 1995), and Fourier-transform ion-cyclotron resonance (Wu et al., 1995) mass spectrometers, but by far the most common application of MALDI has been on TOF instruments.

Typical TOF mass spectrometers can be classified into two broad categories, linear and reflector-type instruments. A simple linear instrument (Fig. 10.21.2, panel A) consists of an ion source, where the MALDI process takes place; a flight tube, where ions of different masses are separated from one another; and a detector. All of these components, with the exception of the laser, are housed in a high vacuum maintained at 10^{-5} to 10^{-8} Torr. After ions are formed by the MALDI process, they are accelerated out of the source under the influence of a strong electric field. All of the ions have essentially the same final kinetic energy upon entering the flight tube; thus, the arrival time of a given ion at the linear detector will vary depending on its mass. These relationships are mathematically expressed by classical equation for kinetic energy (here expressed in

two forms), where E is the kinetic energy of an ion, m is its mass, and v is its velocity:

$$E = \frac{1}{2} mv^2$$

$$v = (2E/m)^{0.5}$$

These equations tell us that because all ions of the same charge have been accelerated to the same energy, their velocities (and therefore, their flight times) will be inversely proportional to the square root of their molecular masses. Thus ions of greater mass will travel slower than lighter ones and will therefore reach the detector later.

Simple linear MALDI-TOF instruments are rather low-resolution mass spectrometers, operating at a resolving power of ~450 to 600 for peptides and 50 to 400 for proteins. For peptides, this means that one cannot measure the distribution of the various naturally occurring isotopes for each peptide, or separate peptides which differ in mass by only a few daltons. It also means that given a resolution (R) of 400, it will be difficult to resolve two proteins >30 kDa that differ only by an initiator Met residue

(e.g., see Fig. 10.21.8). These issues are considered in more detail in the discussion of Fundamentals of Mass Measurement Accuracy and Mass Resolution.

Several important considerations relating to the production of ions in the MALDI source limit the resolving power of linear TOF instruments. The most important of these is the initial kinetic energy spread of individual ion populations: as a result of this spread, ions of any particular mass will, after reaching final accelerating voltage, exhibit a spread in velocities. This means that various members of the same ion population will arrive at the detector at slightly different times, and that in turn gives rise to a broader peak for each ion than would be observed if there were no initial kinetic energy spread. Because the initial energy spread is mass dependent, peaks for higher-mass ions will be disproportionately broader than those for lower-mass ions. Resolution in a linear TOF instrument can be improved by increasing the length of the flight tube. This enhances the time dispersion of ions of different m/z ; unfortunately, it also increases the spread of arrival times for ions of the same m/z due to the initial kinetic energy distribution. This energy spread is typically reduced in magnitude by increasing the final accelerating voltage.

A more effective way to correct for energy distributions is through the use of an ion mirror, or reflectron. A reflectron TOF instrument (Fig. 10.21.2, panel B) corrects for the initial energy spread by acting as an energy-focusing device. The reflector works by slowing an ion down until it stops (the back of the reflector is at a voltage slightly higher than the source-accelerating voltage), turning it around, and then reaccelerating it back out to a second detector. Ions with an initial kinetic energy (and velocity) slightly lower than full accelerating potential will not penetrate the reflector as deeply, and will therefore turn around sooner, catching up to those ions with full kinetic energy. Ions with slightly greater energies (and thus higher velocities) will penetrate more deeply into the reflector, be turned around later, and have their flight times retarded, allowing the other ions to catch up. All of this causes ions of a given mass-to-charge ratio to be spatially focused into packets having flight times that are closer together, thus improving the resolution. This improvement in resolution is illustrated in Figure 10.21.3, which shows the molecular ion region of the linear (panel A) and reflector (panel B) spectra of a synthetic tyrosine phosphorylated peptide TRDIYETDpYYRK. The

isotopically resolved ion cluster in the reflector spectrum shows the contributions of all of the isotopes of C, H, N, O, and P that make up the elemental composition of this peptide. The improvement in resolution is most noticeable at masses of ~ 3000 and lower. For larger molecules, where the resolution is no longer sufficient to provide separation of the isotopes, the natural width of the unresolved isotopic envelope has a large influence on the apparent resolution of the instrument, as explained in the discussion of Fundamentals of Mass Measurement Accuracy and Mass Resolution. In addition to resolution, mass accuracy is also improved when spectra are recorded in the reflector mode (Vorm and Mann, 1994).

Tremendous improvement in the resolution achievable on MALDI-TOF instruments has recently been demonstrated using a focusing technique developed many years ago by Wiley and McLaren (1953). This method, referred to as time-lag focusing or “delayed extraction,” has been shown to provide a resolution of ~ 2000 to 4000 (full-width, half-maximum; or FWHM) in linear mode for peptides and resolution of ~ 3000 to 6000 FWHM in reflecting mode, on a 2-meter-long instrument (Brown and Lennon, 1995; King et al., 1995; Vestal et al., 1995; Whittal and Li, 1995). In a delayed extraction source, ions are created in a field-free region and allowed to spread out before an extraction voltage is applied and the ions are accelerated into the drift tube. The delayed extraction also probably limits the number of collisions the ions undergo on their way out of the source, thereby reducing additional peak broadening caused by metastable decomposition. Mass accuracy with the use of an internal reference standard may also be improved with the use of the delayed extraction source.

Assigning an accurate m/z value to an ion whose flight time has been measured requires that the mass spectrometer be properly calibrated. This is usually accomplished by measuring the flight times of two compounds whose molecular weights are accurately known. In practice, it is usually best to select two compounds with molecular weights that bracket the mass range over which samples are to be examined. For molecules $>10,000$ Da, the $[M+H]^+$ and the $[M+2H]^{2+}$ ions of a well-characterized protein standard work very well for calibration. Application of an internal calibration, where the calibrant peaks are present in the same spectrum as the sample, can provide accuracies of 0.01% to 0.05% (e.g., 0.1 to 0.5 Da at $m/z = 1000$). Internal calibration is sometimes experi-

Figure 10.21.3 Molecular ion region from MALDI spectra of the peptide TRDIYETDpYYRK (monoisotopic $M_r = 1701.8$) recorded in the (+) ion mode. Spectra were recorded in (A) the linear mode, where the average mass is measured at the centroid of the unresolved isotopic cluster, and (B) the reflector mode, where the monoisotopic mass is measured at the centroid of the first peak in the cluster. This peak contains the lightest isotopes of the elements present (see discussion of Fundamentals of Mass Measurement Accuracy and Mass Resolution).

mentally difficult owing to the need to adjust the amount of calibrant compounds added so that the calibrant peaks and the analyte peaks are simultaneously observed with reasonable intensity.

MALDI mass spectra may also be calibrated externally; this approach is experimentally simpler. In this method calibrant compounds are measured using the same matrix and laser irradiance as were used for sample analysis. A mass accuracy of ~ 0.1 to 0.2% (e.g., ± 1 to 2 Da at $m/z = 1000$) can be achieved in linear mode using external calibration (Karas et al., 1989). In reflector mode, one can routinely expect mass accuracies on the order of 0.01% to 0.05% using external calibrations. In reflector mode it is also possible to use either the $[M+H]^+$ ion or the $[2M+H]^+$ ion (the protonated gas-phase dimer) of the matrix as one of the two calibrant peaks, which means that only one calibrant compound needs to be added.

MALDI Post-Source Decay MS for Peptide Sequencing

A peptide molecular ion that is sufficiently stable to be transported out of the ion source

but insufficiently stable to survive the flight to the detector will decompose in the flight tube, giving rise to a series of fragment ions that are characteristic of the molecule's original structure. This process is referred to as metastable decay or post-source decay. It is believed that molecular ions acquire excess internal energy necessary for fragmentation via multiple collisions with matrix ions in the source (Kaufmann et al., 1994). When a precursor ion decomposes in the flight tube, all of the fragment ions will have the same velocity as the precursor, but they will have only a fraction of its kinetic energy. This means that the precursor and metastable fragments will all strike the linear detector at the same time and will be detected at the same apparent mass. Thus metastable or post-source-decay fragment ions are never observed in a linear spectrum.

In contrast, a reflector TOF is capable of discriminating fragment ions by flight-time dispersion. Although all ions will have essentially the same velocity, the kinetic energy of a post-source-decay fragment ion will be determined by the ratio of its mass to the mass of the precursor. Thus the fragments, which have less

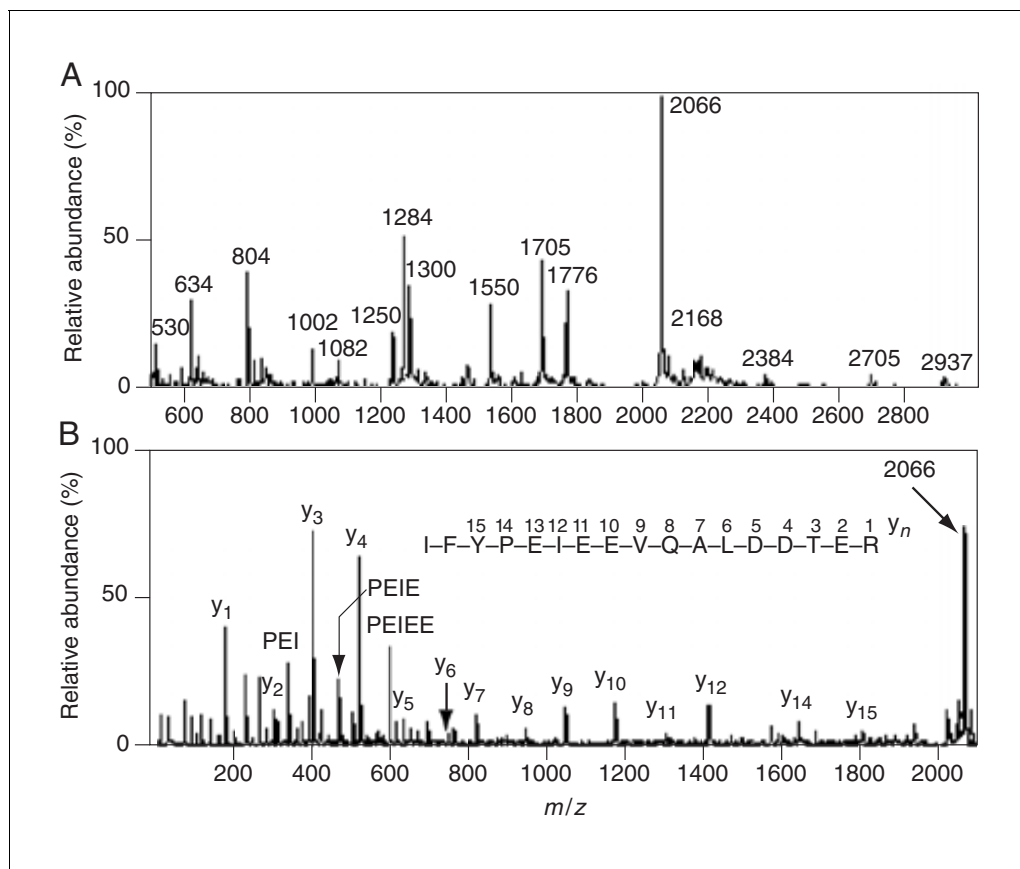

Figure 10.21.4 MALDI-MS analysis of a tryptic digest of an 18-kDa protein (Ladner et al., 1996). A total of 30 pmol of protein was separated on an SDS-PAGE gel, the band of interest excised from the gel, and the protein digested in situ with trypsin; then $\frac{1}{20}$ of the sample was analyzed by MALDI-MS. **(A)** MALDI mass spectrum of the tryptic peptides recorded in the linear mode; **(B)** MALDI-PSD spectrum of the $[M+H]^+$ ion at m/z 2066. The peak was selected using an ion gate ($R = 100$). A nearly complete series of y_n ions (see Fig. 10.21.1) makes it possible to deduce the sequence of residues 3 to 17.

kinetic energy than the precursor, will not penetrate as deeply into the ion mirror, and so will have their flight times decreased relative to the precursor. The fragments are therefore detected at a lower mass. By successively lowering the reflector voltage, thereby bringing lower- and lower-mass fragment ions into focus, a complete post-source decay fragment ion spectrum can be acquired in segments. The individual segments are calibrated and assembled afterward automatically by the data system.

The energy-focusing features of reflectron-type mass spectrometers make it possible to use post-source decay for peptide sequencing (Kaufmann et al., 1994). Post-source decay spectra resemble low-energy collision-induced dissociation (CID) spectra, similar to those commonly recorded on triple-quadrupole mass spectrometers (Hunt et al., 1986). The spectra contain mainly b_n and y_n ions, often with very abundant internal fragments and immonium ions (see Fig. 10.21.1 and Table 10.21.2). The

use of an ion gate makes it possible to perform a low-resolution ($R = 100$) selection of a precursor ion of interest from an unfractionated mixture, such as a protein digest. This approach is very powerful for providing internal sequence information on in situ-digested proteins that have been purified by SDS-PAGE (see Fig. 10.21.4 for an example).

ESI-MS

In electrospray ionization (ESI)-MS, ions are formed from peptides and proteins by spraying a dilute solution of these analytes at atmospheric pressure from the tip of a fine metal capillary (Fig. 10.21.5). The spray process, often assisted by pneumatic nebulization, creates a fine mist of droplets (Fenn et al., 1990; Kebarle and Tang, 1993). The droplets are formed in a very high electric field created by applying a high voltage (~ 4 kV) to either the spray tip (Fig. 10.21.5) or the counter electrode; in this process, the droplets become highly

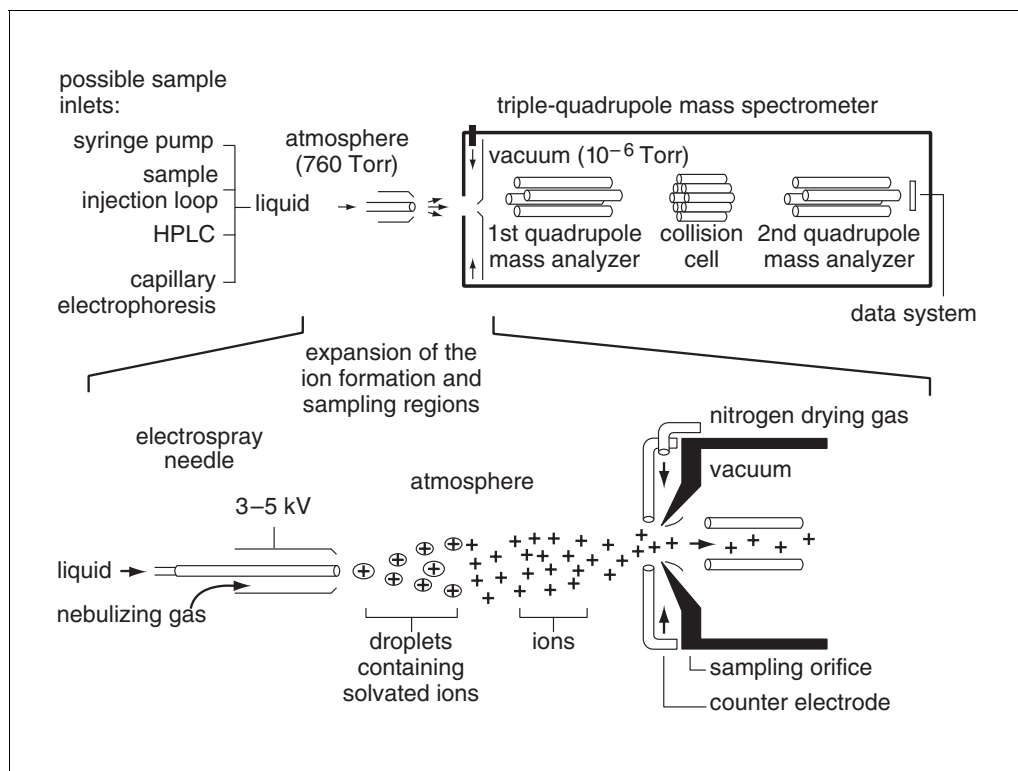

Figure 10.21.5 Schematic diagram of a triple-quadrupole mass spectrometer (top) and the electrospray interface (bottom).

charged. Solvent evaporation is rapid from these small droplets. As the droplets evaporate, the peptide and protein molecules in the droplets pick up one, two, or more protons from the solvent to form singly or, more frequently, multiply charged ions (e.g., $[M+H]^+$, $[M+2H]^{2+}$, etc.). The number of charges acquired by a molecule is roughly equivalent to the number of possible sites of proton attachment. As the droplets continue to shrink, the charge density on the surface of each one increases to the point where charge repulsion overcomes the forces holding together the droplet and the solvated ions contained within it. Ions are then “emitted” or “evaporated” from the droplet surface. The ions are sampled into the high-vacuum region of the mass spectrometer for mass analysis and detection, most often using a quadrupole (or triple-quadrupole) mass analyzer (Fig. 10.21.5). Usually little or no fragmentation is observed in the normal ESI mass spectra of peptides. The typical solvent for peptides and proteins is a mixture of water, an organic modifier such as CH_3CN , and up to a few percent by volume of acetic, trifluoroacetic, or another volatile acid (the latter included to enhance ionization of sample constituents). Because the ions are produced at atmospheric pressure from flowing liquid

streams, ESI is ideally suited for on-line coupling to high-performance liquid chromatography, making it possible to analyze mixtures of peptides and proteins rapidly (see below).

As mentioned above, a key feature of the electrospray process is the formation of multiply charged molecular species from analytes that contain more than one possible site of proton attachment (Fenn et al., 1990; Smith et al., 1991). Proteins usually exhibit a characteristic series of multiply charged ions (e.g., see Fig. 10.21.8). As one proton (i.e., one charge) is typically attached for each 1000 Da of molecular mass, the ion series for a protein, even a large protein, will fall in the m/z range of 800 to 3000. This makes it possible for simple instruments like quadrupole mass spectrometers to be used for mass analysis of ions produced by ESI. The molecular mass of the protein can easily be calculated using the observed masses of any two adjacent ions in the series (Covey et al., 1988; Mann et al., 1989; Reinhold and Reinhold, 1992). Normally these calculations are performed automatically by the data system. Because each multiply charged peak provides an independent measure of the molecular mass of the protein, an ion series from a single experiment provides a measure of the mass measurement precision. Most data sys-

Figure 10.21.6 Electrospray analysis of an HPLC fraction from the tryptic digest of a 17-kDa phosphoprotein. The protein was purified by SDS-PAGE, electroblotted onto PVDF membrane, eluted, digested with trypsin, and the peptides analyzed by on-line LC-ESI-MS using a phosphopeptide-selective scanning method (Huddleston et al., 1993b). The column flow was split after UV detection, with 10% going to the mass spectrometer and 90% to a fraction collector. **(A)** Nanoelectrospray mass spectrum of a putative phosphopeptide-containing fraction. Peaks labeled (+Na) and (+K) correspond to $[M + H + Na]^{2+}$ and $[M + H + K]^{2+}$, respectively. **(B)** Collision-induced decomposition (CID) spectrum of the doubly charged ion ($[M+2H]^{2+}$) at $m/z = 673.8$. This spectrum confirms the sequence of the peptide and identifies the site of phosphorylation as Tyr⁵.

tems also provide algorithms for transforming the mass-to-charge axis into a molecular mass axis for simplifying interpretation and presentation of the data. Proteins with molecular masses of up to 150,000 Da have been successfully analyzed by ESI using commercially available quadrupole instrumentation. Mass assignment accuracies of 0.01% are routine (see Table 10.21.1 and discussion of Fundamentals of Mass Measurement Accuracy and Mass Resolution). ESI has also been successfully interfaced with ion-trap mass spectrometers (Korner et al., 1996), Fourier-transform ion-cyclotron resonance mass spectrometers (Winger et al., 1993; O'Conner et al., 1995; Wu et al., 1995; Smith et al., 1996), and TOF mass spectrometers (Mirgorodskaya et al., 1994; Verentchikov et al., 1994).

In the case of peptides, the maximum number of charges observed often correlates reasonably well with the number of amino acid side chains that can readily accept a proton at the low pH of the analyte stream (i.e., Arg, Lys, and His, plus the free amino terminus). In the case of tryptic peptides, at least two charge sites are normally present, and tryptic peptides with molecular weights of 800 to 3000 typically exhibit a major, if not dominant, $[M+2H]^{2+}$ ion. For example, the ESI mass spectrum of an HPLC fraction from a tryptic digest of a phosphoprotein shows a simple mixture of peptides, in which doubly charged forms of the major peptide predominate (Fig. 10.21.6). In this spectrum, in addition to proton attachment, doubly charged ions due to Na and K adduction are also abundant. In general, the smaller the pep-

tion, the more likely it is that the singly charged $[M+H]^+$ ion will also be observed. As the size of the peptide increases, triply and higher-charged states of the peptide will increase in abundance in the spectra while the abundance of ions with lower charge states will decrease (Fig. 10.21.7).

Electrospray mass spectra are keen reminders that mass spectrometers measure the ratio of mass to charge (m/z) and not molecular mass directly. The peak at $m/z = 1346.6$ in Figure 10.21.6 (panel A) is the monoisotopic $[M+H]^+$ of a peptide of molecular weight 1345.6 (see section on Fundamentals of Mass Measurement Accuracy and Mass Resolution for a discussion of monoisotopic mass). Evidence that this ion carries a single charge (1^+) as opposed to a higher number of charges is obtained from the spacing of the isotope peaks, which are one m/z unit apart. The doubly charged form of this same peptide is observed on the m/z scale at $[1345.6 + 2]/2 = 673.8$. The isotope peaks in the $[M+2H]^{2+}$ isotope cluster are spaced 0.5 m/z units apart, indicating that these ions are doubly charged. Quadrupole mass analyzers can routinely achieve resolution sufficient to distinguish singly from doubly charged ions up to $m/z = 3000$ (if sufficient sample is available and the instrument is scanned slowly). This capability is particularly relevant to tryptic digests of proteins where, as noted above, the doubly charged ion may be the only ion observed for a given peptide. In the absence of the peak spacing information, the analyst could have difficulty determining if such an ion is singly or doubly charged. For ions with three or more charges, a charge series (e.g., 2^+ and 3^+) is usually present that permits the analyst to determine the charge state and mass of any given ion in the spectrum without the need to determine the isotopic peak spacing.

LC-ESI-MS

Electrospray ionization has made on-line liquid chromatography (LC)-MS a practical and robust method for sample introduction because gas-phase ions, as opposed to liquid droplets, are what is mainly being sampled by the instrument. The ideal milieu for presenting a sample to any mass spectrometer, regardless of the ionization mechanism, is in mixtures of highly pure water and volatile organic solvents containing low levels of volatile acid or base. Fortunately, such mixtures (e.g., water, acetonitrile, and trifluoroacetic acid at 0.05% to 0.1% by volume) are also those that provide optimal separation of peptides and proteins by reversed-

phase liquid chromatography. From a practical standpoint, LC-MS reduces or eliminates the need to preparatively fractionate complex mixtures prior to MS, thereby saving valuable instrument time and preventing possible sample losses. LC-MS data may also be searched retrospectively for components present at very minor levels that may not have been considered worthy of collection based on a weak UV response.

In an LC-MS experiment, mass spectra are recorded continuously as the components elute from the HPLC column. If the mass spectrometer is made to scan once every 4 sec, the LC-MS data file will contain ~900 mass spectra. To identify regions of data that are likely to contain useful spectra, the mass spectrometer's data system produces a plot of the total number of ions detected during each mass spectrum scan versus time (the scan number). This plot, which is called a mass chromatogram or a total ion current (TIC) trace, looks very much like the UV chromatogram (Fig. 10.21.7). If it is of interest to know whether a particular peptide is present in the digest and where it elutes, the analyst simply requests the data system to display a selected ion-current trace for the specific masses of the most likely charge states (e.g., 1^+ to 4^+). Figure 10.21.7 illustrates the type of data typically acquired during the LC-ESI-MS analysis of a protein digest. In this example, the protein is heterogeneously glycosylated at a single site, and the multiplicity of peaks evident is due to differing carbohydrates attached to a single tryptic peptide (Fig. 10.21.7, panel C).

Because an ESI mass spectrometer behaves as a concentration-dependent detector, much like a UV detector, only a few percent of the total column effluent (~1 to 5 $\mu\text{l}/\text{min}$) needs to be directed into the mass spectrometer. The remainder can be diverted, via a flow splitter, through an in-line UV detector to a fraction collector. This arrangement makes it possible to perform straightforward correlation of the UV trace with the total ion current trace and then analyze individual fractions further by MS/MS (see discussion of ESI MS/MS for Peptide Sequencing) or some other method. The UV response is also useful for estimating the amount of a peptide that has been injected on the column. This is generally not possible to do by MS without appropriate internal standards (see section entitled Is MS Data Quantitative?). LC-ESI-MS has become a key analytical method for the analysis of natural and recombinant proteins, and data from these experiments is now often included in the regulatory

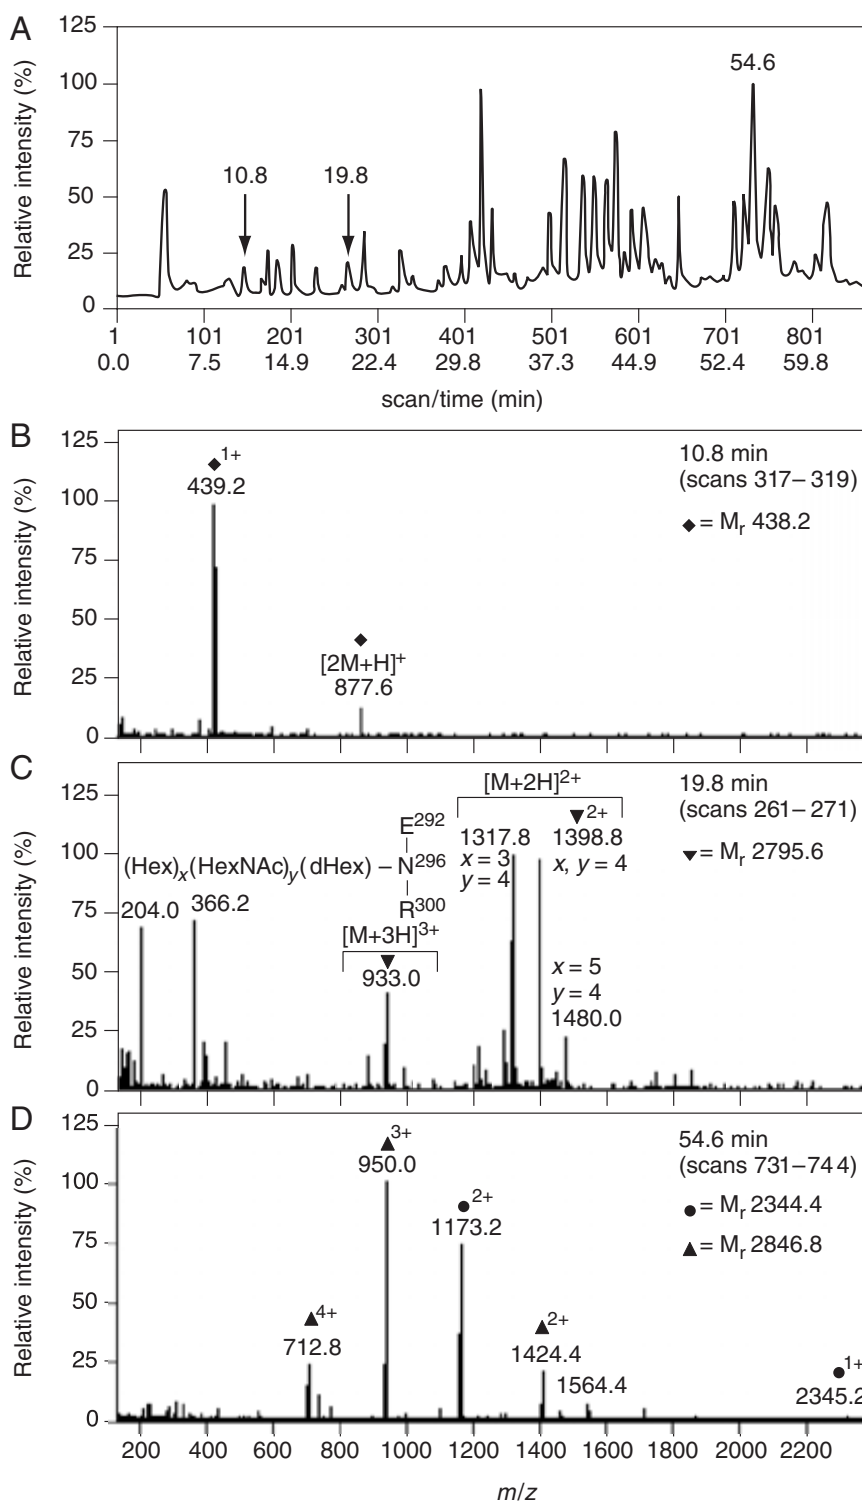

Figure 10.21.7 On-line LC-ESI-MS analysis of a tryptic digest of reduced and alkylated heavy chain (51 kDa) from a recombinant monoclonal antibody. **(A)** Total ion current trace showing the distribution of tryptic peptides. **(B)** ESI spectrum of the peak at 10.8 min showing a small singly charged peptide and its gas-phase dimer. **(C)** ESI spectrum of the peak at 19.8 min corresponding to a tryptic glycopeptide with heterogenous carbohydrate. At least five different carbohydrate structures are indicated. Abundant low- m/z ions at $m/z = 204$ and $m/z = 366$ are characteristic fragment ions produced from the carbohydrate (Roberts et al., 1995). **(D)** ESI spectrum of the peak at 54.6 min showing two large tryptic peptides, each represented by several different charge states.

filings for new biopharmaceutical products (Carr et al., 1989; Palczewski et al., 1994; Stults et al., 1994; Watts et al., 1994; Resing et al., 1995; Roberts et al., 1995; Rush et al., 1995; Schindler et al., 1995; Hemling et al., 1996).

ESI MS/MS for Peptide Sequencing

The principles of MS/MS using triple-quadrupole mass spectrometers have been reviewed (Yost and Boyd, 1990). Briefly, the first quadrupole (Fig. 10.21.5) acts as a mass filter to select specifically the $[M+nH]^{n+}$ ion (where n is typically 1, 2, 3, or 4) of a peptide of interest and isolate it from other ions produced in the source. The selected precursor ion is then fragmented with a neutral gas such as nitrogen or argon in a quadrupole collision cell. This process is known as collision-induced decomposition. The fragment or product ions produced are then transmitted into the quadrupole second mass analyzer, which is being used as a scanning mass analyzer. The product ions are separated based on m/z and detected. The result is a product-ion mass spectrum of the selected precursor that is free of interferences from other components present in the mixture. An example of this process is shown in Figure 10.21.6. The fragmentation of this peptide reveals its sequence and the location of the phosphorylated residue.

Fragmentation can also be induced in the ESI source by increasing the energetics of the ion sampling process. This is done by adjusting the lens potentials in the high-pressure region upstream from the first quadrupole mass filter. Ions with increased kinetic energy undergo decomposition via collisions with residual gas molecules (Katta et al., 1991). Structurally useful fragmentation can thus be obtained on a single-quadrupole instrument, with the caveat that because this method has no ability to preferentially select precursor ions, it requires a highly purified sample. Recently strategies have been developed that take advantage of this ability of the ESI interface to generate fragment ions prior to mass analysis. Selective detection of glycosylated peptides (Carr et al., 1993; Huddleston et al., 1993a), phosphorylated peptides (Huddleston et al., 1993b; Till et al., 1994), and sulfated peptides (Bean et al., 1995) during on-line LC-ESI-MS analysis of protein digests can be accomplished by monitoring the total ion current trace for highly diagnostic low- m/z fragment ions produced in the ESI interface. These procedures are equally applicable to the detection of these modifications in unseparated mixtures.

IS MS DATA QUANTITATIVE?

A question that frequently arises in the analysis of peptide or protein mixtures is whether the relative peak heights (or areas) are quantitatively representative of the relative solution concentrations of the sample components. Unfortunately, the answer to this question is no, unless appropriate internal reference standards are used. Due to differing ionization and desorption efficiencies, the absolute yields of different ions from one peptide in a mass spectrometer can vary by perhaps as much as 2 orders of magnitude, depending on the sequence, composition, and size of the peptides (Dunayevskiy et al., 1995; Jespersion et al., 1995; Cohen and Chait, 1996). Furthermore, strongly ionizing components can frequently suppress the ionization of more weakly ionizing components present in the same sample or chromatographic fraction. In MALDI, the matrix itself can strongly influence the detectability of specific sample constituents. Quantitation by mass spectrometry requires that the response of a specific sample component be determined relative to that of a reference compound added to the sample and analyzed under identical conditions. In certain cases, semi-quantitative estimates of relative amounts of components may be made if the components are of nearly identical structure and their chemical differences do not significantly affect the overall charge or hydrophobic/hydrophilic character of the molecules. For example, the relative ratios of the variants of β -casein observed in the ESI mass spectrum (Fig. 10.21.8) are probably a good reflection of the relative solution concentrations of these variants, as they differ from one another by only one or two amino acid substitutions out of more than 200 amino acids. The smaller the molecule, the more likely it is that such estimates will be in error.

SAMPLE PREPARATION

The ideal method for preparing samples for any type of MS analysis is reversed-phase high-performance liquid chromatography (RP-HPLC). If purification by RP-HPLC is not an option because of known problems with sample loss, then the cleanup protocol employed should produce a sample composition that resembles as closely as possible that of a sample which has been purified by RP-HPLC. That is, the sample should contain the least amount possible of buffers, salts, detergents, and anything else besides water, organic modifier, and volatile acid or base.

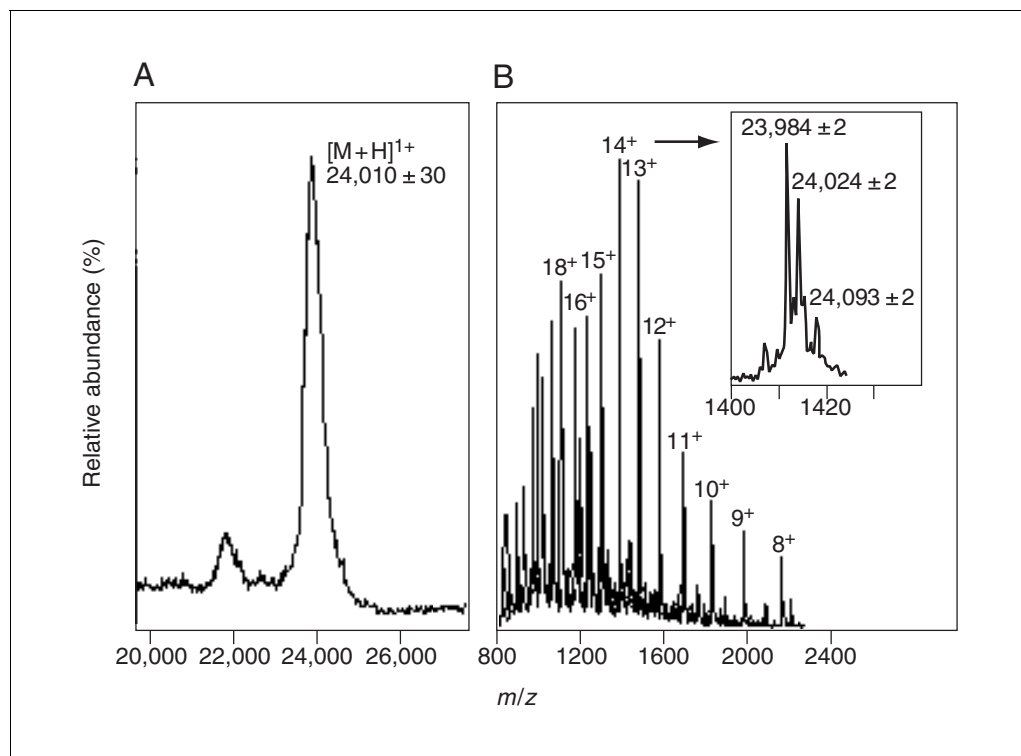

Figure 10.21.8 Molecular weight determination of β -casein, a 24-kDa phosphoprotein with known sequence heterogeneity. **(A)** Linear MALDI-TOF spectrum. Molecular weight was determined from the centroid of the smoothed peak using an external calibration. **(B)** ESI spectrum. The inset, an expansion of the region around the 14^+ charge state, reveals the presence of at least three variants. The molecular weights shown are the averages of determinations made from ten individual charge states.

The quality of the data obtained using ESI-MS is very dependent on the type and concentration of excipients present in the sample. If buffers are necessary for protein solubility or enzymatic digestion, it is best to use a volatile buffer such as ammonium bicarbonate or ammonium acetate at a concentration of ≤ 30 mM. In general it is best to avoid using any ionic detergents (surfactants), even though it is possible to obtain spectra for some proteins when these are included as long as the surfactant concentration is kept $< 0.01\%$. ESI tolerates nonionic detergents better. Analytically useful data may be obtained for sample solutions containing certain nonionic detergents at concentrations between 0.01% and 0.1% (Ogorzalek Loo et al., 1994).

Samples containing unacceptable amounts of buffers, salts, and detergents need to be purified prior to ESI-MS analysis. If the sample can be eluted from an RP column, some type of on-line procedure is both rapid and efficient. For water-soluble salts and buffers, a short, small-i.d. RP cartridge installed in place of the sample loop on a HPLC injector serves to both concentrate and purify samples (Stoney and

Nugent, 1995). By placing the trapping cartridge in the injector loop, it is possible to wash the buffers and salts into waste rather than into the mass spectrometer. After loading the aqueous sample onto the trap (sample volume is no longer important except for very hydrophilic sample components), the trap is washed with 1% to 5% organic solvent and the salts and buffers are diverted to the waste line. The trap column is then put in-line with the solvent delivery pump by switching the valve, and the sample is eluted into the mass spectrometer with the appropriate solvent. This is also a convenient way to analyze dilute solutions, as the trap serves to preconcentrate the sample.

The same approach can be used to purify samples containing anionic and nonionic detergents (Stoney and Nugent, 1995). However, on-line use of detergent columns require that this step be done in tandem with an RP column, because either the sample will have to be eluted with a buffer and thus will need to be desalted prior to introduction into the mass spectrometer, or it will not be retained on the column and will need to be trapped on an RP column. An alternative approach for removing SDS from

samples is to load the sample, dissolved in a high concentration of organic solvent, onto a polyhydroxyethyl aspartamide column (Jeno et al., 1993). Under these conditions, peptides and proteins are retained while the SDS passes through with the solvent front. The sample is then eluted using a gradient of decreasing organic strength.

All of the purification strategies described above can, of course, also be performed off-line. In either case, the use of small-bore HPLC columns and a low-flow HPLC system will provide better results with sample amounts in the picomole range or below. Because the ESI mass spectrometer acts as a concentration-dependent detector, the highest sensitivity will be achieved using the smallest-i.d. columns. For off-line cleanup, the use of the lower flow rates required for small-bore columns means that samples are collected in smaller volumes. This can be important for small amounts of sample, where losses associated with reducing solvent volumes prior to the next step of analysis often are great. The authors have found that 0.5- to 1-mm-i.d. columns provide a practical compromise between on-line sensitivity and easy collection of fractions using a post-column flow splitter. A number of groups have developed sample purification and fraction collection methods that use packed fused silica capillary columns and solvent flow rates of 0.1 to 5.0 $\mu\text{l}/\text{min}$ (Zhang et al., 1995; Gulden et al., 1996) or micropipets filled with packing material (Houthaeve, et al., 1995).

Other approaches to protein purification for MS include ultrafiltration (APPENDIX 3C), TCA precipitation, size exclusion chromatography (UNIT 10.14), and microdialysis (APPENDIX 3C). Among these alternatives, the authors find the easiest and most reliable methods for desalting samples or effecting a buffer change to be ultrafiltration using membranes of varying molecular weight cutoff (MWCO), and small-column (1-mm-i.d.) size-exclusion chromatography. Final volumes of 25 μl can be achieved using the ultrafiltration devices.

If the protein is being purified for subsequent proteolytic digestion with the ultimate goal being mass spectrometry-based peptide mapping, a suitable approach is SDS-PAGE followed by *in situ* enzymatic digestion (Stone and Williams, 1995; Williams and Stone, 1995; Shevchenko et al., 1996; Wilm et al., 1996). The broad applicability and high resolving power of SDS-PAGE applied to protein mixtures makes this approach very useful for achieving difficult separations or for working

with proteins that have poor solubility characteristics. Electrophoresing as little as a few micrograms of individual protein on an analytical gel will usually provide an informative peptide map. Following SDS-PAGE, the protein can also be blotted onto a membrane and enzymatically digested (Hess et al., 1993; Fernandez and Mische, 1995; Patterson, 1995). Recovery of peptides from individual proteins appears to be similar regardless of whether they were produced from an *in-gel* digest or digestion off a membrane. If the peptide map is to be recorded using MALDI, the peptides can be sampled either directly from the digest or from the peptide extract. If the map is to be recorded using ES, then on-line LC-MS is usually the best approach.

Although MALDI is very much more tolerant of the presence of salts, buffers, and some detergents, it too generally benefits from having the sample in the purest form possible, especially when dealing with subpicomole amounts of proteins or low femtomole amounts of peptides. All of the methods discussed above work equally well for preparing samples for MALDI-MS analysis.

FUNDAMENTALS OF MASS MEASUREMENT ACCURACY AND MASS RESOLUTION

Monoisotopic Mass and Average Mass

Most of the elements that comprise typical biological molecules have more than one naturally occurring isotope, each with a unique mass and natural abundance. For example, carbon has two principle isotopes, ^{12}C and ^{13}C (see Table 10.21.3). The lighter, more abundant isotope of carbon has, by definition, a mass of 12.000000 and a natural abundance of 98.9%, while the heavier isotope has a mass of 13.003355 and a natural abundance of 1.1%. In a mass spectrometer one measures a large, statistical sampling of the molecules present and, therefore, observes all of the isotopes for each element present. The **monoisotopic mass** of a molecule is the sum of the accurate masses (including the decimal component, referred to as the mass defect) for the most abundant isotope of each element present (Yergey et al., 1983). As the number of atoms of any given element increases, the percentage of the population of molecules having one or more atoms of a heavier isotope of this element also increases. The most significant contributor to the isotopic peak pattern for biomolecules is the ^{13}C isotope of carbon. For peptides with mo-

^bLide (1995).

lecular masses <2000 Da, the first peak in the resolved isotopic cluster corresponding to the all-¹²C species will be the most abundant (Fig. 10.21.9, panel A). However, for peptides with molecular masses ≥2500 Da, the first peak in the isotopic cluster will no longer be the most abundant (Fig. 10.21.9, panel B). In this example, the species containing one ¹³C atom is now the most abundant.

For proteins, the heavy isotopes of nitrogen, sulfur, and oxygen (in addition to carbon) make significant contributions to the mass, and, as a result, the monoisotopic peak in the molecular ion cluster appears to vanish (Fig. 10.21.9, panels C and D). In this case a different definition for the mass of the molecule must be used. Whenever it is not possible to observe the all-¹²C peak for a molecular ion, the average

mass should be used. The **average mass** of a molecule is the sum of the chemical average masses of the elements present (Fig. 10.21.9, peaks labeled A). The chemical average mass of an element is the sum of the abundance-weighted masses of all of its stable isotopes (Yergey et al., 1983). For example, the isotope-weighted average mass of carbon is 12.0111, of hydrogen is 1.0079, of nitrogen is 14.0067, of oxygen is 15.9994, of sulfur is 32.0666, and of phosphorus is 30.9738. These masses are known with less precision than the monoisotopic masses of the elements because of variations in the natural abundances of the isotopes. The theoretical appearance of a molecule's isotope envelope may be precisely modeled by solving a polynomial expression that calculates the abundance-weighted sum of the isotopes of

Figure 10.21.9 Effect of resolution (10% valley definition) on the appearance and relative peak intensity of the isotopic envelopes for representative peptides and proteins in four different mass ranges. Abbreviations: *R*, resolution; *M*, monoisotopic mass (Mono.); *A*, average mass (Ave.); *P*, peak top. **(A)** $C_{60}H_{86}N_{16}O_{15}$: $M = 1270.7$, $A = 1271.5$, $P = 1270.8$. **(B)** $C_{115}H_{161}N_{31}N_{35}$: $M = 2536.2$, $A = 2537.7$. **(C)** $C_{254}H_{377}N_{65}O_{75}S_6$: $M = 5729.6$, $A = 5733.6$. **(D)** $C_{1080}H_{1697}N_{268}O_{325}P_5S_6$: $M = 23968.2$, $A = 23983.3$.

each element to the molecular ion cluster (Yergey, 1983). Nearly all modern mass spectrometer data systems come with programs that perform these calculations and can simulate the appearance of the resulting isotope pattern at different instrumental resolving powers.

Resolution

Whether or not one observes the individual isotopes that make up the molecular ion cluster for a given compound depends on the mass

resolution of the instrument being used. The resolution of the mass analyzer is a measure of its ability to separate signals of adjacent molecular mass. Mass resolution is often expressed as the ratio $m/\Delta m$, where m and $m + \Delta m$ are the masses (in atomic mass units or Da) of two adjacent peaks of approximately equal intensity in the mass spectrum (Fig. 10.21.10). There are presently two definitions of resolution in widespread use. In the “10% valley” definition, the two overlapping, adjacent peaks

Figure 10.21.10 Schematic representation of the two common definitions of resolution used in mass spectrometry—10% valley and full-width, half-maximum (FWHM).

each contribute 5% to the resulting 10% valley between them (Fig. 10.21.10). The resolution of the mass analyzer may also be determined using a single peak by measuring the peak width (in m/z) at the 5% level and dividing this number into the m/z of the peak. The 10% valley definition is most frequently used for molecules with masses <5000 Da, where it is possible on certain analyzers to resolve the isotope peaks. For *unresolved* isotopic clusters the “full-width, half-maximum” (FWHM) definition is used. By this definition, the resolution is equal to the mass of the peak (in m/z) divided by the width (in m/z) of the isotopic envelope measured at the half-height of the peak (Fig. 10.21.10). An unfortunate consequence of the use of this definition is that, given an FWHM resolving value, it is more difficult to visualize what the separation between two peaks of a given masses will be. For example, a resolution of 1000 by the FWHM definition means that a peak at mass 1001 will be unresolved from the peak at mass 1000. Creation of a detectable separation between these two peaks would require a FWHM resolution >1200. A useful rule of thumb is that the value for the resolution determined using the FWHM definition is approximately twice that obtained using the 10% valley definition. For example, a resolution of

1000 using the 10% valley definition is approximately equivalent to a resolution of 2000 using the FWHM definition (i.e., the measured degree of separation of the peaks in Da/ z is identical).

Mass Accuracy

Getting as accurate a molecular weight as possible is, of course, a central goal of any MS experiment. Here mass accuracy is taken to mean the difference in mass between the experimentally measured value and the theoretical value. By definition, the mass measurement accuracy can be directly determined only for compounds of known elemental composition and, therefore, known molecular mass. For unknown samples, the accuracy of the mass determination is approximated by measuring the mass of a peptide or protein of known elemental composition and similar mass to the unknown. It is important that these measurements be made under experimental conditions as close as possible to those used for analysis of the unknown. How useful this estimate of the mass measurement accuracy is depends on how well the instrument has been calibrated and on the reproducibility of the measurement. The reproducibility, or precision, of the measurement is best evaluated by making replicate measure-

ments of the sample. However, in cases where the amount of sample is limited or the data is too noisy, a reasonable approach is to estimate the precision from replicate measurements of a known peak of mass and intensity similar to the unknown. It cannot be overemphasized that the mass spectrometer's performance with respect to mass measurement accuracy and precision must be regularly evaluated using well-characterized standards covering the mass range of interest in order to provide confidence in the measurements of unknowns being made. It is desirable to achieve a mass measurement precision of ± 0.5 Da or less for peptides and ± 1 Da for proteins. In practice, it is relatively easy to achieve the stated value for peptides but more difficult for proteins (Table 10.21.1). Whether the monoisotopic mass or the average mass should be used when measuring and reporting molecular weights will depend on the mass of the substance and the resolving power of the mass spectrometer (see discussion of Interplay Between Resolution and Molecular Weight).

The accuracy of the mass measurement may be stated in several different ways: as either an absolute mass error or a percentage of the measured mass (e.g., molecular mass = 1000 ± 0.1 Da or $\pm 0.01\%$), or as parts per million (e.g., molecular mass = 1000 ± 100 ppm). As the mass being considered increases, the absolute mass error corresponding to the percent or ppm error will also increase proportionally (e.g., 0.01% or 100 ppm = 0.1 Da at $m/z = 1000$, 0.5 Da at $m/z = 5000$, or 5 Da at $m/z = 50,000$). It is important not to confuse mass accuracy with the term "accurate mass"; the latter is reserved for mass measurements accurate to ≤ 10 ppm.

Interplay Between Resolution and Molecular Weight

In the mass range up to ~ 3000 Da it is recommended that, if possible, a resolution sufficient to partially resolve the isotope cluster be used to facilitate mass assignment of the monoisotopic peak (Ingendoh et al., 1994). Resolution sufficient to separate single-mass-unit differences is also important in order to detect the presence of modifications such as deamidation of Asn to Asp and to make it possible to directly determine the charge state of an ESI ion by measuring the isotope peak spacing. For poorly resolved or unresolved isotope clusters, the mass accuracy can be dramatically affected by how the data is treated by the instrument's data system. It is important to be aware of whether the data system is assigning

masses to the centroid of the peak or to the peak top. In general, the centroid and the peak top mass will not be the same in this mass range because the isotopic distribution comprising the unresolved envelope of peaks is asymmetric in shape. Below mass ~ 3000 it is sometimes difficult to accurately determine the centroid, and therefore the average mass, of an unresolved isotope cluster. The reason for this difficulty is that the bottom of the cluster, which must be included to get an accurate determination of the centroid for peaks in this mass range, is often distorted or poorly defined due to sample background (or, in MALDI, matrix) noise and/or poor ion statistics. These factors can easily contribute errors of ≥ 1 Da to the mass determination for compounds in the mass range of 1000 to 3000 Da. Furthermore, it should be noted that the peak top mass, which is the most easily determined value, corresponds to neither the monoisotopic mass or the average mass in this mass range. At ~ 1200 and below, the mass at the peak top of the unresolved envelope will be closer to the monoisotopic mass, whereas at ~ 3000 Da and above, the peak top will be closer to the average mass. For these reasons the use of resolved isotopes in this mass range is clearly preferable.

Determining the monoisotopic mass of a protein is difficult or impossible due to the insignificant contribution that the monoisotopic peak makes to the isotopic envelope (Fig. 10.21.10, panel D). Furthermore, quadrupole and TOF mass analyzers cannot provide the resolving power necessary to separate the isotope peaks for molecules with masses in excess of ~ 8000 Da. Fortunately, at masses above $\sim 10,000$, the unresolved peak profiles are quite symmetrical and the mass at the peak top is nearly identical to the chemical average mass of the protein. For proteins, errors in measuring the centroid can be caused by the presence of unresolved adducts along with the protonated molecular ion (with, for example, Na^+ , K^+ , or photochemical adducts of MALDI matrices) or of other proteins of similar but not identical mass that are not resolved. The relative abundance of any of these adducts is unpredictable, and will shift the apparent centroid of the unresolved cluster to higher mass in an unpredictable fashion. In these cases, it will be impossible to obtain an accurate mass assignment unless the instrument resolving power can be increased or the contributing adduct ions can be removed by more stringent cleanup of the sample (Ingendoh et al., 1994; Zubarev et al., 1995).

Thus it is still important even at higher mass to have a reasonable amount of resolving power. Resolution should be sufficient to enable detection of common protein variants that may be present in the sample. For example, β -casein exists as a family of isoforms differing by the substitution of one or more amino acids. The MALDI and ESI mass spectra of β -casein are compared in Figure 10.21.8. Detection of one of these variants, which differs by 40 Da in 24,000 Da, requires a resolution of ~ 1200 FWHM ($24,000/40_{10\% \text{ valley def.}} \times 2$), which is easily achievable by ESI-MS on quadrupole mass analyzers. The resolution in MALDI-MS with a TOF analyzer is typically <1000 at this mass, and is insufficient to detect such small modifications. The minimum desirable resolution can be estimated from the natural width of the molecular ion envelope obtained from the computer programs mentioned above. For example, the envelope of isotopes for a 24-kDa protein has a width of ~ 10 Da at the half-height of the peak (Fig. 10.21.9, panel D). This corresponds to an apparent resolution of 2400 ($24,000/10$). Having an *instrumental* resolution higher than 2400 but less than $\sim 20,000$ (see Fig. 10.21.9) will not improve the apparent resolution because the minimum width of the unresolved protein molecular ion cluster is determined by the weighted average of the natural abundance of the isotopes present. It should be clearly stated, however, that having a higher resolution than is theoretically required is not detrimental (as long as it does not result in a decrease in sensitivity), and it may have some beneficial effect on the ability to precisely define the peak top and therefore the average mass.

OUTLOOK

Mass spectrometry and its application to biological problems are clearly enjoying a second childhood. MS-based methods for protein sequencing have sensitivity in the femtomole range, exceeding that of Edman-based sequencing, and MS-based methods are uniquely capable of analyzing the ever-broadening spectrum of protein modifications. Mass spectrometry is even showing promise as a tool for studying protein folding (Englander, 1993; Smith and Zhang, 1994; Wagner and Andereg, 1994) and noncovalent interaction (Smith and Light-Wahl, 1993; Cheng et al., 1995). Further increases in the understanding of the ionization/desorption processes in ESI and MALDI are likely to translate into even higher sensitivity through higher ion-sampling efficiency. It

can also be expected that new methods for dissociating molecular ions of peptides and proteins (possibly involving surface-induced collisions or photoexcitation) will be developed that will be more efficient or more selective than collision-induced or post-source decay. One can also anticipate that computer algorithms for the interpretation or “fingerprinting” of MS/MS data will continue to improve so that soon a minimum amount of human intervention will be required for identification (for an example, see Eng et al., 1994). Although MS-based approaches have sufficient raw sensitivity to analyze low femtomole amounts of peptides and proteins, purifying and handling samples at these levels remains a significant challenge for which there is no general strategy at present. With further improvements, gel- and membrane-based methods and microchromatography-based methods for immobilizing minute amounts of sample for biochemical manipulation and cleanup may meet this challenge.

The mantra for MS now and into the next millennium is “smaller, cheaper, faster, simpler, more sensitive.” These criteria are based in large part on the need to make MS more accessible to the biological community. A variety of new types of mass spectrometers have recently been introduced that satisfy one or more of these criteria, and certain of these new instruments may provide unique benefits for molecular mass determination and sequencing of minute amounts of peptides and proteins. ESI and MALDI have shown particular promise when coupled to quadrupole ion trap analyzers (Qin and Chait, 1995; Korner et al., 1996). These devices are capable of very high resolution and very rapid scanning, and can perform MS^n experiments, in which fragment ions formed in the first MS/MS (MS_2) experiment are further fragmented to provide additional structural information. TOF mass analyzers have been coupled to ESI sources (Mirgorodskaya et al., 1994; Verentchikov et al., 1994) and offer the promise of improved resolution, very high sensitivity, and very fast sampling rates. An interesting variation on these two approaches couples an ion trap to a TOF analyzer, providing structural information as well as molecular mass data (Lee and Lubman, 1995). Additional variations on this theme of connecting two different, relatively inexpensive analyzers together to produce a more versatile instrument are under development. Although neither small or inexpensive, Fourier-transform ion-cyclotron resonance mass spectrometers equipped with MALDI and ESI are extremely versatile

instruments with the potential for simultaneously providing very high mass accuracy, high resolution (routinely $\geq 20,000$), and extremely high sensitivity for peptide and protein mass measurement (Winger et al., 1993; O'Conner et al., 1995; Wu et al., 1995; Smith et al., 1996). These devices are also capable of performing MSⁿ experiments.

Protein Identification and Characterization by Mass Spectrometry

UNIT 10.22

Many aspects of science are driven by technological advances. The pace of molecular biology research continues to increase through such advances, many of which are described in *Current Protocols in Molecular Biology*. However, in the last decade significant technological advances in many aspects of protein chemistry have been realized. Most of these advances have been driven by new ionization capabilities of mass spectrometers, making the analysis of biological materials feasible, and most importantly, by a wider range of scientists. Together with the massive increase in the amount of nucleotide sequence data that is publicly available, this has led to the development of new methods for protein identification using mass spectrometry-derived data (reviewed in Patterson and Aebersold, 1995; and Pennington et al., 1997). In addition, protein identification by mass spectrometry-based methods is being adapted for massively parallel analysis on the one hand or very rapid serial analysis on the other, thereby resembling some of the extremely powerful molecular biological approaches currently available.

As we enter a post-genome era for many organisms, including ultimately *Homo sapiens*, these technologies will be applied to high-throughput approaches as well as in more traditional settings (Patterson, 1997). Such approaches will facilitate analyses of many of the proteins expressed by a given tissue or cell, now being referred to as proteome analysis. The term proteome refers to the *protein* complement expressed by a *genome* (Wilkins et al., 1996) and is often applied to two-dimensional gel electrophoresis-separated proteins and their subsequent analysis (James, 1997; Pennington et al., 1997). With so much nucleotide sequence information at hand in the form of full-length cloned genes and expressed sequence tags (ESTs) for a few species, the need for traditional de novo amino acid sequencing for these genetically well-characterized species is rapidly diminishing. A new era of protein identification by correlation of primary structural data with these databases has begun.

This overview will describe some of the new technologies that can be employed to facilitate rapid identification and characterization of proteins, including the use of correlative approaches for protein identification, rapid post-

translational modification analysis, identification of components in complex mixtures, and direct mass analysis of gel-separated proteins. Other fields of protein chemistry that have been impacted by the advances in mass spectrometry include analysis of protein:protein interactions of both purified proteins and ligands in solution/gas phase (Chapter 20; Robinson et al., 1994; Loo, 1997), and direct screening of specific analytes in natural fluids through the use of affinity surfaces (Nelson et al., 1995). Determination of domain structure through accurate mass analysis after limited proteolysis has also been used as an adjunct to X-ray crystallographic studies, including designing molecules of appropriate size for crystallization (Cohen, 1996). However, as it is not possible within this overview to cite all of the relevant literature, only a limited number of examples of each approach will be given, and where relevant, more extensive reviews will be cited.

The mass spectrometric methods that will be referred to in this overview include matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) and electrospray ionization mass spectrometry (ESI-MS). This overview will not include a detailed description of the technical side of mass spectrometry, as this is well covered in *UNIT 10.21*, and a discussion of its use for analysis of biological molecules appears in Chapter 16 of *Current Protocols in Protein Science* (Coligan et al., 1997). However, a brief description of the two types of mass spectrometers utilized in the studies mentioned in this overview follows.

Mass spectrometers can be thought of simply as having two main components, an ionization source and a mass analyzer. Charged molecules are generated by an ionization source, e.g., MALDI or ESI, into the gas phase of a mass analyzer which is held under vacuum. MALDI sources are usually coupled with time-of-flight (TOF) mass analyzers. In MALDI-MS, the sample (analyte) is cocrystallized in a matrix that absorbs at the wavelength of the laser—either an ultraviolet (UV) laser at 337 nm, or an infrared (IR) laser at 2.94 μm . Ionization occurs in a static electric accelerating field that is generated by holding the sample at high potential (e.g., 20 to 30 kV) with respect to a closely spaced grounded electrode. The accelerated analyte ions pass through an orifice

in the grounded electrode (referred to as continuous extraction) into a field-free drift region of 50 to 300 cm, and signals are recorded when they strike a detector at the end of the flight tube. All of the ions are accelerated by the same potential difference, hence their velocity is proportional to their mass over charge (m/z), i.e., smaller ions arrive at the detector sooner than larger ions, and all of the ions generated in each ionization event are measured. Analytes of known mass can be used to calibrate the instrument. Depending upon the matrix used to cocrystallize the sample, the analytes are usually singly charged, i.e., only one proton has been added to the analyte. Mass over charge ratios of up to ~500,000 have been measured with MALDI-MS. In addition to continuous extraction, another form of analyte extraction from the MALDI probe has recently been introduced onto commercial MALDI-MS instruments and is referred to as delayed extraction (time-lag focusing; see *UNIT 10.21*). This allows the extracted ions time to focus prior to an acceleration of the gas-phase ions into the field-free drift tube resulting in improved sensitivity and increased mass accuracy by reducing the spread of flight times of ions of the same mass (e.g., due to surface nonhomogeneity; Vestal et al., 1995).

In ESI-MS, the analytes are introduced into the gas phase by passing them through a fine needle at high potential at atmospheric pressure (e.g., +5 kV, for positive-ion spectra) resulting in the formation of a fine spray of highly-charged droplets. This spray is directed across the small inlet orifice (held at a low potential, e.g., +50 V) to the evacuated quadrupole mass analyzer. Between the spray needle and the orifice, the droplets are desolvated by directed flows of dry inert gas and/or heat. These dry ions can now be mass analyzed in the quadrupole device. Due to this process, most analytes entering the mass analyzer are multiply charged, i.e., more than one proton has been added to the analyte during the ionization process; peptides, for example, are often only doubly (mass of peptide + 2 protons divided by 2 = m/z value) or triply charged, but proteins can carry many protons. Quadrupole mass analyzers are scanning instruments, unlike the TOF mass analyzer, where the masses of all of the analytes are measured following each ionization event. At any one point in time, only ions of one particular m/z value are passed through the quadrupoles; all other ions are lost for further analysis. A detector counts the number of ions transmitted at each specific m/z value,

and by scanning a mass range, a spectrum of m/z versus abundance (a mass spectrum) can be plotted. The mass range of quadrupole instruments is limited compared with TOF analyzers, usually up to 2000 to 4000 m/z , but as stated above, analytes ionized by ESI are multiply charged, and hence their m/z values are measurable in these instruments even when their masses are considerably lower than 2000 u (atomic mass units, equivalent to Da). In addition, in some mass spectrometers designed for that purpose, intact molecules (peptides usually) can be caused to break apart (i.e., fragment in a sequence-specific manner), and the masses of the resulting pieces can be measured (see Protein Identification Using Mass Spectrometry-Based Correlative Approaches and *UNIT 10.21*). For instruments that are appropriately equipped, this is referred to as collisional-induced dissociation (CID), or tandem MS (MS/MS) for ESI-MS, and as post-source decay (PSD) for MALDI-MS (see *UNIT 10.21*). The fragment ions produced are predominantly formed via fragmentation through the peptide bonds. The mass difference between fragment ions of the same series (either N- or C-terminal) is the residue mass of the amino acid at that position. Thus, the fragment-ion spectrum can be correlated with the peptide amino acid sequence.

Most simply put, mass spectrometers are very accurate balances providing an absolute physical measurement of analytes including proteins, peptides, and following fragmentation in the gas phase, sequence-specific fragment-ion spectra of peptides selected in the mass spectrometer.

PROTEIN IDENTIFICATION USING MS-BASED CORRELATIVE APPROACHES

Peptide-Mass Searching

Definitive protein identification for many years has been achieved by generating an amino acid sequence through chemical degradation of the N-terminus of the isolated protein (Edman degradation), or peptides derived from it (*UNIT 10.19*). Proteins have also been identified by immunodetection with antibodies recognizing the protein of interest (*UNIT 10.8*). A few years after it was practical to accurately measure the mass of peptides generated from gel-separated proteins, several groups published variations on the following theme as a means to identify proteins already resident in a sequence database: use an algorithm to match a set of peptide

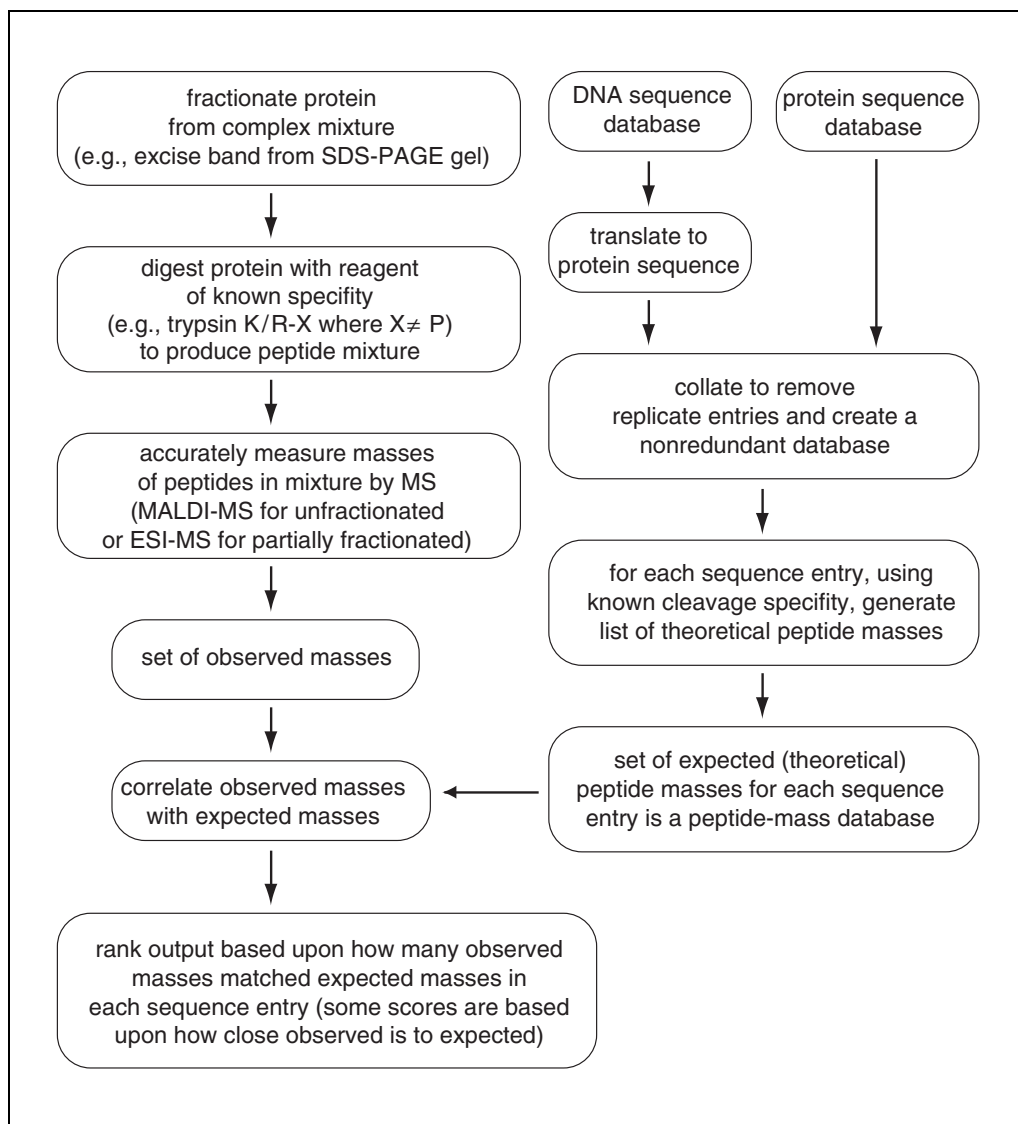

Figure 10.22.1 Protein identification using peptide-mass data generated by accurate mass measurement by either ESI-MS or MALDI-MS

masses generated in a specific manner (e.g., by enzymatic digestion with trypsin) from the protein of interest, with theoretical peptide masses calculated from each sequence entry in the database using the same cleavage specificity as the reagent in the experiment. Then derive a ranking (or score) to provide a measure of the fit between the observed and expected peptide masses (see Fig. 10.22.1; reviewed in Cottrell, 1994; Patterson, 1994; Patterson and Aebersold, 1995). Many of these original groups and others have placed their search programs on the World Wide Web for public access, and many include examples for their use (see Table 10.22.1).

The obvious caveat to such an analysis is that the protein to be identified already exists within a sequence database, either translated

nucleotide or protein sequence database. Therefore, this approach is ideal when the protein to be identified is derived from an organism whose genome is sequenced or at least whose major proteins are sequenced. Of course, such searches are not suited to translations of expressed sequence tag (EST) databases which consist of only limited coding regions and therefore, may not contain sufficient information for a match. Peptide-mass data is most rapidly obtained by MALDI-MS analysis of an aliquot of a protein digest. However, peptide-mass data can also be obtained from liquid chromatography (LC)-MS analysis of a protein digest.

It is rare that all of the input peptide masses match with the highest ranking sequence entry, and it is important to determine the origin of

these masses (Patterson and Aebersold, 1995). The following should be considered as reasons for additional masses. (1) The correct protein was identified in the search, but the masses are the result of posttranslational or artifactual modification or posttranslational processing. Plausible modifications may be taken into consideration but should only be considered tentative unless confirmed experimentally. (2) The correct protein was identified, but some peptides were derived by nonspecific proteolysis or cleavage by a contaminating protease. This theory can be tested by determining whether the protein candidate can produce the peptide masses without any assumptions as to the cleavage specificity. (3) The correct protein was identified, but the “pure” protein was contaminated with one or more additional proteins. If there are enough additional masses, a separate peptide-mass search using these masses can be performed to attempt to identify the contaminant(s). (4) A sequence homologue, or processing variant, from either the same or a different species was identified. Some search programs allow species-specific searches to be performed, and that could eliminate this possibility; however, if confirmatory data is obtained, matches to proteins from other species can be useful, especially for scientists working with organisms whose genomes are relatively poorly characterized. (5) The match was a false positive! This potentially disastrous result is difficult to verify or disprove, particularly if the highest ranked protein did not have a high score; sometimes confidence in the highest-ranked score can be gained from the difference

between it and the second highest and subsequent scores; the protein may also not yet reside in the database and it may be truly novel.

Implicit to the theory of peptide-mass searching is the accurate measurement of peptide masses. Therefore, the greater the accuracy, the greater the confidence of the assignment. In addition, the reagent used to generate the peptides should also be one that shows a high degree of specificity. This latter point is limited to the specificity of enzymes and chemical cleavage reagents. Trypsin is the most commonly used reagent for peptide-mass searching analyses, but it can also cleave at sites other than C-terminal to Lys or Arg, if not followed by a Pro, and as with most enzymes it may not cleave a substrate to completion (i.e., missed cleavage sites). The number of missed cleavage sites is often a variable for peptide-mass search routines, but spurious cleavage sites for trypsin or other enzymes cannot be predicted. Endoproteinase LysC is another good enzyme used in such analysis, but it can also miss cleavage sites and cleave nonspecifically; this enzyme has the advantage that there are few if any autolysis products. Thus, there is little that can be done to improve the specificity of the reagents to cleave isolated proteins, but more accurate mass measurement is in large part dependent upon the type of mass spectrometer employed.

Most peptide-mass analyses are performed on MALDI-mass spectrometers due to the tolerance of the MALDI process to sample buffers and its rapid and simple analysis. This has increased further in the last couple of years

following implementation of delayed extraction which dramatically improves the mass accuracy obtainable on an ever-increasing range of commercial instruments (Vestal et al., 1995). The ability to measure masses at 5 ppm allows assignment of monoisotopic masses and the use of very tight tolerances in peptide-mass searches, thereby limiting the number of potential matches (Jensen et al., 1996a; Takach et al., 1997). Even though increasing the mass accuracy can't affect any of the situations mentioned above, there is less chance of a spurious match.

In addition to more accurately measuring the mass, a number of orthogonal methods can be performed on a separate aliquot of the peptide digest (or sometimes for MALDI-MS on the probe after the original data has been obtained) to provide information on the amino acid composition of each peptide, which can be used as an additional piece of information for the peptide-mass search algorithms. This is achieved through one of the following approaches: site-specific chemical modification [e.g., methyl esterification, which adds +14 u for each acidic residue—Asp, Glu, or C-terminus—in the peptide (Pappin et al., 1995) or iodination, which adds +126 u for each tyrosine (Craig et al., 1995)]; determination of partial amino acid composition of the peptide (hydrogen/deuterium exchange in which each amino acid can exchange a defined number of its hydrogens for the heavier deuterium, and the total mass increase reflects the peptide composition from 0 to 5 u per residue; James et al., 1994); one-step Edman degradation to determine the N-terminal amino acid of each peptide in the mixture (Jensen et al., 1996b); or an additional enzymatic digestion [subdigestion (Pappin et al., 1995), or parallel digestion (James et al., 1994)].

These approaches have proven quite successful for a number of investigators (reviewed in Patterson and Aebersold, 1995; Jungblut et al., 1996; Lamond and Mann, 1997). Most importantly, the data can be obtained very rapidly when using MALDI-MS of peptide mixtures, and some groups have implemented automated approaches so that large numbers of proteins can be analyzed in an unattended mode (see below). In one report, a peptide-mass search result provided sufficient information to be able to clone a homologous gene because the sequence of the matched peptides could be used to generate primers (Salmeron et al., 1996).

Peptide-Sequence Tags, Uninterpreted Fragment-Ion Searching, and de Novo Sequencing by MS/MS

The most discriminating criteria used to identify a protein is contiguous amino acid sequence information. The amino acid sequence information can be obtained either by chemical sequencing (automated Edman degradation) or by generating sequence-specific fragment ions from individual peptides in the gas-phase of a mass spectrometer (see *UNIT 10.21* for detailed description of fragmentation; see Figure 10.21.1 for fragmentation nomenclature). If sufficient contiguous amino acid sequence is obtained from either method, it is unnecessary to generate additional data to confirm the identification of the protein because standard string-based search protocols (e.g., TFASTA; see *UNIT 19.3*) can be employed. However, this is not always possible, and use of accurate mass measurement in conjunction with partial amino acid sequence information can be a very powerful approach.

Measurement of the masses of fractionated peptides (usually by reversed-phase-HPLC) prior to automated Edman sequencing provides the researcher with a number of options in addition to the amino acid sequence obtained. (1) Mass information can make it possible to determine more accurately the number of sequencing cycles required, thus minimizing reagent expense and sequencer time. (2) The peptide mass can confirm the determined peptide sequence and whether the sequence is complete (the sum of the masses of the identified amino acids should equal the mass of the peptide). (3) The mass analysis usually indicates the purity of the sample, thereby avoiding sequencing mixtures (although this is not always the case). (4) Given that proteins are cleaved with rather high enzyme-to-substrate ratios, knowledge of the mass of the peptide to be sequenced can avoid sequencing of an enzyme autolysis product. (5) An amino acid sequence can sometimes be completed if only a couple of amino acid residues have not been assignable, i.e., by summing the masses of the assigned residues and determining which residues could account for the mass difference between that and the mass of the intact peptide (Tempst et al., 1995). Thus, simple measurement of the mass of a peptide is an extremely useful exercise. Another scenario, often faced when sequencing low levels of peptides, is that only a few amino acid residues of a sequence are obtained, insufficient to identify the protein or to construct an oligonucleotide primer. If the

mass of the peptide has been determined, this limited amino acid sequence data may still be sufficient for further use (e.g., Patterson et al., 1996).

The partial amino acid sequence, which does not need to be contiguous, and the mass of the peptide can be used to construct a “peptide-sequence tag.” This term was coined by Mann and Wilm (1994) to reflect the power of this relatively small amount of information to identify the protein from which specific peptides were obtained, much the same way short stretches of nucleotide sequence as expressed sequence tags (ESTs) have proven so useful. By using the partial amino acid sequence, the cleavage specificity of the enzyme or other reagent used to generate the peptide, and the peptide mass, the peptide-sequence tag can be used to search amino acid sequence databases (including translations of EST databases). Mann and Wilm (1994) also described a method by which partial interpretation of sequence-specific MS/MS fragment-ion spectra (see UNIT 10.21) combined with the mass of the peptide from which the spectrum was obtained can be used to construct a peptide-sequence tag (see Fig. 10.22.2). In this case a portion of the fragment-ion spectrum is interpreted to determine whether an ion series (either *b* or *y*; see Fig. 10.21.1 in UNIT 10.21) can be established, i.e., a series of fragment ions whose mass differences correspond to known amino acid residues. The peptide-sequence tag is composed of three regions: the mass of the first ion in the series which provides the mass of the peptide fragment from an end of the peptide to the uninterpreted region; the interpreted amino acid sequence for anywhere from one to many residues; and the mass of the last ion in the series (the difference between this and the mass of the intact peptide is the mass of the uninterpreted region between the sequence and the other end of the peptide; Mann and Wilm, 1994; see Fig. 10.22.2). If the cleavage specificity of the enzyme is used, two additional pieces of information are then included in the search—the N-terminal and C-terminal specificity. These can also be left out if the search is conducted in error-tolerant mode which allows for either database sequence errors or posttranslational modifications.

Yates and colleagues have developed identification algorithms, referred to as SEQUEST, that are based upon automated interpretation of MS/MS fragment-ion spectra in a manner compatible with direct searching of sequence databases (Eng et al., 1994). In this approach, the

program first generates a list of theoretical peptide masses for each sequence entry, using either enzyme cleavage specificity rules or the sum of contiguous amino acid residues, and calculates which of these match the measured mass of the peptide ion (within a stated tolerance), thereby generating a list of candidate peptides. In the second step, the program then calculates the fragment ions expected for each of the candidate peptides if they were fragmented under the experimental conditions employed to generate a predicted spectrum; then it compares the experimentally determined MS/MS spectrum with the predicted spectra using cluster-analysis algorithms. Each comparison receives a score, and the highest-scoring peptide sequences are then reported. If a significant score is achieved, the protein is identified based on the peptide MS/MS spectrum without any explicit determination of the peptide sequence (see Fig. 10.22.2).

The advantages of such an approach include the following (Patterson and Aebersold, 1995). (1) Proteins can be effectively identified in complex mixtures because each peptide that generates an MS/MS spectrum provides data for an independent database search. (2) When applied to analysis of a digest from a single protein, the results are inherently autoconfirmatory, and with the same protein as a top-ranked candidate for a number of peptides, identification is absolutely confirmed. (3) The approach allows for easy automation when ions for fragmentation are selected in a data-dependent fashion, and the MS/MS results are automatically analyzed (Yates et al., 1995). (4) The method is able to be adapted to find peptides carrying specific posttranslational modifications (the program can be set to anticipate a modification of a specific mass on specific residues) as well as to identify the protein from which the peptide originated (Yates et al., 1995). A number of other investigators have developed algorithms for uninterpreted fragment-ion searches based upon matching of observed and expected fragment-ion masses, and a list of sites on the Internet that provide these search capabilities is provided in Table 10.22.1. One of these referred to as MS-Tag (Matsui et al., 1997), developed at the University of California, San Francisco, uses an algorithm to match the observed fragment-ions with a user-selected list of specific ion series; this is also shown in Figure 10.22.2.

Manual or computer-assisted interpretation of MS/MS spectra can be very difficult in many instances because it is impossible to determine

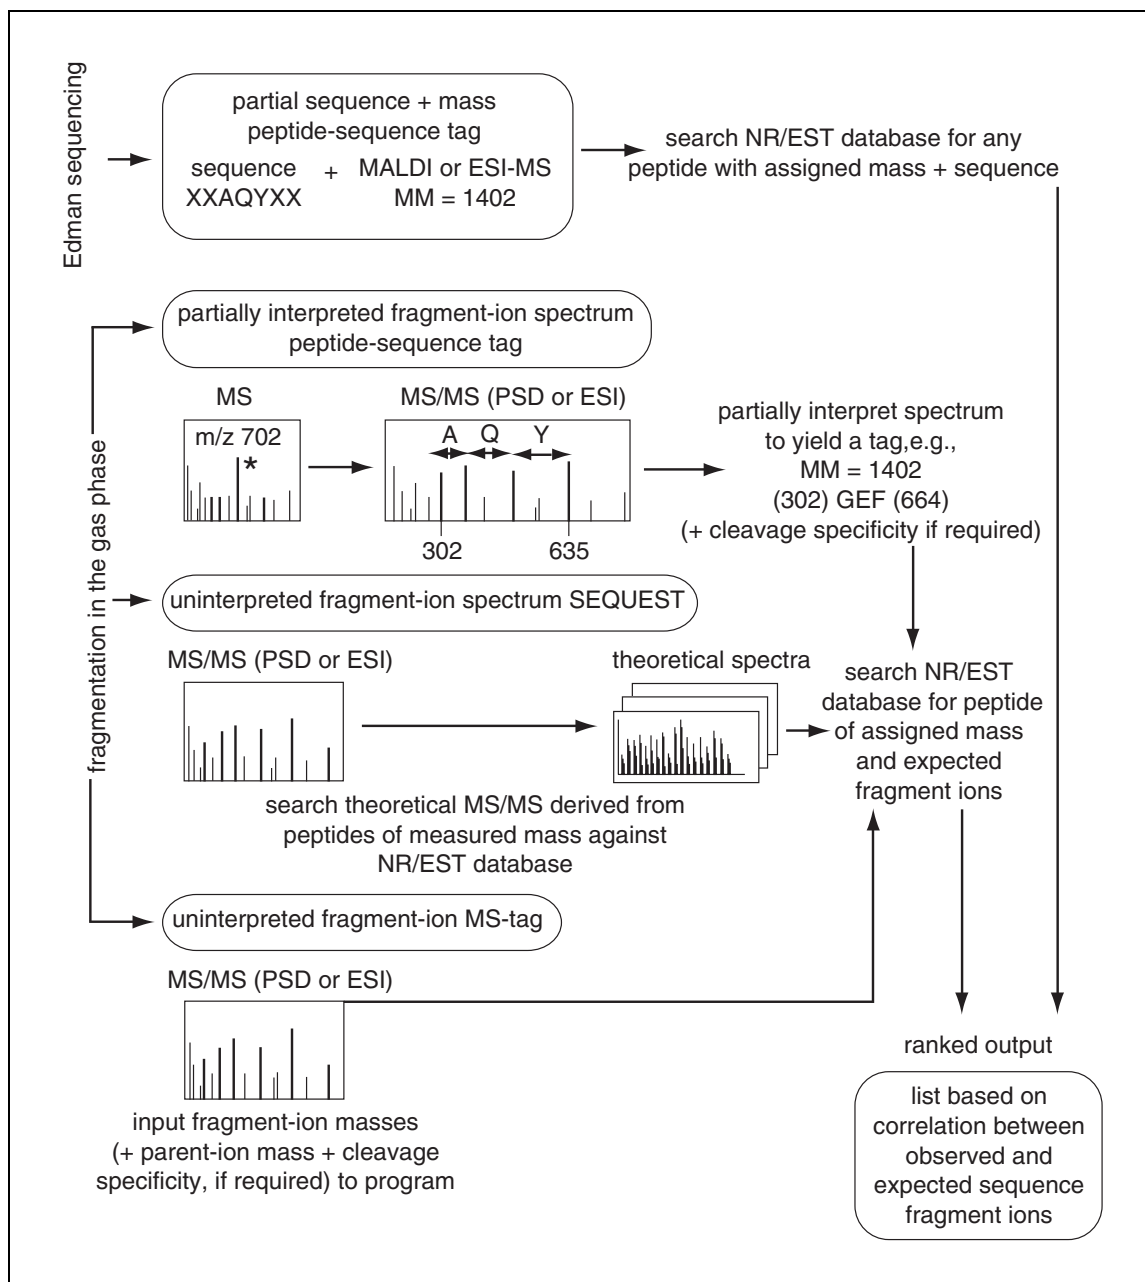

Figure 10.22.2 Protein identification using fragment-ion data, interpreted or not. For a peptide of interest the mass is accurately measured by MS and sequence information is generated by either Edman sequencing (if an incomplete sequence is obtained), fragmentation in the gas phase by ESI-MS/MS, or PSD-MALDI-MS to yield a fragment-ion spectrum.

which series-specific ions belong to N-terminal- (*b*) or C-terminal- (*y*) derived peptides; hence, the great utility of the methods described above for peptide sequence tagging and uninterpreted fragment-ion searching is for searching protein sequence and translated nucleotide sequence databases. However, for these approaches to be successful, the sequence that matches the peptide under analysis has to reside in the database. ESTs constitute only a portion of the sequence of many but not all expressed genes. Many widely used experimental organ-

isms are poorly represented in the sequence databases, and although conserved regions between proteins may be able to be matched (Cordwell et al., 1997), more often than not an accurate extended amino acid sequence is required so that oligonucleotide primers can be made to obtain the gene of interest from an appropriate library via the polymerase chain reaction (PCR; *UNIT 22.1*).

Mass spectrometry-based approaches are the methods of choice for generating sequence-based information from very low levels of pro-

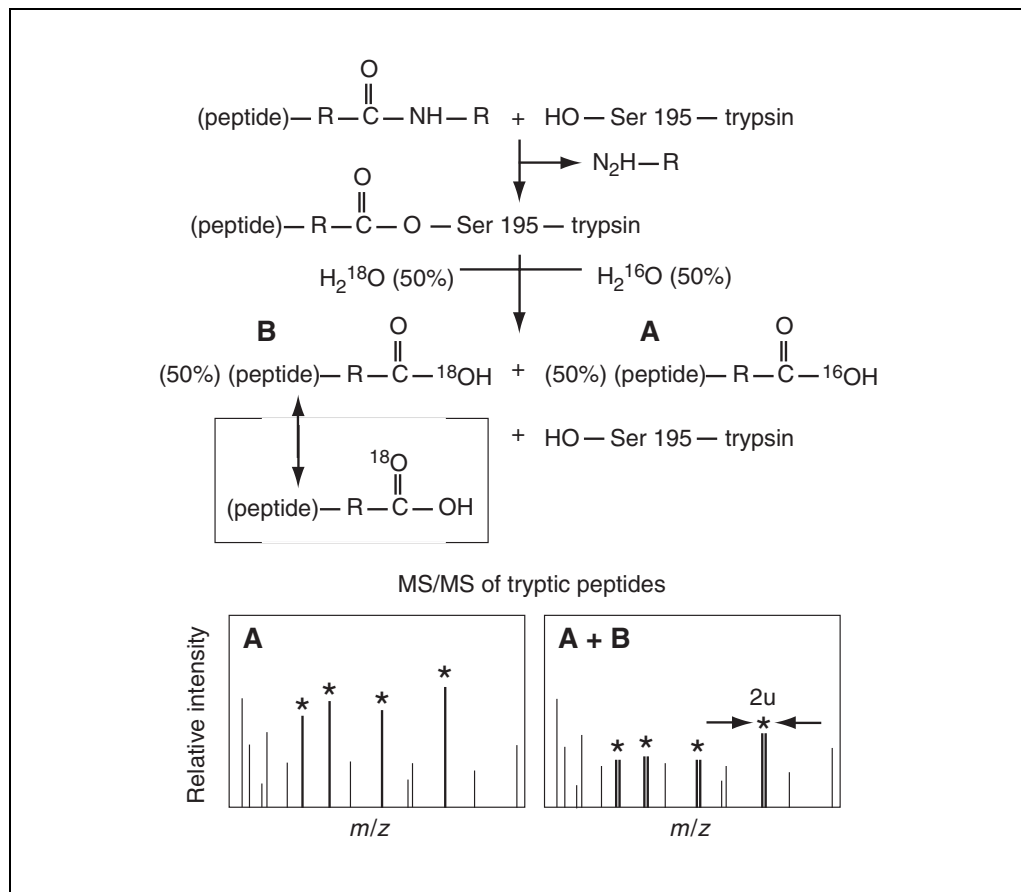

Figure 10.22.3 A scheme for de novo sequencing using H_2^{18}O . Tryptic digestion in the presence of 50% H_2^{18}O facilitates de novo sequencing by MS/MS by generating two sets of γ series ions (*) that differ in mass by 2 u (compare MS/MS of peptide A with the mixture of peptides A and B).

tein. Therefore, for proteins from species with limited sequence information, de novo sequencing from MS/MS spectra is important. This can be accomplished in two ways; (1) by generating two MS/MS spectra of the peptide with and without methyl esterification, and (2) by conducting tryptic digestion in the presence of 50% (v/v) H_2^{18}O (see Fig. 10.22.3). In the first method, a MS/MS spectrum is obtained after all of the carboxyl groups have been modified by esterification with a methyl group thereby increasing the mass of the peptide by 14 u for each carboxyl group present. This method is most useful when the peptide of interest does not contain any acidic residues, and it is of least use when either multiple acidic residues are present or the one acidic residue is located on the N-terminus. If there are no acidic residues, then comparison of the MS/MS spectra with and without esterification will reveal that all γ -series ions are 14 u heavier in the methyl-esterified spectrum and that all of the other ions are unaffected. If there are acidic residues in the peptide, the comparison becomes more complicated.

A more rapid approach for de novo sequence interpretation is afforded by conducting the original tryptic or LysC digestion in the presence of 50% (v/v) H_2^{18}O /50% (v/v) H_2^{16}O (Schnolzer et al., 1996). This results in all of the newly generated peptides but not the C-terminal peptide being present as doublets differing in mass by 2 u; it also reduces the intensity of the total signal for the intact species by half. This occurs because trypsin cleaves the peptide bond after lysine or arginine via the activated OH group of serine-195 (of trypsin), which forms a covalent ester bond with the carboxyl group of the lysine or arginine residue (the newly formed N-terminus is released). This intermediate is then cleaved by attack of an activated water molecule, leading to release of the peptide fragment, whose carboxyl group contains one oxygen from solvent water (Schnolzer et al., 1996). If the solvent water is 50% H_2^{18}O then half of the peptides will have a mass 2 u greater than those that incorporate ^{16}O from normal water. Therefore, when these peptides are fragmented, all of the C-terminal-derived peptides (γ -series ions) will exist as

doublets allowing identification of one ion series. In many cases complete interpretation of the MS/MS spectrum in a single experiment is possible, especially if high-resolution MS instruments are employed (Shevchenko et al., 1997).

DIRECT MS ANALYSIS OF GEL-SEPARATED PROTEINS AND OTHER MULTI-DIMENSIONAL APPROACHES FOR PROTEIN SEPARATION AND MASS MEASUREMENT

MS and MS/MS Analysis of Proteins and Peptides Following Gel Electrophoresis

The last separation step prior to protein identification and/or characterization often involves electrophoretic separation. As described, mass spectrometry has provided many powerful approaches to protein identification. Methods compatible with mass spectrometry analysis are most often applied to gel-separated proteins and involve generation of peptides by digestion of the protein in the gel or following transfer to a membrane (reviewed in Patterson, 1994; Patterson and Aebersold, 1995). The peptides are then extracted and analyzed as a mixture or alone following separation. One way to speed up this process and potentially avoid losses due to multiple handling steps is to perform all of the mass spectrometry analyses either directly out of the gel or following transfer to a membrane. As MALDI-MS is compatible with solid-phase methods, it is the analytical method of choice. It also provides an opportunity to measure the mass of the intact molecule prior to digestion and analysis of the resulting peptides.

Transfer of the intact proteins to a membrane has always been a preferred step because it allows many potential ionization-suppressing contaminants to be washed away and matrix to be introduced easily. Therefore, it was considered appropriate to transfer proteins to a membrane prior to any attempt to ionize them intact in a mass spectrometer. A number of different membranes have been evaluated for subsequent MALDI-MS analysis of intact proteins using either ultraviolet (UV) or infrared (IR) lasers (reviewed in Vestling and Fenselau, 1995). For proteins or peptides to be ionized directly from a membrane, they first have to be extracted into a solvent that contains matrix, so the protein can cocrystallize with matrix. Therefore, the stronger the interactions between the protein

and the membrane, the less protein will be available for ionization. The choice of solvent for the matrix is also important as solvents with high organic content can eliminate the spatial resolution of the electrophoretically separated proteins due to diffusion (Vestling and Fenselau, 1994a; Loo et al., 1996). In addition, when proteins are electroblotted onto membrane, they often penetrate the surface of the membrane and may not be accessible to the laser (especially the short-wave-length UV lasers generally employed in commercial MALDI-MS instruments). Data suggests that UV lasers are not as efficient at ion extraction as IR lasers are when the analyte is embedded in a membrane following electroblotting, although the effect is less pronounced when the protein is spotted and not electroblotted onto the membrane (Strupat et al., 1994; Schreiner et al., 1996). This was confirmed by the rather large quantities of protein required for detection on the membrane compared to that which could be analyzed by enzymatic digestion (Patterson, 1995; Schreiner et al., 1996). IR-MALDI-MS has been shown to be more efficient at extracting proteins from electroblotted membranes (Strupat et al., 1994), and it has recently been shown to be directly compatible with two-dimensional gel electrophoresis separations and blotting to PVDF (Eckerskorn et al., 1997). This latter study revealed that an area of a blotted membrane could be effectively converted into a mass contour plot that displayed significant microheterogeneity within individual two-dimensional gel electrophoresis-separated protein spots that were not resolved electrophoretically (Eckerskorn et al., 1997). Thus the power of two-dimensional gel electrophoresis combined with accurate mass measurement of intact proteins by IR-MALDI-MS will no doubt be of significant benefit to identification and characterization projects. Current limitations include the small area of the membrane that can be placed into the MALDI-MS, but more of an issue is the amount of data generated and its collation into a format for easy analysis. However, there is no reason to imagine that either of these problems is insurmountable.

Another important issue to be addressed is the further analysis of the protein after the intact mass has been determined. The intact mass is very useful for characterization purposes, but it will not lead to confident identification, which requires generation of peptides for peptide-mass searches and sequence-specific fragment ions from individual peptides for peptide-

sequence tag or uninterpreted fragment-ion searches (see Protein Identification Using Mass Spectrometry–Based Correlative Approaches). This has already been demonstrated, at relatively high picomole loads on the gel, by a number of investigators where chemical or enzymatic cleavages followed by direct UV-MALDI-MS of the resulting peptides (without elution) have been achieved, allowing peptide-mass searching to be used for protein identification (Vestling and Fenselau, 1994a,b). Fabris et al. (1995) also demonstrated that peptides generated by enzymatic cleavage on the membrane could be fragmented by post-source decay (PSD) UV-MALDI-MS. These latter two steps have been achieved for IR-MALDI-MS in a continuation of previously published work (Eckerskorn et al., 1997), according to reports at a recent meeting (F. Lottspeich, pers. comm.), where results were shown for measurement of the intact mass of the protein, peptide masses produced by enzymatic digestion, and PSD-MALDI-MS spectra of some individual peptides, all obtained from individual electrobotted proteins. Such analyses demonstrate the utility of the approach and lay the groundwork for its adaptation to larger scale “proteome” projects.

Originally it was also considered difficult for proteins and peptides to be extracted in an electric field from a gel-matrix, so membrane-based methods were used. However, the Andrews group has demonstrated in a series of proof-of-principle experiments that direct UV-MALDI-MS from certain types of gels is possible (Loo et al., 1996). By separating proteins in an isoelectric focusing (IEF) gel and subjecting this gel to delayed extraction-MALDI-MS after drying the gel and applying matrix, they were able to generate a virtual two-dimensional gel (Loo et al., 1996; see Fig. 10.22.4). The same considerations outlined above for membrane-based approaches apply to analyses of proteins out of the gel—e.g., sensitivity, visualization of the protein in a manner compatible with further analysis, matrix and solvent combinations to allow cocrystallization of the protein from the gel without loss of the spatial resolution, thin gels so that the protein concentration per gel volume ratio isn't too low, and methods compatible with peptide generation and subsequent sequence-specific fragmentation generation. This research was originally performed on a standard continuous-extraction UV-MALDI-MS, but with delayed-extraction UV-MALDI-MS significant improvements in mass accuracy were realized for the analysis of

intact ultrathin (0.35-mm) IEF gel-separated proteins, as well as cyanogen bromide digests of these same proteins (Loo et al., 1997). Sensitivities were in the low to subpicomole range, were most compatible with IEF gels, but were also successful, albeit at higher protein loads, with SDS-PAGE gels (Loo et al., 1997). It is yet to be demonstrated whether PSD-MALDI-MS can be performed on peptides generated in the gel, but as this is an ionization-dependent event, it would not be considered to be a problem.

Therefore, these new approaches for direct analysis of gel-separated proteins either from the gel or following transfer to a membrane show considerable promise for future automated protein identification and characterization protocols.

Multidimensional Separations with MS as the Final Dimension

In classical two-dimensional gel electrophoresis the second dimension provides a mass estimate based upon comparison of SDS-denatured proteins with similarly treated standards. As described in the previous section, substitution of mass spectrometric detection for gel electrophoresis (or as an addition) provides a very accurate mass for each separated component that can be ionized. By employing a liquid-phase first dimension, introduction of the protein mixtures into ESI-mass spectrometers becomes possible by facilitating integration of a series of on-line separation devices (see Fig. 10.22.5). Two examples of such approaches are described for protein analysis, one using IEF coupled to ESI-MS, the other using two orthogonal steps of chromatography on-line with ESI-MS.

Tang et al. (1997) described a capillary IEF gel system interfaced to an ESI-MS for the analysis of total cellular proteins from *E. coli*. They were able to discern just over 100 proteins by this approach, which is comparable with a minigel two-dimensional gel electrophoresis approach where an equal number of proteins were observed by silver staining. Comparison with high-resolution two-dimensional gel electrophoresis would have yielded a dramatically different result, but as with other methods described in this unit, it provides a glimpse of potential future approaches for analysis of complex protein mixtures. Opiteck and coworkers (Opiteck et al., 1997a) utilized two types of chromatography, cation-exchange and reversed-phase, coupled to two separate sets of LC pumps under computer control to separate

proteins on-line for subsequent ESI-MS analysis. Storage loops were used to collect effluent from the cation exchanger for subsequent injection onto the RP-HPLC which was connected to a UV detector as well as an ESI-MS. A limited protein mixture as well as an *E. coli* lysate were separated using this approach in a 2-hr run time (Opiteck et al., 1997a).

Both of these approaches demonstrate the ability to separate and accurately mass analyze

complex protein mixtures with some success. Before such approaches are competitive with two-dimensional gel electrophoresis, they will need to be able to detect proteins over a much larger range of concentrations and to demonstrate that the ionization intensity of any species is not affected by the concentration of a co-ionizing species, so the approach is truly as quantitative as is possible within limits for two-dimensional gel electrophoresis. Another draw-

Figure 10.22.4 Direct mass measurement of gel-separated proteins. By inserting either dried thin gels or blotted membranes into a MALDI-MS with an ultraviolet (UV) or an infrared (IR) source, accurate mass measurements of the gel-separated proteins can be made. A “virtual” two-dimensional gel is the result of multiple MALDI-mass measurements of isoelectric (IEF) gel-separated proteins along the length of the IEF gel, thereby generating a mass contour plot of the IEF separation. Ultimately, sequential mass analyses (intact, following enzymatic/chemical cleavage, and sequence-specific fragmentation of individual peptides) will be able to be performed on the same protein spot/band as illustrated.

back of the approach is the inability (at this stage) to fragment the proteins from coeluting mixtures and determine the mass or sequence of the fragments, thereby allowing protein identification. However, it has been demonstrated that using a high-resolution mass spectrometer, CID fragmentation of intact proteins yielded short stretches of sequence-specific fragment ions that could be used in peptide-sequence-tag searches to identify the protein (Mortz et al.,

1996). This was applied to pure protein preparations but as specific ions from each protein were chosen, this approach may become suitable for application to the on-line protein-separation methods described above. With the significant advances that have been made in this field, it will be one to watch in the future.

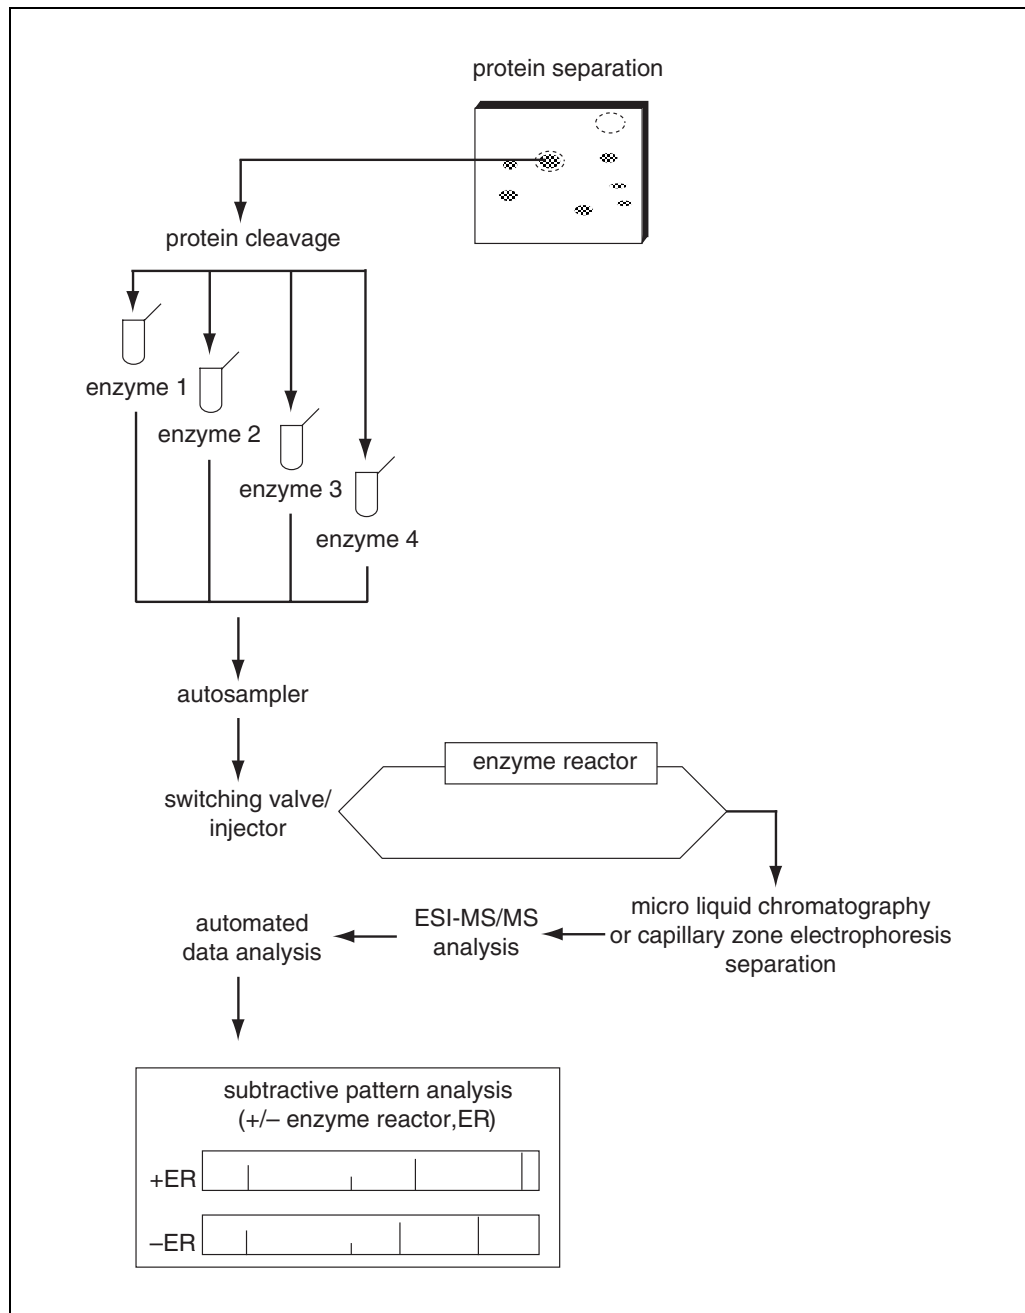

Figure 10.22.5 Schematic representation of an integrated system for determining posttranslational modifications. A range of enzymes can be employed to generate peptides covering the entire sequence of the protein of interest, and when a specific modification is being targeted, an enzyme reactor column can be placed on-line to remove the modification from an aliquot of the peptide digest (modified from figures supplied by Dr. R. Aebersold, University of Washington, Seattle, USA).

RAPID POSTTRANSLATIONAL MODIFICATION ANALYSIS

Given that mass spectrometers are accurate balances, they are ideal instruments to identify posttranslational modifications in an unbiased manner without the use of radioactive precursors, e.g., one will only observe phosphorylation if radiolabeled phosphate is measured in an experiment. An ideal situation would be to be able to identify and characterize all of the posttranslational modifications present on a protein in a single experiment. To achieve this aim requires an approach to unambiguously characterize any and all posttranslational modifications that are stable to the mass spectrometric ionization process on an identified protein. This can be accomplished by mass measurement of (1) the intact protein to estimate the type and number of modifications, (2) peptides which represent all of the protein to localize the site of modifications, and (3) fragment ions of the modified peptide(s) to identify the site of modification. Many posttranslational modifications have been identified in an unbiased manner through the use of mass spectrometry analysis, and in many cases Edman sequencing, of recombinant proteins, often as a consequence of their overexpression (Tu et al., 1995 and references therein). However, fulfilling all of the above-mentioned criteria is a daunting task even when the protein has been obtained from recombinant sources and is therefore available in relatively high quantity. Characterization of *in vivo* protein modifications is the ultimate aim, and progress is being made towards this end. The applications of new protein technologies to this field are demonstrated through examples of analysis of phosphorylation.

The most reported posttranslational modification is that of phosphorylation due to its critical role in signaling pathways, predominantly through either the addition or removal of phosphate esters from the hydroxyl groups of serine, threonine, and tyrosine residues (Hunter, 1987; Charbonneau and Tonks, 1992). Phosphoramidates can also be formed with histidine, arginine, and lysine residues, and acylphosphates with aspartic and glutamic acid residues, but these are considered less frequent and therefore, their functions are less well understood. However, due to the labile nature of some of these modifications they may well be more frequent and important than currently assumed (Huang et al., 1991).

Classical Approaches for Study of Protein Phosphorylation

Briefly, classical methods for the analysis of protein phosphorylation use two different approaches to add radiolabeled phosphate to proteins—metabolic labeling which involves equilibration of the cellular ATP pool with $^{32}\text{PO}_4$ (see *UNIT 18.2*) or an *in vitro* kinase reaction in which purified kinases (possibly immunoprecipitated) are used to phosphorylate crude or fractionated (sometimes coimmunoprecipitated) cell lysates using $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (*UNIT 18.7*). The mixture is then separated by gel electrophoresis and the migration of the labeled protein detected by autoradiography. The type of amino acid residues modified can be identified by mild base hydrolysis of the excised proteins, and separation of the amino acids by thin-layer chromatography (TLC) or electrophoresis (*UNIT 18.3*). To determine the site of modification, the protein must be fragmented and the resulting peptides separated, usually by two-dimensional TLC with autoradiographic detection, or sometimes by RP-HPLC with Cerenkov counting of collected fractions. Again, the type of residue phosphorylated can be determined by mild base hydrolysis followed by one- or two-dimensional TLC (see *UNIT 18.3*). Alternatively, the site can be revealed by Edman sequencing of the fractionated peptide, in the rare cases where sufficient sample is available, or by comigration of synthetic phosphorylated peptides designed from potential sites of phosphorylation within the protein of interest. For both of these approaches to work the amino acid sequence of the protein has to be known. The ability to raise antisera to phosphotyrosine has provided a very simple nonradioactive means of identifying proteins carrying this modification (see *UNITS 18.5 & 18.6*). Antibodies are available from several commercial sources, providing a rapid and sensitive means of monitoring tyrosine phosphorylation on SDS-PAGE (including two-dimensional gel electrophoresis) separated proteins. Antisera directed against phosphoserine and phosphothreonine detect some but not all proteins modified in this manner.

MS Approaches for Identifying Regions and Sites of Phosphorylation

A number of mass spectrometry-based approaches have been developed to address the issue of protein phosphorylation. They fall into two main categories: searching for mass differences consistent with phosphorylation (i.e.,

+80 u or multiples thereof) and then treating with phosphatases to confirm the assignment, and searching for phosphorylated peptides through the use of high-orifice scanning in ESI-MS to find phosphate-specific signature ions (see *UNIT 10.21*). Although it is always preferable to determine the intact mass of the protein as the first step in analysis, this is often not possible; therefore, the protein is enzymatically digested and the masses of the resulting peptides are determined.

If the entire sequence of the protein under investigation is known, then putative phosphorylated peptides can be assigned based upon which peptides do not match the expected masses. Of course, this only localizes the site of modification, but doesn't confirm that the expected residue is modified with phosphate; that requires sequencing of the peptide either chemically or by MS/MS. Confirmation of the observed mass difference can be made by treating the digest with a phosphatase and measuring the peptide masses again. This can be conducted with a separate aliquot in solution, or as Craig et al. (1994) and Liao et al. (1994) have demonstrated for MALDI-MS, directly on the probe, making the analysis rapid and with minimal sample loss. If the putative assignments were correct, those previously phosphorylated peptides will now display masses 80 u, or multiples thereof, less than the first analysis. This seems relatively straightforward, but the approach may not always result in complete assignment of all phosphorylated sites. Independent of the mass spectrometer used (MALDI-MS or ESI-MS), not all of the peptides generated from the digest may be able to be mass analyzed, e.g., some peptides may only be ionized in either positive- or negative-ion mode but not both, or some peptides may become insoluble following digestion. Mass spectrometry of peptides is usually conducted in positive-ion mode (see *UNIT 10.21*), but because phosphorylation is a negatively charged modification, it sometimes changes the properties of the peptide such that it will only be ionized in negative-ion mode. For MALDI-MS, conducting experiments in both modes sequentially is not a problem because the sample is immobilized, and many analyses can be performed on the same sample. In ESI-MS, the analysis is usually performed in one mode (positive or negative) or the other.

To overcome the problem of incomplete coverage of the protein due to insolubility or other problems, a parallel digest with an enzyme of differing specificity is often used. In

an elegant study of a PAK/STE20 homolog from *Acanthamoeba castellanii*, Szczepanowska et al. (1997) used MALDI-MS on both a TOF and an ion-trap instrument to identify the site of *in vivo* modification by analysis of unfractionated tryptic and Glu-C digests. In this study, all of the possible sites of phosphorylation were observed as tryptic or Glu-C-derived peptides, and the one site of phosphorylation was identified in both the baculovirus-expressed truncated form of the protein as well as the endogenous full-length form. Both phosphatase treatment and MS/MS fragmentation were employed for confirmation that the peptide was phosphorylated and to determine the site of modification.

In the second approach, advantage was taken of the observation that under ionization conditions that leave most peptide bonds intact, phosphate ester bonds in phosphopeptides can be dissociated at the source (or in a collision cell) of an ESI-MS. When the analysis was conducted in negative-ion mode (the potential on the spraying needle is negative) with the orifice voltage at a high potential (e.g., -350 V), phosphopeptides containing phosphoserine or phosphothreonine yielded signature low-mass fragment ions at 97, 79, and 63 u, and phosphotyrosine-containing phosphopeptide low-mass ions at 79 and 63 u. In the original methods of Huddleston et al. (1993, 1994) and Ding et al. (1994), peptide digests were separated by RP-HPLC. On-line ESI-MS was employed to determine both the mass of the peptide as well as its phosphorylation status by switching the voltage on the orifice between a high potential when scanning (measuring masses) in the low-mass region, to a normal potential when scanning over the remainder of the mass range, in a cyclical manner. Of course, fractions can be collected during the run for subsequent analysis. This is a rapid method to identify which peptides in a given mixture are phosphorylated, as well as what their intact masses are (unless the mixture is too complex and many peptides coelute on the RP-HPLC). However, as with the MALDI-MS approach, this only localizes the modified residues and does not confirm the site of modification until the fractionated peptides are sequenced either chemically or by MS/MS. Another feature of the approach is that even when the RP-HPLC is conducted on a 320- μm -i.d. capillary column, the limit of detection is suggested to be 50 pmol (Huddleston et al., 1993), thereby limiting the RP-HPLC/ESI-MS approach to *in vitro* phosphorylation site analysis.

The ability to spray sample into the ESI-MS at very low flow rates (so called nanospray, due to low nanoliter per minute flow rates; Wilm and Mann, 1994), has dramatically increased the sensitivity of MS/MS sequencing. This method can also be used to advantage for post-translational modification analysis of *in vivo*-generated samples due to the high sensitivity. In addition to the method where high-orifice scanning generates signature low-mass ions for phosphorylated residues, another MS/MS-based approach can also be used in conjunction with a triple quadrupole instrument (see *UNIT 10.21*). This instrument can be run in a number of modes, two of which are described here. In normal MS/MS mode to generate fragment ions from a specific precursor ion (peptide), the first set of quadrupoles (Q1) is set to allow transmission of only the peptide ion of interest into Q2 which in turn is set to transmit all ions, not just a specific m/z into which a curtain of gas (e.g., argon) has been injected. The peptide ions undergo collision-induced decomposition (CID) into sequence-specific fragment ions, whose masses can be determined by scanning Q3. Thus, the fragment ions from a specific precursor ion can be generated and measured. In a mode referred to as precursor (or parent)-ion scanning, the third set of quadrupoles (Q3) are set to transmit only a specific m/z ; in this example for identification of phosphorylated peptides in a mixture, this is set to $m/z = 79$. The collision gas is left on in Q2, and ions are scanned over the mass range in Q1. Therefore, a signal will only be recorded when a fragment ion of 79 u is generated from a parent ion of the mass being scanned at that point in time in Q1. A spectrum is produced of any peptide that following CID produces a fragment ion of 79 u, i.e., a phosphopeptide. The advantage of this approach of precursor-ion scanning is that the phosphopeptides can be selected from a mixture for fragmentation analysis in the normal mode (i.e., select in Q1, fragment in Q2, mass analyze in Q3).

This approach has been employed successfully by Betts et al. (1997) in their identification of sites of *in vivo* phosphorylation on neurofilament proteins (NF-M and NF-L) isolated from rat brain. They separated the neurofilament-enriched fraction from rat brain by SDS-PAGE, digested the protein in the gel, desalted it, and performed nanoESI-MS/MS on the resulting mixtures. They also analyzed peptide mixtures that had been enriched in phosphopeptides by binding the *in-gel* digest eluant to an immobilized metal-affinity column

(IMAC; *UNIT 10.11B*) equilibrated with FeCl_3 followed by elution with Tris-Cl (Betts et al., 1997). They analyzed not only the phosphopeptides but all of the peptides possible to determine whether the phosphorylation was heterogeneous at the identified sites. By using three enzymes, trypsin, Glu-C, and Asp-N, they achieved 81% sequence coverage for NF-L and 64% sequence coverage for NF-M. Interestingly, no sites of phosphorylation were found on NF-L, and the four sites identified on NF-M were shown to be heterogeneous.

Automated Approaches for Identifying Phosphorylation Sites

The nanoESI-MS/MS approach described above provides high-sensitivity analytical capability for both protein identification and post-translational modification determination. The drawbacks are that setup of the device is not rapid (although a number of simpler devices are now becoming available), and the analysis is manual, i.e., an operator manually sets the instrument in all different modes and selects peptides for fragmentation. Other groups have been investigating automating posttranslational modification analysis by constructing integrated on-line systems. These consist of an RP-HPLC-ESI-MS/MS (LC-MS/MS) system for automated MS/MS of separated peptides, with an additional column on-line in front of the RP-HPLC system which provides the specificity to the system. Such columns include an IMAC column (for general capture of phosphorylated peptides), immunoaffinity and SH2-domain affinity column (phosphotyrosine specific), and an enzyme reactor (a tyrosine phosphatase). A general schema for such devices is shown in Figure 10.22.5 and a brief description of these approaches follows.

Watts et al. (1994) used an on-line IMAC column in front of a LC-MS to capture phosphopeptides in a protocol that resulted in determination of the sites of *in vivo* tyrosine phosphorylation of the lymphocyte-specific protein tyrosine kinase ZAP-70. In this approach, standard two-dimensional TLC phosphopeptide maps were produced for both *in vivo* phosphorylated ZAP-70 and recombinant ZAP-70 phosphorylated with recombinant p56lck *in vitro*. From the *in vitro* generated two-dimensional TLC plate, spots were excised, the slurry extracted and recovered peptides subjected to IMAC-LC-MS to determine the mass of the phosphopeptides and identify the sites of phosphorylation. Comparison (including comigration of excised spots) of the *in vivo*- and *in vitro*-

vitro-generated two-dimensional TLC patterns allowed identification of the sites of autophosphorylation and T cell receptor-stimulated phosphorylation. The sensitivity of the system was demonstrated to be ~250 fmol (Watts et al., 1994). This approach provides a high-sensitivity system that complements the extensively utilized two-dimensional TLC mapping procedure (Watts et al., 1996).

Specific capture of tyrosine-phosphorylated peptides has been achieved using an antiphosphotyrosine column in-line with an LC-MS (Kassel et al., 1995). The specificity of the system was demonstrated, but the sensitivity of the approach was not determined. Kassel et al. (1995) also produced a more specific affinity column by immobilizing a recombinant SH2 domain to the first column, thus allowing capture of only tyrosine phosphopeptides containing the specific sequence motif recognized by this domain. Amankwa et al. (1995) developed an “enzyme reactor” system employing a broad-specificity tyrosine phosphatase on-line prior to either capillary zone electrophoresis (CZE)-MS or LC-MS. Comparison of peptide maps with and without passage through the enzyme reactor allowed determination of sites of tyrosine phosphorylation at low levels (2.6 pmol).

Role of MS in Posttranslational Modification Analysis

More than 400 posttranslational modifications have been described to date (Krishna and Wold, 1993), and mass spectrometry has been used extensively in the characterization of many of them (for a list of posttranslational modifications and their masses see *APPENDIX 1B*, Table A.1C.4, or for an extensive on-line list see Dr. K. Mitchell-Hill’s Delta Mass site at <http://www.medstv.unimelb.edu.au/WWWD/OCS/SIVMRDocs/MassSpec/deltamassV2.html>). However, mass spectrometry has yet to be employed in a high-throughput mode for a variety of modifications, and in many cases it is not the primary method of choice in characterization of posttranslational modifications. With the increased sensitivity, availability, and ease of use of these instruments, mass spectrometry will be used more and more in routine analyses to detect and characterize posttranslational modifications. As stated previously, characterization of the posttranslational modifications present on a protein requires an initial measurement of the intact mass of the protein. For electrophoretically separated proteins, this has proven to be a difficult task at low levels

when the protein is eluted from the gel slice for subsequent ESI-MS analysis. Although a few protocols recently have been demonstrated for mass analysis of low-picomole quantities of pure protein eluted from gels (e.g., Schuhmacher et al., 1996; Cohen and Chait, 1997), the methods described previously for direct mass measurement of gel-separated proteins either off membranes or out of gels may simplify this first step in the analysis. Enzymatic digestion and analysis of the resulting fragments allows the region of modification to be determined, and generation of fragment-ion spectra from these peptides in most cases will assign the site of modification. Thus, the ability to characterize small quantities of gel-separated proteins is close to becoming reality.

An extremely promising advance in posttranslational modification analysis is the demonstration by Bean et al. (1995) of the lability of a number of posttranslational modifications to stepped high-orifice scanning in LC-MS analyses as described for phosphorylation analysis. This approach results in the generation of signature ions for specific modifications to indicate their presence on peptides eluting at that retention time, and in combination with MS analysis at normal orifice voltage, the intact mass of the modified peptides. Modifications amenable to stepped high-orifice scanning include phosphorylation, palmitoylation, sulfation, and glycosylation (Bean et al., 1995). In the case of glycosylation the presence of individual classes of carbohydrates present on individual peptides—hexose, hexosamine, and neuraminic acid—are revealed. Fragmentation of the peptide in an automated mode may reveal the site of modification. However, in some cases (e.g., glycosylation), the modifying group has to be removed for sequence-specific fragment-ion data to be obtained.

Identification of the site of modification is critical to complete analysis, but if the modification is not stable to the mass spectrometry ionization or fragmentation process, then the modifying group needs to be removed and in doing so, “tag” the site from which it was removed. In this case the peptide is then fragmented and the site of former modification identified. Gonzalez et al. (1992) used this approach to identify sites of N-glycosylation by using the enzyme peptide-*N*-4(*N*-acetyl- β -glucosaminyl)asparagine amidase F (also known as PNGase F) in the presence of 50% H₂¹⁸O. PNGase F completely removes the carbohydrate side chain from the asparagine residue and in so doing results in conversion of this

residue to aspartic acid, which is 1 u heavier than asparagine following incorporation of H₂O from the solvent (see *UNIT 17.14A*). By conducting the reaction in 50% (v/v) H₂¹⁸O, 50% of the oxygen atoms incorporated during the removal of the carbohydrate side chain and conversion of asparagine to aspartic acid will have a mass 2 u greater than normal aspartic acid (see Fig. 10.22.6). Therefore, a pair of peptides differing in mass by 2 u will be produced following this reaction. MS/MS analysis of this peptide pair will result in doublets 2 u apart for all fragment ions containing the site of modification thereby allowing identification of the site of former modification (Gonzalez et al., 1992).

MS/MS analysis of peptides containing O-linked sugar or phosphate on serine and threonine residues does not always allow unambiguous determination of the site of modification due to the lability of the O-linked modifying group; often significant neutral loss occurs during MS/MS, complicating the analysis. However, removal of either of these modifying groups by β -elimination results in dehydration of the serine and threonine residues, leaving unique residue masses for each, 18 u less than normal (see Fig. 10.22.6; see *UNIT 17.15B* for β -elimination protocols applied to glycosylated peptides). This has been applied to determination of sites of O-GlcNAc modification of intracellular proteins and to characterize sites of phosphorylation in the highly phosphorylated profilaggrin (Resing et al., 1995; Greis et al., 1996). In both cases, the altered residue mass (-18 u for each site of modification) was used to localize the peptides upon which the modification occurred, and the site was identified by MS/MS. Greis et al. (1996) demonstrated the ability to determine the intact mass of glycopeptides by LC-MS analysis of the native sample and, following β -elimination, the site of glycosylation on the peptides. Resing et al. (1995) noted that MS/MS fragmentation was more pronounced at the peptide bonds either side of the dehydrated residue thus facilitating analysis of the fragment-ion spectrum.

Tagging sites of modification by changing the mass of the amino acid carrying the modifying group provides a powerful tool in determining the site of modification. Conducting MS and MS/MS analysis of the sample prior to removal of the group also allows some characterization of the modifying group. Interestingly it has recently been demonstrated that mixtures of N-linked oligosaccharide structures can be determined from gel-separated proteins at the

low microgram level by in-gel PNGase F digestion followed by MALDI-MS analysis, after which the remaining protein can be digested for subsequent peptide-mass mapping experiments (Kuster et al., 1997).

HIGH-THROUGHPUT PROTEIN IDENTIFICATION

The highest-resolution protein separation method is still two-dimensional gel electrophoresis. Two-dimensional gel electrophoresis provides the ability to display literally thousands of proteins in one experiment, revealing their relative levels of expression and, depending on how the sample was prepared, their subcellular localization and predetermined posttranslational modifications (i.e., by radiolabeling with specific metabolic precursors). Since the method of two-dimensional gel electrophoresis was first introduced in 1975 (Klose, 1975; O'Farrell, 1975; Scheele, 1975; also see *UNIT 10.3*), a frustrating aspect has been the inability to identify individual proteins and extensively characterize their modifications. This unit and others in this volume (and *Current Protocols in Protein Science*) describe the increasing ability to identify minute quantities of gel-separated protein, but large-scale identification of many proteins in a two-dimensional gel electrophoresis pattern has only recently begun to be addressed successfully.

One semiautomated approach uses existing methods for parallel enzymatic digestion of excised spots and automated loading of a fraction of the digest onto a MALDI-MS plate for subsequent unattended data generation and capture followed by peptide-mass searching (Shevchenko et al., 1996). This approach was used in a yeast proteome project where proteins isolated by two-dimensional gel electrophoresis were identified using a two-part strategy: peptide-mass searching employing an automated 32-port parallel enzyme digestion robot (Houthaeve et al., 1995), followed by automated MALDI-MS with delayed-extraction of a small aliquot of the peptide digest and subsequent automated peptide-mass searching. If this didn't conclusively identify the protein, nano-ESI-MS/MS to generate a sequence tag was undertaken using half of the remaining sample after it was reduced in volume and cleaned up using a microdesalting step. Peptide-sequence tags generated from a number of peptides in the mixture were then used in searches to identify the protein. If this was not successful, then the remainder of the digest could be derivatized by methyl esterification

Figure 10.22.6 “Tagging” sites of posttranslational modification for mass spectrometric analysis. **(A)** Tagging sites of N-linked glycosylation. PNGase F is used to remove N-linked carbohydrate side chains in the presence of 50% H₂¹⁸O (50% normal water) changing the asparagine residue (residue mass 114 u) to an aspartic acid residue (which exists as a doublet of residue masses 115 u and 117 u). **(B)** Tagging sites of O-linked phosphorylation or glycosylation. β -elimination (base hydrolysis) will remove O-linked phosphate or sugar from threonine (residue mass 103 u, shown) or serine (residue mass 87 u) residues and in doing so dehydrate the side chain resulting in a 18 u decrease in mass to yield dehydroamino-2-butyric acid (residue mass 83 u) and dehydroalanine (residue mass 69 u) respectively. The amino acid residues of interest are bracketed.

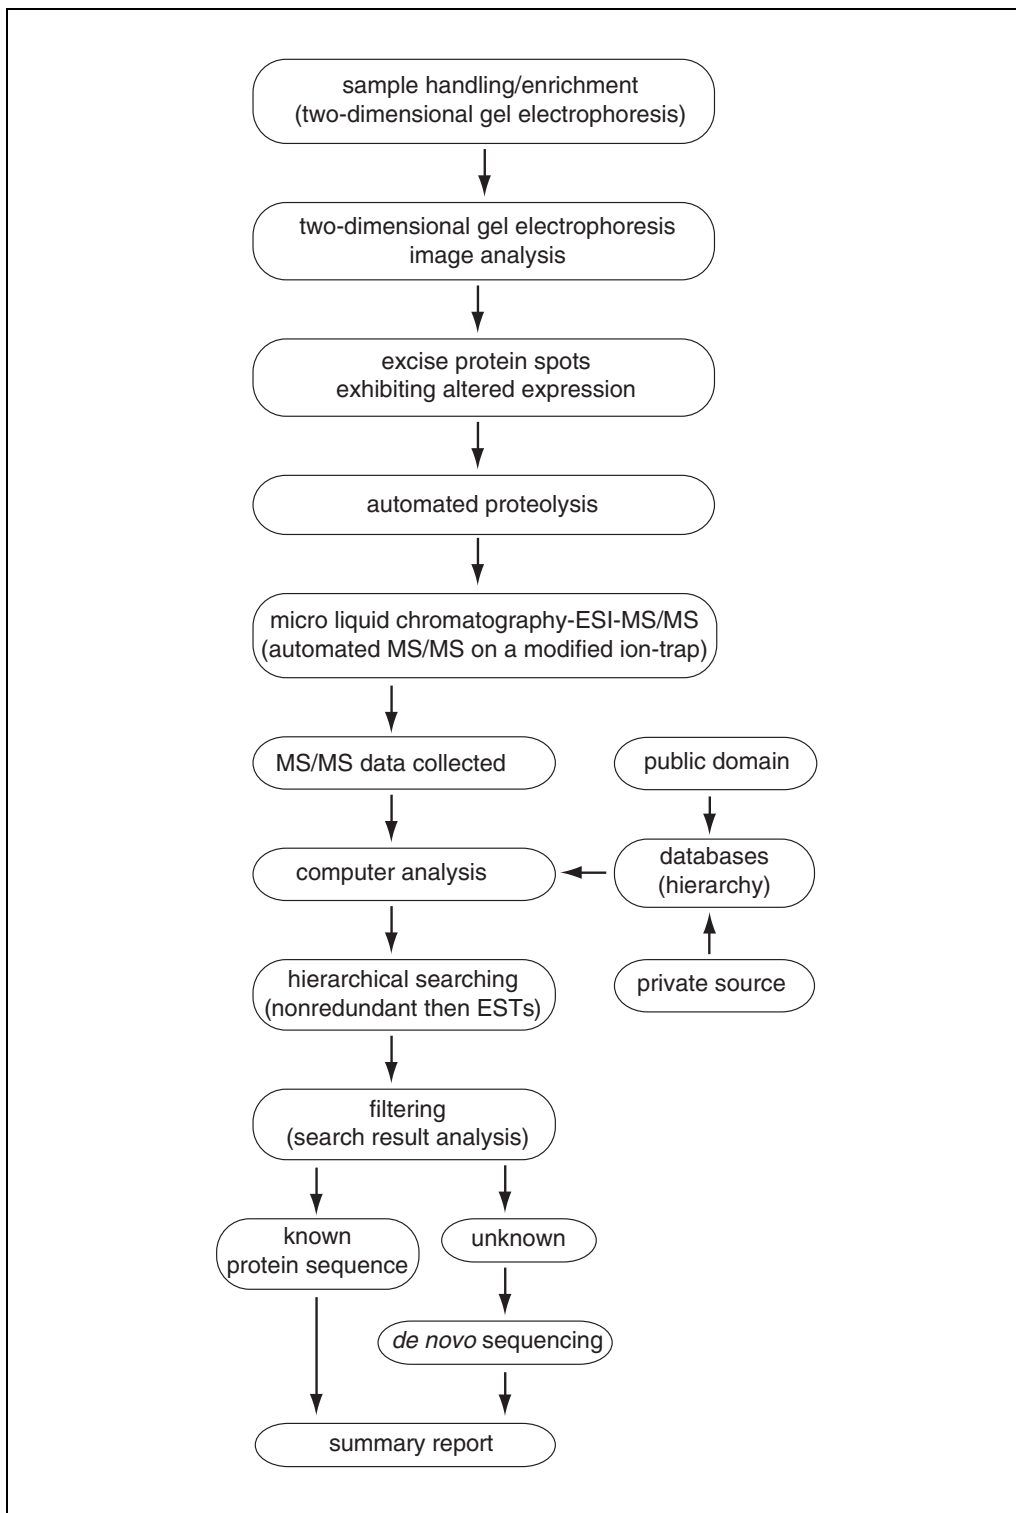

Figure 10.22.7 A scheme for automated identification of proteins exhibiting altered expression when assayed by two-dimensional gel electrophoresis (adapted from figures supplied by Dr. R. B. Parekh, Oxford GlycoSciences, Abingdon, UK). The samples to be analyzed are fractionated as appropriate prior to two-dimensional gel electrophoresis separation using an automated system. The two-dimensional gel electrophoresis–resolved proteins are imaged and differences between samples highlighted by a computer system, which then excises protein spots from the gel and digests them—all under robotic control. The digest is then separated by micro-LC-ESI-MS/MS in an automated mode, and the MS/MS spectra are transferred to a database from which automated searches are conducted against protein and translated nucleotide (including ESTs) databases. If the sequence resides in a database, the match is determined; if not, the MS/MS pattern is used to interpret the sequence *de novo*.

and subjected to an additional nano-ESI-MS/MS analysis to interpret the sequence de novo from the fragment-ion spectra (Shevchenko et al., 1996). This approach was able to identify 150 yeast proteins separated by two-dimensional gel electrophoresis in a high-throughput mode.

A fully automated system has been developed by Oxford GlycoSciences (Dr. R. B. Parekh, pers. comm.), where two-dimensional gels are run under computer control followed by automated image analysis of fluorescently labeled proteins. This allows the user to select spots of interest on a computer screen for automated excision, digestion, LC-MS/MS, and SEQUEST software analysis (see Fig. 10.22.7). For large-scale two-dimensional gel electrophoresis projects this type of approach can be advantageous, and it fulfills the requirements of a proteomics approach to two-dimensional gel electrophoresis-separated proteins. However, these approaches are most likely to be adapted only in core facilities or even more specialized laboratories.

When the mixtures are less complex, a chromatography-based approach has been demonstrated to provide rapid automated protein identification without employing any steps of electrophoresis. All of the approaches described so far analyze peptides derived from one or a few proteins and therefore, a number of fragment-ion spectra are obtained from each protein, and these allow redundant identifications. Other automated approaches rely upon only one peptide fragment-ion spectrum for identification as the protein mixture is digested prior to peptide separation. This provides a simpler approach for automation, but at least one peptide from each protein in the mixture must be analyzed for a completely successful analysis to be performed.

Enzymatic digestion of relatively complex protein mixtures followed by data-dependent LC-MS/MS (i.e., the mass spectrometer selects the peptides on which to perform MS/MS on-the-fly) and automated uninterpreted fragment-ion searching of sequence databases using the SEQUEST program, has been demonstrated to be capable of identifying many components within a mixture (McCormack et al., 1997). The key to the success of such an approach is the ability to isolate mixtures of limited complexity that are of biological interest. Yates and colleagues (McCormack et al., 1997) demonstrated identification of components of a co-immunoprecipitation (see UNIT 10.16), a micro-

tubule complex, as well as a set of protein standards, to demonstrate the ability to detect a component at lower concentration in a mixture where the other components were at a much higher level. This analysis revealed that fragment-ion spectra from only a few peptides were usually obtained, but of course, in using this approach only one MS/MS spectrum needs to be obtained per protein if the spectral quality is good enough. The main advantage of this approach is the speed with which the analysis can take place compared even with automated two-dimensional gel electrophoresis approaches and the relative simplicity of the setup. The described system uses capillary LC which allows low amounts of proteins to be analyzed. The disadvantages of the approach include: (1) difficulty in comparing relative protein levels, aside from presence or absence; (2) generation of MS/MS data from contaminants when they could have been excluded from analysis if a comparative (e.g., electrophoretic) analysis had been performed; and (3) the limited number of components that can be analyzed in one experiment. However, given these caveats there are still many applications that could benefit from an analytical approach capable of rapidly identifying a mixture of protein components through analysis of their derived peptides. For example, in addition to the examples presented above, identification of the major components present during a specific purification step may allow the purification to be directed to remove unwanted components. An increased number of peptide components could be analyzed if a two-dimensional chromatographic system were employed.

Opiteck et al. (1997b) described a two-dimensional chromatography system where peptides were separated by size-exclusion chromatography (SEC; UNIT 10.14) and loaded alternately onto one of two HPLC columns for sequential, rapid RP-HPLC separation followed by ESI-MS analysis. Four-minute SEC fractions were loaded onto the RP-HPLC column, and while this was being separated over 3 min (with 1 min reequilibration), the other HPLC column was being loaded. The two HPLC columns were run alternately over 160 min, each running 20 gradients in that time (40 consecutive gradients were run by the one set of HPLC pumps). This approach provided a much greater resolving power than either method alone and in an automated format (Opiteck et al. 1997b). Of course, such a system could be used in conjunction with an ESI-MS

system capable of data-dependent fragmentation, yielding fragment-ion spectra for each peptide component as well.

In an extension of the LC-MS/MS method, additional on-line steps have been added at the beginning to automate the entire analysis by allowing (1) immunoaffinity chromatography purification, (2) desalting and buffer exchange on a mixed-bed strong ion-exchange absorbent, (3) digestion on an immobilized trypsin column, (4) capture of the tryptic peptides on a short perfusion capillary reversed-phase column, and (5) separation on an analytical reversed-phase column with the column effluent being analyzed by ESI-MS(/MS) (Hsieh et al., 1996). The entire computer-controlled setup requires an autosampler, five columns, and three 10-port switching valves to allow all of the steps to be performed on-line without any manual transfers of material (Hsieh et al., 1996). The method was described only for analysis of protein purified by the system, but it may be able to be extended to the analysis of many components of a complex protein mixture.

CONCLUSION

This unit has provided the reader with a glimpse into some new technologies that have been developed for protein analysis. Not all aspects of protein analysis have been covered, with an emphasis being placed on protein identification and characterization. However, it is hoped that the reader will have a better understanding of how mass spectrometry techniques can be used to answer questions of biological importance both rapidly and accurately. Proteome analysis in its broadest definition should provide evidence of the steady-state level of expression for all individual gene products in a cell and their modifications at a defined point in the life of the cell. In its simplest form, it can be used just to confirm open reading frames in DNA sequences. In addition, unless the cell population is truly synchronous, such an analysis needs to be undertaken on a very small number of cells. Unless radiolabelling of newly synthesized proteins is performed, only the steady-state levels of proteins can be determined. In addition to expression levels, the subcellular localization of each protein needs to be identified, and this is an extremely complex process requiring many parallel experiments. Such an analysis is still far from being realized without using a large number of experimental protocols. However, with the tools currently in hand, the prospect of attaining such

a goal in a reasonable time frame looks a little less daunting.

Difference Gel Electrophoresis (DIGE) Using CyDye DIGE Fluor Minimal Dyes

UNIT 10.23

DIGE (difference gel electrophoresis) is a technique used for labeling protein samples, prior to electrophoresis, with different fluorescent dyes that have distinct spectral characteristics, to analyze quantitative differences between multiple samples on the same gel. In this technique for multiplex analysis of related but different protein samples, the labeled samples are mixed together and then subjected to gel electrophoresis. The reagents and technical advice to perform this technique using CyDyes are available from Amersham Biosciences (now part of GE Healthcare; http://www4.amershambiosciences.com/aptrix/upp01077.nsf/content/na_homepage). Three different CyDye DIGE fluor minimal dyes are available for DIGE analysis: CyDye DIGE fluor Cy2, CyDye DIGE fluor Cy3, and CyDye DIGE fluor Cy5. Two-dimensional (2-D) gel electrophoresis (UNITS 10.3 & 10.4) is usually carried out for multiplex analysis of CyDye-labeled protein samples. However, prior to carrying out the 2-D separation, it is important to check the efficiency of labeling of protein samples by one-dimensional (1-D) sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (SDS-PAGE; UNIT 10.2A). Other potential applications of 1-D PAGE of CyDye-labeled proteins are discussed in Background Information.

LABELING OF PROTEINS WITH CyDye DIGE FLUOR MINIMAL DYES

**BASIC
PROTOCOL**

There are three different steps that need to be performed for labeling of proteins with CyDye DIGE fluor minimal dyes: (1) preparation of the CyDye DIGE fluor minimal dye stock solution, (2) dilution of the CyDye DIGE fluor minimal dye stock solution, and (3) labeling of protein samples with CyDye DIGE fluor minimal dyes. The same protocol is applicable to CyDye DIGE fluor Cy2, CyDye DIGE fluor Cy3, and CyDye DIGE fluor Cy5. The entire labeling procedure can be carried out on the same day or on different days.

The protocol described here is according to the manufacturer's instructions for the Ettan DIGE system (Amersham Biosciences).

Materials

CyDye DIGE fluor minimal dyes (store at -20°C in dark)
Dimethyl formamide (DMF)
Protein sample (see Support Protocol)
10 mM lysine
2 \times gel loading buffer (see recipe)
5% to 15% (w/v) acrylamide gradient gel (UNIT 10.2A)
Low-fluorescence glass plates (Amersham Biosciences)
Typhoon variable mode imager 9400 series (Amersham Biosciences) *or*
charge-coupled device (CCD)-based imaging system (AC1 Autochemisystem
from UVP) with UV transilluminator (UVP)
ImageQuant software (Amersham Biosciences) or similar software
Additional reagents and equipment for 1-D SDS-PAGE (UNIT 10.2A)

Prepare CyDye DIGE fluor minimal dye stock solution

1. Remove CyDye DIGE fluor minimal dye tubes from -20°C and allow tubes to reach room temperature (in the dark) before opening.

Absorption of moisture will lead to the hydrolysis of the dyes.

Each tube contains a known amount of a specific CyDye DIGE fluor minimal dye.

**Analysis of
Proteins**

10.23.1

2. Add required volume of DMF to each tube of stock CyDye DIGE fluor minimal dye to reconstitute the dye to a final concentration of 1 nmol/ μ l.
3. Close the cap of microcentrifuge tube containing dye, vortex vigorously for 30 sec to dissolve the dye, and centrifuge 30 sec at $12,000 \times g$ in a tabletop microcentrifuge. Store the stock solution of the dyes at -20°C . Wrap tubes with aluminum foil.

Dilute stock solution

4. Dilute the stock solution of each dye to the required working dye concentration before using in the labeling reaction. Briefly microcentrifuge the dye stock solution (30 sec) in a microcentrifuge at room temperature.

This is to prepare 5 μ l of working dye solution (400 pmol/ μ l). Follow the same ratio for preparing larger volumes of working dye solution.

5. Add 3 μ l DMF to a microcentrifuge tube. Add 2 μ l of dye stock solution to the tube. Ensure that all dye is removed from the pipet tip by pipetting up and down several times into the working dye solution.

The commonly recommended dye/protein ratio is 400 pmol of dye for labeling 50 μ g of protein. Although a different dye/protein ratio can be used, it must be tested by 1-D PAGE for optimum labeling. Since the labeling efficiencies of the CyDyes depend on the dye/protein ratio, it is recommended that for the same experiment, the same dye/protein ratio should be used for all samples.

The working dye solution is only stable for 2 weeks at -20°C .

Label protein samples

6. Add the required volume of protein sample (see Support Protocol) containing 50 μ g of protein to a microcentrifuge tube. Add 1 μ l of the working dye solution to the microcentrifuge tube containing the protein sample.

For labeling with a CyDye DIGE fluor minimal dye, the recommended concentration of the protein sample is 5 to 10 mg/ml. However, protein samples of 1mg/ml have been labeled successfully. If necessary, the process can be scaled up for labeling a larger amount of samples. All new protein lysates or samples containing new chemical components should always be checked for successful labeling.

For this example, 50 μ g of protein is labeled with 400 pmol of dye.

7. Vortex to mix the dye and protein solution thoroughly and microcentrifuge for 30 sec.
8. Wrap tubes with aluminum foil to carry out the labeling reaction in the dark. Leave on ice for 10 min to complete the labeling reaction.
9. Stop the reaction by adding 1 μ l of 10 mM lysine. Mix and briefly microcentrifuge.
10. Immediately analyze the sample by 1-D PAGE (steps 11 to 15).

If necessary, the aluminum foil-wrapped tubes may be stored for up to 3 months at -70°C (in dark) before performing gel electrophoresis.

Analyze samples by 1-D PAGE

11. Transfer the labeled sample from step 9 to a clean microcentrifuge tube. Add an equal volume of $2\times$ gel loading buffer to the CyDye-labeled samples.
12. Heat the samples 5 min at 95°C to carry out the reduction of the protein samples.
13. Pour a 5% to 15% acrylamide gradient gel using low-fluorescence glass plates.
14. Load the serially diluted protein samples (5 to 25 μ g) in successive lanes on the gel. Carry out the electrophoresis until the bromophenol blue (the dye front) almost reaches the bottom of the gel.

Table 10.23.1 Detection of Fluorescence of CyDye DIGE Fluor Minimal Dyes: Laser Excitation Source and Emission Filters^a

Fluorescent dye	Laser excitation source (nm)	Emission filter (nm) ^b
CyDye DIGE fluor Cy2 minimal dye	Blue2 (488)	520 BP 40
CyDye DIGE fluor Cy3 minimal dye	Green (532)	580 BP 30
CyDyeDIGE fluor Cy5 minimal dye	Red (633)	670 BP 30

^aGade et al. (2003).

^bBP, bandpass.

Figure 10.23.1 This photograph of gels depicts 50 μg of BSA labeled with 400 pmol of Cy2, Cy3, or Cy5 using CyDye DIGE fluor minimal dyes. Lanes 1, 2, and 3 were loaded with 5 μg BSA labeled with Cy2, Cy3, and Cy5, respectively, on a polyacrylamide gel (5% to 12.5% w/v acrylamide) and subjected to 1-D PAGE. Images were captured using a UV-transilluminating light source and CCD camera (AC1 Autochemisystem, UVP). The following emission filters were used for the detection of the CyDye-labeled proteins: green filter (515 to 570 nm) for Cy2-labeled BSA (**A**); red filter (570 to 640 nm) for Cy3-labeled BSA (**B**); and blue filter (650 to 690 nm) for Cy 5-labeled BSA (**C**).

15. After electrophoresis, take the gel cassette out of the apparatus and thoroughly clean the outside of the glass plates with deionized water. If using plastic backing, take that off before taking images of the gel.
16. Take the images of the gel at the appropriate wavelength using a laser-based scanner such as a Typhoon variable mode imager.

The excitation and emission wavelengths used for all three CyDyes are listed in Table 10.23.1. A 100- μm pixel resolution is recommended to obtain accurate image information.

Alternatively, images can be captured using a UV transilluminator, appropriate emission filters, and a CCD camera (Fig. 10.23.1).

17. Quantify the labeling of each protein sample using ImageQuant software or similar software available from other vendors.

PREPARATION OF SAMPLE FOR LABELING

Prior to carrying out the labeling reaction, the samples have to be prepared in a way compatible with the labeling reaction. Since most of the biological samples to be analyzed by DIGE are usually of cellular origin, this protocol focuses on such samples.

Materials

Cells of interest: 20 to 50 ml of microbial culture medium (e.g., *Escherichia coli*, $\sim 1 \times 10^8$ cells/ml), 20 to 50 ml of tissue culture medium for mammalian cells ($\sim 5 \times 10^5$ cells/ml), or ~ 200 mg of tissue

Cell wash buffer (see recipe)

Lysis buffer (see recipe)

1. Wash cells with cell wash buffer.

This wash allows the removal of the cell culture medium or tissue fluids, depending on how the cells were collected. It will not lyse the cells.

2. Lyse cells in an appropriate lysis buffer.

The pH of the lysis buffer is important since maximum labeling efficiency is obtained at a pH between 8.0 and 9.0. Since the pH of the Tris-Cl buffer is temperature dependent and the labeling reaction is carried out in the cold, it is important to check and adjust the pH when the solution is cold.

3. Collect cells by centrifuging 10 min at $12,000 \times g$, 4°C . Discard any liquid present.

4. Resuspend the cell pellet in 1 ml of cell wash buffer. Centrifuge 10 min at $12,000 \times g$, 4°C , and repeat this wash step two additional times.

5. Resuspend the final cell pellet in the lysis buffer, leave on ice for 10 min, and then sonicate intermittently to lyse the cells.

6. Centrifuge cell lysate 10 min at $12,000 \times g$, 4°C , and collect the supernatant. Discard the pellet.

The pH of the supernatant should be checked by spotting a few microliters on a pH indicator strip. If the pH is below 8.0, adjust, e.g., by careful addition of 50 mM sodium hydroxide.

7. Store the cell lysate up to several months at -70°C until further use.

Before performing the labeling reaction, the protein concentration of the lysate should be determined with a protein assay kit that is detergent-, urea-, and thiourea-compatible.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Cell wash buffer

10 mM Tris-Cl, pH 8.0

5 mM magnesium acetate

Store for several months at 4°C or at room temperature as long as there is no visible microbial growth.

Gel loading buffer, $2\times$

120 mM Tris-Cl, pH 6.8

20% (v/v) glycerol

4% (w/v) SDS

200 mM dithiothreitol

Store for several months at room temperature.

Lysis buffer

7 M urea
2 M thiourea
30 mM Tris·Cl, pH 8.5
4% (w/v) CHAPS
Alternatively, use:
8 M urea
30 mM Tris·Cl, pH 8.5
4% (w/v) CHAPS

Store in small aliquots for several months at 4°C.

COMMENTARY

Background Information

In 1997, Ünlü and co-workers first described the DIGE technique to profile proteins (Ünlü et al., 1997). It involves the pre-electrophoretic labeling of samples with one of three spectrally distinct fluors, cyanine-2 (Cy2), cyanine-3 (Cy3), or cyanine-5 (Cy5). More than one set of samples is prepared, each of which is first labeled with a different CyDye, and then combined. The sample containing the mixture is then subjected to gel electrophoresis and viewed individually by scanning the gel at different wavelengths, thus circumventing problems with spot matching between gels. Image analysis programs are then used to generate volume ratios for each spot. Volume ratios essentially describe the intensity of a

particular spot in each test sample, and thus enable expression differences to be identified and quantified. This methodology has since been commercialized by Amersham Biosciences and all three CyDye DIGE fluors are available.

CyDye DIGE fluors have a reactive *N*-hydroxysuccinimide ester group that forms a covalent bond with the ϵ -amino group of lysine side chains (Fig. 10.23.2). The content of lysine is generally very high in most proteins such that an excessive amount of dye is required to direct the reaction to completion. When the proteins undergo such extensive chemical modification, they may become insoluble (Ünlü et al., 1997; Patton, 2002) and cannot be analyzed using 1-D PAGE or 2-D gel electrophoresis. However, with the

Figure 10.23.2 Schematic presentation of the reaction of CyDye DIGE fluor minimal dyes containing *N*-hydroxy succinimidyl (NHS) ester group with the ϵ -amino group of a lysine residue of a protein. A covalent amide bond is formed between the NHS ester active group of the CyDyes and the ϵ -amino group of the lysine residue of a protein.

Table 10.23.2 Absorption and Emission Maxima of CyDye DIGE Fluor Minimal Dyes

Fluorescent dye	Absorption maxima (nm)	Emission maxima (nm)
CyDye DIGE fluor Cy2 minimal dye	482	501
CyDye DIGE fluor Cy3 minimal dye	552	570
CyDye DIGE fluor Cy5 minimal dye	640	660

Table 10.23.3 Molecular Weight Added to Proteins Following Labeling with CyDye DIGE Fluor Minimal Dyes

Fluorescent dye	Molecular weight added to protein (Da)
CyDye DIGE fluor Cy2 minimal dye	435.52
CyDye DIGE fluor Cy3 minimal dye	467.69
CyDye DIGE fluor Cy5 minimal dye	465.67

minimal fluor technology, labeling reactions are designed such that the stoichiometry of protein to fluor results in only 1% to 2% of the total number of lysine residues being labeled.

All three CyDye DIGE fluor minimal dyes have different absorption and emission spectra (Table 10.23.2). Because of the different absorption and emission spectra, the CyDyes can be used for multiplexing of up to three different protein samples on the same 1-D or 2-D gel. Due to the high degree of sensitivity of CyDye labeling, a single protein as low as 125 pg can be detected following polyacrylamide gel electrophoresis. A linear response can be obtained with protein concentrations up to five orders of magnitude. Labeling with CyDyes allows a greater level of detection of protein spots than Coomassie Blue and a comparable level of detection of protein spots as with silver stain or SYPRO Ruby (Tonge et al., 2001; Gharbi et al., 2002; Gade et al., 2003).

The CyDye DIGE fluor minimal dyes are matched for charge and mass. As a result, if the same protein is labeled with different CyDyes, they will migrate to the same position following 1-D PAGE (resolved according to molecular mass) or 2-D gel electrophoresis (resolved according to isoelectric point in the first dimension and molecular mass in the second dimension). At a neutral or acidic pH, the amino acid lysine carries a net +1 charge. CyDye DIGE fluor minimal dyes also carry a +1 charge. During its reaction with the lysine residues of proteins, the intrinsic +1 charge in the dye molecule compensates for the loss of the +1 charge of the lysine side chain. Hence, the isoelectric points of the proteins do not alter significantly. Also, due to the addition of each CyDye DIGE fluor minimal dye, the mass of

the protein is altered ~500 Da (Table 10.23.3). Other than the low-molecular-weight proteins, this mass shift is not significant on 1-D PAGE or 2-D gel electrophoresis.

The advantage of multiplex analysis using CyDyes is the ability to use the same internal standard (a pool of all the samples within an experiment) on every 1-D PAGE or 2-D gel electrophoresis. A major drawback of 2-D gel electrophoresis, where each sample is loaded on a separate gel, is the gel-to-gel variation observed with the separation profile, even between the same samples. This can interfere with the interpretation of the data. Inclusion of an internal standard and running different samples on the same gel is particularly useful to overcome the above problem.

Although DIGE is mainly used for 2-D gel electrophoresis, there are some definitive applications of 1-D PAGE using DIGE technology. For example, before carrying out a 2-D gel electrophoresis using DIGE technology, it is necessary to optimize the protein/dye ratio for the labeling reaction and test the efficiency of the labeling reaction using 1-D PAGE. This is particularly important for labeling new samples or samples containing any new chemical component.

One-dimensional PAGE using DIGE technology is also good for comparing expression of recombinant proteins under different sets of experimental parameters, such as variation of growth conditions and use of different microbial strains. It can also be used for comparative analysis of relative protein profiles in fractions obtained from chromatographic separation of a mixture of cellular extracts.

The technique is also useful for comparing differential expression of proteins in

isolated fractions of cellular extracts that are less complex in terms of number of proteins present or are difficult to separate by 2-D gel electrophoresis. Membrane fractions, such as bacterial outer-membrane protein fractions from different strains (e.g., pathogenic and non-pathogenic strains of the same bacterial species), seem to be well suited for 1-D PAGE using DIGE technology. Identification of these classes of proteins is very important for drug and vaccine discovery. These proteins are often underrepresented in 2-D gel electrophoresis due to their insolubility under conditions used in the isoelectric focusing step of 2-D gel electrophoresis. On the contrary, use of SDS in 1-D PAGE aids in the solubilization of membrane proteins. Due to compatibility of CyDye minimal labeling technique with mass spectrometry, the proteins of interest can be subsequently characterized by mass spectrometry following trypsin digestion of the gel bands of interest. In this connection, 1-D PAGE, rather than 2-D gel electrophoresis, followed by mass spectrometric analysis was used to identify a large number of proteins in the membrane fractions of *Streptococcus pneumoniae* as putative vaccine candidates (Chakravarti et al., 2002).

The images obtained following 1-D PAGE using DIGE technology can be analyzed by appropriate 1-D image analysis software such as ImageQuant (Amersham Biosciences) and expression of protein(s) can be compared. Subsequently, the bands of interest can be excised, subjected to trypsin digestion and identified by mass spectrometry.

Critical Parameters

General considerations

Since CyDyes are transported as dry powders in microcentrifuge tubes, the powder may spread around the inside surface of the tube during transportation. Therefore, in order to achieve maximum recovery, the reconstituted dye solution should be pipetted around the tube (and the lid) to resuspend all of the dye powder.

Once reconstituted in DMF, the dye is stable for 2 months at -20°C or the date of expiry, whichever is earlier. The dye should be stored in the absence of light. After its use, it should be returned to -20°C as soon as possible to minimize its exposure to the room temperature. The tubes should be wrapped with aluminum foil.

High quality anhydrous DMF ($\text{H}_2\text{O} \leq 0.005\%$, purity $\geq 99.8\%$) should be used. Care should be taken so that there is no water contamination. When the bottle containing DMF

is opened, it starts to generate amine compounds, which react with the CyDyes. This will decrease the concentration of dye available for protein labeling. A new bottle of DMF should be opened every 3 months. The same quality of DMF should also be used for dilution of the stock solution.

Wear powder-free laboratory gloves. The powder present in the gloves may fluoresce and interfere with the quality of the image.

Although different protein assay kits are available, it is important to use kits appropriate for samples containing detergents (as well as urea and thiourea if the lysis solution contains these components).

Labeling of the proteins

Care should be taken about the following: use the recommended protein concentration of 5 to 10 mg/ml; maintain the recommended pH of 8 to 9. A buffer such as Tris or bicarbonate is useful for maintaining the pH range. The buffer concentration should be ~ 30 mM (a high buffer concentration may affect the isoelectric focusing step in 2-D gel electrophoresis). If the appropriate buffer is not used, it may interfere with the labeling efficiency. Also, presence of any primary amine in the solution before labeling should be avoided since these will compete with the proteins for the dye. The presence of the following compounds is not recommended: reducing agents such as >2 mg/ml dithiothreitol, >1 mM (Tris-[2-carboxyethyl]phosphine) TCEP, β -mercaptoethanol at any concentration; detergents are compatible with the labeling reactions at the following concentrations: up to 0.25% for SDS, up to 1% for NP-40, and $<1\%$ for Triton X-100.

Precautions following SDS-PAGE analysis of labeled proteins with CyDye DIGE fluor minimal dyes

Since the proteins in the gel diffuse after electrophoresis is complete, scan the gels and capture the images of the gels immediately following SDS-PAGE analysis and keep the gels between the glass plates. Alternatively, the gels should be stored in SDS-PAGE electrophoresis running buffer in the dark at ambient temperature. However, even those gels should be scanned on the same day. If stored for a longer period of time, a storage temperature of 4°C is recommended and the gels should be kept moist to avoid tearing. Before scanning or taking the image, the gels should attain room temperature. However, the possibility of diffusion of the proteins will still remain. Although the problem of diffusion can be avoided by fixing

the proteins, it is not recommended to do the fixing before scanning because it can interfere with subsequent image analysis using appropriate software such as DeCyder Differential Analysis Software.

Most plastic materials will have intense fluorescence at the wavelength used for fluorescent dyes. Hence, it is recommended that gels with any kind of plastic backing should not be used. For spot picking, the 2-D gel may be placed on a low-fluorescence glass plate. If excision of the spots (2-D gel electrophoresis) or bands (1-D PAGE) is not necessary, the gel can be taken off the plastic backing and images can be captured.

Troubleshooting

If optimal labeling of protein(s) is not observed, the following points should be taken into consideration.

The DMF used should be of high quality as mentioned in Critical Parameters. The presence of moisture in the DMF may lead to the hydrolysis of the CyDye fluor minimal dyes, thereby reducing their effective concentrations and, hence, the labeling efficiencies. Similarly, exposure to light will cause photodegradation of the dyes, therefore, reducing their labeling efficiencies.

An appropriate protein assay reagent compatible with detergent (as well as urea and thiourea if used in the lysis solution) should be used for accurate estimation of protein concentrations to obtain efficient labeling. See UNIT 10.1A for additional details.

The pH of the solution should be checked before labeling and should be ≥ 8.0 .

The samples should not contain any primary amines or thiol reagents at a concentration greater than that mentioned earlier.

Anticipated Results

If one follows the protocol as described above, following 1-D PAGE, the protein(s) labeled with Cy2, Cy3, and Cy5 using CyDye DIGE fluor minimal dyes can be visualized when the gels are scanned using a suitable scanner such as the Typhoon variable mode imager 9400 series (Amersham Biosciences) or the AC1 Autochemi System (UVP; see Fig. 10.23.1).

Time Considerations

Making the CyDye solution should take 15 min. Preparing the protein samples (see Support Protocol) may take >1 hr. The labeling reaction requires 45 min, and the separation

of the labeled proteins by gel electrophoresis can take 45 min to 5 hr, depending upon the gel format used. Scanning and image capture analysis will take 15 min to 1 hr or longer depending upon the type of scanner used to capture the images.

Solution Radioimmunoassay of Proteins and Peptides

UNIT 10.24

**BASIC
PROTOCOL**

Radioimmunoassays (RIAs) allow the identification and quantitation of molecules with endocrinological, immunological, neurological, and toxicological functions. In particular, they are useful for assaying specific proteins (or peptides) in a complex mixture (e.g., plasma, serum, cerebrospinal fluid, urine, tissue culture media, cell lysates, or tissue homogenates). There are two formats for RIAs: solution (homologous) and solid-phase (UNIT 11.17). Solid-phase assays do not work well with small peptides, since the antigen must have two antigenic sites (one for each antibody used in the assay). This unit presents a solution RIA using a double-antibody/polyethylene glycol (PEG) method, in which a secondary antibody and PEG are used to precipitate an antigen bound to a primary antibody. The amount of protein or peptide antigen in an unknown sample is determined based on its ability to compete with a radiolabeled protein or peptide tracer for binding to the primary anti-protein or anti-peptide antibody, as illustrated in Figure 10.24.1. The protocol described here is based on a method developed by LINCO Research (St. Charles, Missouri; see Internet Resources) for measuring primate leptin in plasma, serum, and tissue culture media.

Prior to developing an RIA, a sufficient quantity of the protein (or peptide) being assayed must be isolated and purified. It will be used in the RIA as the protein tracer, and protein standards. Some of the protein is radiolabeled to yield the protein tracer. Unlabeled protein is used as the protein standards. The exact protein concentration in each of the standards must be known, since the cpm values derived from the RIA of the standards are used to construct a standard curve. This standard curve allows the determination of the concentration of the protein from any unknown sample, as long as the concentration is within the operating range of the RIA. Quality controls are used to determine inter-assay variability.

Under ideal conditions, an RIA is capable of measuring picograms (10^{-12} g) of a protein (or peptide) antigen, but only if high-specific-activity radiolabeling of the protein tracer can be achieved. Radioiodine (either ^{125}I or ^{131}I) is the label of choice because of the significant increase in radioactive disintegrations per unit time in comparison to ^3H or ^{14}C . Radioiodination is most commonly done by one of five methods. Four are chemical modifications, employing one of the following reagents: chloramine-T, IODO-GEN (1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycouril; Pierce), PIB (*N*-succinimidyl 4-iodobenzoate), and Bolton-Hunter reagent (*N*-hydroxysuccinimide ester of 3-(*p*-hydroxyphenyl)propionic acid). The other method is enzymic, employing lactoperoxidase. UNIT 11.17 provides protocols for radiolabeling a standard protein (or peptide) with either chloramine-T or IODO-GEN.

Enzyme-linked immunosorbent assays (ELISAs; UNIT 11.2) are alternative methods for those wishing to avoid the use of radioactivity and in situations where a large number of tests will be performed. The cost of assay development is higher for ELISAs than for RIAs, but, for large numbers of assays, the cost of radioisotope and its disposal become significant factors.

Materials

- Assay buffer (see recipe)
- Protein standards (see recipe)
- Protein quality controls 1 and 2 (see recipe)

**Analysis of
Proteins**

10.24.1

Supplement 72

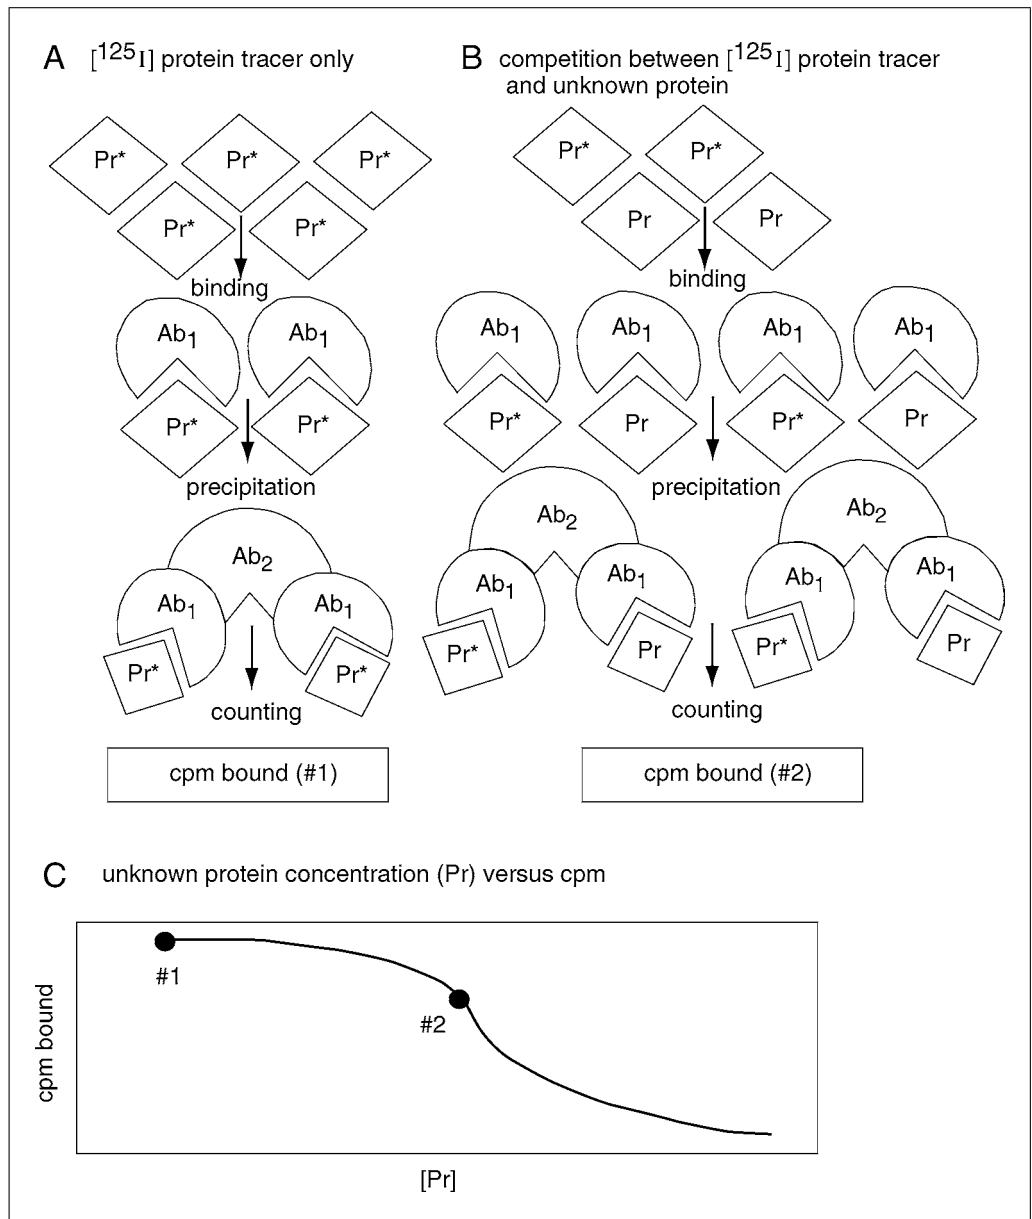

Figure 10.24.1 Solution radioimmunoassay for a protein of interest (Pr) using the double-antibody/PEG method. The protein of interest is isolated, purified, and radiolabeled to generate a protein tracer (Pr^*) that binds specifically to a primary antibody (Ab_1). The soluble $\text{Pr}^*\text{-Ab}_1$ complex is precipitated by adding a specific secondary antibody (Ab_2). The addition of a low concentration of polyethylene glycol (PEG) increases the formation of the insoluble $\text{Pr}^*\text{-Ab}_1\text{-Ab}_2$ complex. **(A)** Measurement the precipitate in the presence of Pr^* only yields the B_0 value (Table 10.24.2), which corresponds to the maximum Pr^* cpm that will bind to the amount of Ab_1 used in the assay. **(B)** In the presence of unlabeled protein (Pr) from standards or unknown samples, Pr and Pr^* compete equally for Ab_1 binding sites, and the soluble $\text{Pr}^*\text{-Ab}_1$ and $\text{Pr}\text{-Ab}_1$ complexes are precipitated equally by Ab_2 and PEG. **(C)** A plot of B values (Table 10.24.2) versus Pr concentration illustrates the principle of the RIA. As the concentration of Pr increases, the amount of Pr^* that binds to Ab_1 decreases. Such a curvilinear plot can be made linear by constructing a log-log plot of various protein concentrations (derived from a series of protein standards) versus % B/B_0 (Fig. 10.24.2). By comparing the % B/B_0 value of an unknown sample to this standard curve, the concentration of the protein in the unknown sample may be determined.

^aAdapted from data derived from a primate leptin RIA kit available from LINCO Research (St. Charles, Mo.). Abbreviations: B₀, bound protein tracer in absence of competing unlabeled protein; QC, protein quality control.

Unknown samples (e.g., plasma, serum, tissue culture medium)

Protein tracer, iodinated with ¹²⁵I (see recipe)

Protein tracer buffer (see recipe)

Anti-protein antiserum (containing primary antibody; see recipe)

Precipitating secondary antibody/PEG solution (see recipe)

Assay tubes: 12 × 75–cm glass test tubes (polypropylene or polyethylene tubes may be used provided that the pellets remain compacted following the decanting step)

Refrigerated centrifuge with swinging-bucket rotor

γ counter

Log/log graph paper

Set up the assay

1. Label a series of 12 × 75–mm glass tubes as described in Table 10.24.1.
2. Pipet 200 µl assay buffer into each of the duplicate nonspecific binding tubes (labeled #3 and #4).

- Pipet 200 μl assay buffer into each of the duplicate B_0 tubes (labeled #5 and #6).

The B_0 value is the amount of radiolabeled antigen ($[^{125}\text{I}]$ protein tracer) that is bound to the amount of primary antibody used in the assay. When the unknown samples are added, the $[^{125}\text{I}]$ tracer will be displaced by antigen contributed by the unknown samples. The lower the concentration of antigen in the unknown samples, the more $[^{125}\text{I}]$ tracer that will remain bound to the primary antibody.

- Pipet 100 μl assay buffer into the duplicate standard tubes, quality control tubes, and the unknown sample tubes (i.e., tube #7 through the final tube of the assay).
- Pipet 100 μl of the 0.5 ng/ml protein standard into the duplicate tubes #7 and #8, 100 μl of the 1 ng/ml standard into tubes #9 and #10, and so forth until all standards have been dispensed.

The lowest level of protein that can be detected by the assay should be used as the lowest concentration of standard to construct the standard curve (i.e., 0.5 ng/ml in this example). The limit of the linear range of the assay determines the highest concentration, which in this assay is 100 ng/ml.

- Pipet 100 μl of quality control 1 into the duplicate tubes #23 and #24.

The quality control samples (also see Reagents and Solutions) are other complex samples with known quantities of the protein of interest, and the values obtained in this assay should agree with the previously determined quantities. Such controls are useful for inter-assay comparisons.

- Pipet 100 μl of quality control 2 into the duplicate tubes #25 and #26.
- Pipet 100 μl of each unknown sample into the appropriately numbered duplicate tubes.

If the antigen is expected to be present in high concentration in the unknown sample, or if the sample quantity is limited, smaller aliquots of sample may be used. If so, add assay buffer to bring the sample volume to 100 μl . The sample may be plasma, serum, tissue culture medium, or some other complex biological mixture.

- Pipet 100 μl of $[^{125}\text{I}]$ protein tracer in protein tracer buffer ($\sim 5,000$ to 20,000 cpm per tube) into all tubes.

The assay results illustrated in Table 10.24.2 indicate that $\sim 11,500$ cpm per tube were used.

- Pipet 100 μl primary antibody into all tubes except #1, #2, #3, and #4.

Perform the radioimmunoassay

- Vortex tubes, place in a rack, and cover with Parafilm. Incubate 24 hr at 4°C.

Covering the tubes with Parafilm prevents evaporation and contamination during the incubation.

- Pipet 1 ml cold (4°C) precipitating secondary antibody/PEG to all tubes except tubes #1 and #2.
- Vortex, then incubate 30 min at 4°C.
- Centrifuge 20 min at $2500 \times g$, 4°C, in a centrifuge with a swinging-bucket rotor.
- For all tubes except #1 and #2, invert the tubes to decant the supernatant and gently place the tubes upside-down in a wire test tube rack that has paper towel on top of the rack base. Allow the tubes to drain onto the paper towel for 1 min.

Invert the tubes only once, since the precipitant pellets are fragile. With the paper towel on top of the rack base (not on the benchtop), the excess liquid from the open ends of the tubes will wick into the paper towel.

- Count all the tubes in a γ counter for 1 min.

Required counting times will vary depending on the cpm used in the assay.

Many γ counters are capable of processing the data from assays such as the one described in this protocol. If not, the raw data can be processed using commercially available software for RIAs (e.g., Hewlett-Packard 41, Beckman EIARIA). Alternatively, the data can be manually processed as described below.

Process data and calculate results

- Average the duplicate counts for the total counts added (tubes #1 and #2), nonspecific binding (#3 and #4), total tracer bound to primary antibody (B_0 ; tubes #5 and #6), all standard dilutions (tubes #7 to #22), quality controls (tubes #23 to #26), and all unknown samples (tubes #27 and #28, #29 and #30, and so on).

If the difference between the duplicate results is >10%, repeat the assay for that sample.

- Subtract the average nonspecific binding counts (average of tubes #3 and #4) from each average count of all tubes except the total counts (tubes #1 and #2).

In this assay, nonspecific binding refers to tracer protein that remains in the tube without addition of primary or secondary antibody.

- Calculate the percent of tracer bound to primary antibody according to the equation:

$$\% \text{ tracer bound} = \{(\text{total tracer bound})/(\text{total tracer added})\} \times 100$$

See Table 10.24.2 for sample assay results. Total tracer specifically bound to primary antibody (average of tubes #5 and #6 minus average of tubes #3 and #4) equals $\sim 2,200$ cpm. The total counts of tracer added to each tube (average of tubes #1 and #2) equals $\sim 11,500$ cpm/tube. Ideally, the amount of tracer bound would equal 15% to 50%. In this case, it is $\sim 19\%$. If the amount of tracer bound does not fall within this ideal range, a primary antibody with higher affinity for the protein or peptide of interest must be prepared or obtained.

- Calculate the $\% B/B_0$ for each standard and unknown sample, where B is the net average counts (the average counts minus the average nonspecific binding, as determined in step 18) and B_0 is the total tracer bound (determined in step 19).

See sample calculations in Table 10.24.2.

- Using log/log graph paper, plot $\% B/B_0$ for each standard on the y axis and the known concentration of each standard on the x axis (see Fig. 10.24.2).

- Construct a standard curve by joining the points in a smooth curve.

A standard curve should be generated for each protein assay.

- Calculate the concentration (ng/ml) of antigen in the unknown samples by comparison with the standard curve.

If the unknown sample volumes used are less than 100 μl and a dilution was performed (see step 8), it will be necessary to account for the dilution in the calculations (e.g., if 25 μl was used, the calculated quantity of protein must be multiplied by 4).

The $\% B/B_0$ values for unknown samples #1 and #2 were 39.4 and 61.3, respectively, which correspond to 7.6 and 3.0 ng/ml (see Table 10.24.2 and Fig. 10.24.2).

- Calculate the concentration (ng/ml) of antigen in the quality control samples (tubes #23 and #24 and tubes #25 and #26) and compare to the known values.

The quality control samples (also see Reagents and Solutions) are other complex samples with known quantities of the protein of interest, and the values obtained in this assay should agree with the previously determined quantities. Such controls are useful for inter-assay comparisons.

Table 10.24.2 Calculations of B/B_0 and Protein Concentration for a Sample RIA^a

Tube #	Identification	cpm	Avg. cpm	Avg. net cpm	% B/B_0	Protein conc. (ng/ml) ^b

^aAdapted from data derived from a primate leptin RIA kit available from LINCO Research. Abbreviations: B , cpm of bound protein tracer in presence of varying amounts of unlabeled protein; B_0 , cpm of bound protein tracer in absence of competing unlabeled protein; QC, protein quality control.

^bCalculated from standard curve illustrated in Figure 10.24.2.

Figure 10.24.2 Log-log plot of protein concentration versus % B/B_0 . This graph is derived from the data in Table 10.24.2. The protein concentration range is between 0.5 ng/ml and 100 ng/ml. This range was determined by using protein standards at the concentrations of 0.5, 1, 2, 5, 10, 20, 50, and 100 ng/ml. The B/B_0 values are determined by dividing the B values (cpm of bound tracer in the presence of variable amounts of unlabeled protein standard) by B_0 (cpm of bound tracer without the presence of competing, unlabeled protein standard).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Anti-protein antiserum (primary antibody solution)

This solution contains the primary (first) antibody used to complex the [¹²⁵I]tracer or the unlabeled antigen in the standards, quality controls, and unknown samples. If the unknown samples are of human origin, an example of an appropriate primary antibody might be a rabbit monoclonal or polyclonal antiserum against the human protein to be quantitated (see Chapter 11 for production of monoclonal and polyclonal antisera). Dilute the antiserum 1:20 to 1:200 in assay buffer (see recipe), depending on the titer of specific immunoglobulin in the antiserum. Prepare dilution on day of use and keep at 2° to 8°C.

The primary antibody is either a polyclonal antibody (derived from serum; therefore referred to as an antiserum) or a monoclonal antibody (derived from ascites fluid or hybridoma supernatant). The serum, ascites fluid, or hybridoma supernatants may be used without purifying the primary antibody from these sources. In each case, a dilution with the diluting buffer is required. A dilution of 1:20 to 1:200 is specified above; however, the titer of a primary antibody directed at a protein (or peptide) of interest will differ depending on the immunogenicity of the antigen. Hence, the dilution of the anti-protein (or anti-peptide) antiserum, ascites fluid, or hybridoma supernatant may be increased (e.g., to 1:10,000) if the titer is high. The amount of primary antibody must be sufficient to bind 15% to 50% of the radiolabeled protein (or peptide) tracer used in the assay.

Assay buffer

Phosphate-buffered saline (PBS), pH 7.4 (see recipe)

0.025 M EDTA (APPENDIX 2)

0.1% (v/v) Triton X-100

0.08% (w/v) sodium azide

1% (w/v) BSA (RIA grade; Sigma-Aldrich)

Store short term (up to 24 hr) at 2° to 8°C or long term at –20°C

CAUTION: Sodium azide may react with lead or copper plumbing to form explosive metal azides; dispose of azide solutions according to local regulations and institutional guidelines; also see APPENDIX 1H.

Phosphate-buffered saline (PBS)

1.15 g NaH₂PO₄ (anhydrous; 9.5 mM)

5.75 g Na₂HPO₄ (anhydrous; 40.5 mM)

9.00 g NaCl (154 mM)

Add H₂O to 900 ml

Adjust to pH 7.4 using 1 M NaOH or 1 M HCl

Add H₂O to 1 liter

Precipitating secondary antibody/PEG solution

This solution contains an antibody against the immunoglobulin of the species used to raise the primary antibody. For example, if the primary antibody is a rabbit anti-human immunoglobulin, an example of an appropriate secondary antibody might be a goat anti-rabbit IgG. The composition of the solution is as follows:

Phosphate-buffered saline (PBS), pH 7.4 (see recipe) containing:

1% to 2% (v/v) antiserum

3% (w/v) polyethylene glycol (PEG; mol. wt. 8000)

0.1% (v/v) Triton X-100

0.025 M EDTA (APPENDIX 2)

0.08% (w/v) sodium azide

Store short term (up to 24 hr) at 2° to 8°C or long term at –20°C

CAUTION: Sodium azide may react with lead or copper plumbing to form explosive metal azides; dispose of azide solutions according to local regulations and institutional guidelines; also see APPENDIX 1H.

Protein quality controls

Select complex samples (e.g., sera, tissue culture supernatants) from the same species as the unknown samples (e.g., human), but in which the concentration of the desired antigen is already known. Before the assay, if needed, dilute in assay buffer (see recipe) to bring the final antigen concentration within the assay range (e.g., 3 and 18 ng/ml, as in Table 10.24.2). Store short term (up to 24 hr) at 2° to 8°C or long term at –20°C.

Protein standards

Dilute the purified protein of interest (antigen) from the same species as the unknown samples (e.g., human) in assay buffer (see recipe) at 0.5, 1, 2, 5, 10, 20, 50, and 100 ng/ml. Prepare dilutions on the day of use and keep at 2° to 8°C.

Protein tracer buffer

Prepare assay buffer (see recipe) containing 2% (w/v) serum from the species of origin of the unknown sample (e.g., human) as carrier. Store short term (up to 24 hr) at 2° to 8°C or long term at –20°C.

This buffer is used to dissolve iodinated protein.

Protein tracer, iodinated with ¹²⁵I

Radiolabel the purified protein of interest (antigen) from the same species as the unknown samples (e.g., human) with ¹²⁵I (see, e.g., UNIT 11.17) to a specific activity of 130 to 140 μCi/μg, and purify by HPLC (UNITS 10.12 & 10.13). To maximize stability of the batch of iodinated protein, lyophilize in aliquots that are sufficient to complete a whole RIA in which each assay tube contains 5,000 to 20,000 cpm. Store lyophilized tracer up to 1 month at –20°C. Before use, dilute in protein tracer buffer (see recipe) such that each 100 μl contains 5,000 to 20,000 cpm, and keep at 2° to 8°C.

COMMENTARY

Background Information

The first radioimmunoassay was developed to measure insulin in human plasma (Yalow and Berson, 1960). RIAs are most commonly used in clinical laboratories. They are used to measure, e.g., peptides and proteins with endocrine function, antibiotics, cocaine, steroids, antigens associated with autoimmunity, bacteria, viruses, parasites, neuropeptides, and expressed proteins.

Radioimmunoassay is a simple, rapid and precise method for measuring picomolar amounts of an antigen if the antigen is radiolabeled to high specific activity. An RIA, as described by Re and Haber (1980), requires: (1) a substance that binds with high affinity to the protein (or peptide) being measured; (2) a radiolabeled protein (or peptide)—a so-called “tracer”—that competes specifically for binding with the protein (or peptide) being measured; (3) a simple method for separating free and bound forms of the radiolabeled tracer; and (4) the availability of sufficient and known amounts of the protein (or peptide) being measured—so-called calibrators or standards—free from any impurities that could also displace the radiolabeled tracer protein (or peptide) from its binding site. The quantification of a specific antigen (protein or peptide) in a complex biological sample results from allowing differing amounts of the antigen of interest contained in a complex mixture (e.g., cell lysates, serum, saliva, urine, cerebrospinal fluid) to combine with a fixed quantity of an antigen-specific antibody in the presence of a fixed quantity of radiolabeled tracer antigen. The radiolabeled

tracer and the antigen being measured compete for binding to the antigen-specific antibody. Labeled and unlabeled antigens bind with equal affinity and in indirect proportion to each other. The smaller the amount of sample antigen, the larger the amount of labeled antigen that will bind. Hence, the higher the number of counts detected on a γ counter, the lower the amount of sample antigen present. A plot (a so-called standard curve) of the percent of bound tracer in the presence of differing amounts of unlabeled standard antigen—referred to as % B/B_0 —versus the concentration of standard antigen can be made, and the concentration of antigen in the unknown samples can be readily determined by comparing the amount of bound radiolabeled tracer in each unknown sample with the standard curve.

RIA reagents and supplies are available from numerous commercial sources (e.g., Sigma Chemical Co., ICN Biochemicals, Perkin-Elmer, Pierce Chemicals, LINCO Research). These are supplied as reagents or kits, which, in the case of double-antibody assays (used in this unit), include labeled antigen, antigen-specific primary antibody, and a secondary antibody (a so-called precipitating antibody) recognizing the primary antibody, which is a component of the bound antigen-antibody complex. Under some circumstances, it is also possible to purchase unlabeled antigen and to iodinate with one of the five available methods: chloramine-T (Hunter and Greenwood, 1962; UNIT 11.17), IODOGEN (Salacinski et al., 1981; UNIT 11.17), PIB (Wilbur et al., 1989), Bolton-Hunter

(Bolton and Hunter, 1973), or lactoperoxidase (Marchalonis, 1969).

As described by Hunter (1973), radioiodine (either ^{125}I or ^{131}I) is the label of choice because of the significant increase in radioactive disintegrations per unit time (in comparison to ^3H or ^{14}C). Unless the radiolabeled antigen is unstable (due to radiochemical damage), ^{125}I , not ^{131}I , is the radiolabel of choice, because of its longer half-life (60 days versus 8 days), the higher isotope abundance available in the carrier-free, commercially available ^{125}I label, its higher counting efficiency (80% versus 40%), and the higher specific activity of labeled protein (or peptide) with one molecule of ^{125}I ($\sim 100 \mu\text{Ci}/\mu\text{g}$ at a molecular mass of 20,000 and $\sim 1,000 \mu\text{Ci}/\mu\text{g}$ at a molecular mass of 2,000) in comparison to ^{131}I .

Chloramine-T (the sodium salt of the *N*-monochloro derivative of *p*-toluene sulfonate) in the presence of NaI (labeled with ^{125}I or ^{131}I) enables proteins (or peptides) containing tyrosyl residues to be specifically labeled in aqueous solutions under mildly alkaline conditions. The method was developed by Hunter and Greenwood (1962). The pH optimum is 7.5. At pH > 8.5, iodination of other amino acids (histidine or tryptophan) is possible. The efficiency of the reaction is dependent on the concentration of the protein (the lower the amount of protein, the less efficient the labeling). However, if only trace labeling is needed, only very low concentrations of chloramine-T are required.

iodo-GEN (1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycouril; a trademark of Pierce developed by Salacinski, 1981), is a more gentle iodination method than chloramine-T, because the reaction occurs on a solid-phase surface of the oxidant, thereby minimizing the exposure of the protein or peptide to oxidative damage. The specific activity of the labeled proteins (or peptides) is less than that achievable by chloramine-T.

The PIB (*N*-succinimidyl 4-iodobenzoate) method, developed by Wilbur et al. (1989), iodinate tyrosine residues. Because these iodinated proteins (or peptides) do not contain an *ortho*-phenol, they are not susceptible to delabeling by natural deiodinases selective for *ortho*-iodophenols. This leads to increased stability of the iodinated proteins (or peptides).

The Bolton-Hunter (1973) method is a two-step labeling approach for introducing an iodinated *p*-hydroxyphenyl moiety (i.e., a tyrosine mimic) into proteins (or peptides) lacking tyrosine residues or under circum-

stances where an active tyrosine is involved in a binding or an antigenic site and therefore should not be iodinated. The first step is the iodination by chloramine-T or IODO-GEN of the *N*-hydroxysuccinimide ester of 3-(*p*-hydroxyphenyl)propionic acid. The second step is the active ester coupling of the iodinated 3-(*p*-hydroxyphenyl)propionic acid to lysyl residues in the protein (or peptide). Addition of a protein solution to the dried reagent residue results in a covalent attachment of the radiolabeled moiety to lysyl residues in the protein. The advantage of this acylating method is that the protein is not exposed to the oxidizing conditions associated with the chloramine-T or IODO-GEN. In addition, the method allows the introduction of a radiolabeled iodine into proteins lacking a tyrosyl residue but containing a lysyl residue. When the antibodies used in the RIA are directed at an antigenic site containing a tyrosyl residue, the Bolton-Hunter method does not affect the antigenic site unless a modified lysyl residue is also in the antigenic site.

The lactoperoxidase method is an enzymic reaction method developed by Marchalonis (1969). Lactoperoxidase catalyzes the oxidation of iodine in the presence of hydrogen peroxide. In turn, selective iodination of tyrosyl residues in proteins occurs. The specific activity of the labeled proteins is less than that achievable by chloramine-T.

Critical Parameters and Troubleshooting

In order to develop an RIA for a given protein (or peptide), the following questions should be asked and answered (http://www.cyfc.psu.edu/funding/L2_dr2.html).

1. Is it feasible to develop a radioimmunoassay for a specific protein (or peptide)? Begin by searching the literature to determine the following:

a. Information about the protein's availability: i.e., has it been isolated and, if so, how easy will it be to obtain the amount required for developing and running subsequent RIAs?

b. What is the molecular mass (and amino acid composition) of the protein?

c. What is its half-life?

d. What is its intracellular, organ, or body distribution? Has a previous assay been reported (i.e., are sensitivity, sample volumes, and assay protocols defined) for measuring the protein of interest? If so, was the assay validated? Such validation requires determination of:

i. Minimal detection limit, defined as the minimum concentration of the protein that may be distinguished from zero at a 95% confidence limit, by extrapolating the mean minus two standard deviations for multiple replicates (e.g., 5 to 10 assays) of the zero calibrator (i.e., not containing standard protein).

ii. Reproducibility of the standard curve using replicate runs (e.g., 5 to 10 assays) by comparing averages, standard deviations, and confidence values for the slope and correlation coefficient.

iii. Precision, by measuring the intra-assay variation (confidence value) for replicate samples at various concentrations (i.e., low, medium, and high).

iv. Accuracy, by adding known amounts of unlabeled protein (or peptide) to samples containing various endogenous concentrations.

v. Drift, due to delays in adding reagents due to distribution of samples in a given assay configuration (i.e., arrangement of tubes or placement of samples with presumed low, medium, or high concentrations).

vi. Sensitivity sufficient to capture the full range of developmental, individual, gender, and diurnal variations.

2. Does an immunodiagnostic vendor provide a source of polyclonal (or monoclonal) antibodies specific to the protein (or peptide) of interest, chemically or enzymatically labeled standard protein (or peptide), and calibrators (i.e., standard protein or peptide at various defined concentrations required to construct a standard curve)? If so, is the laboratory prepared to develop an RIA?

3. Is an RIA commercially available for the protein (or peptide) of interest?

If the answer to any of the above questions is yes, one is ready to develop or purchase a solution RIA. If not, a large amount of work may be required to prepare the required assay reagents, which may involve expressing and/or purifying a sufficient quantity of a standard protein or synthesizing and/or purifying a standard peptide (Chapter 10), preparing polyclonal or monoclonal antibodies (Chapter 11), and radiolabeling the standard protein (or peptide).

A simple method to determine the minimal concentration of iodinating reagent required to label a protein (or peptide) is to carry out the labeling procedure and then measure, in a small aliquot, the amount of labeled protein (or peptide) that can be precipitated using 10% trichloroacetic acid (TCA). Addition of a carrier protein (e.g., 2% to 3% serum) will be required to precipitate most peptides,

since they are not readily precipitated by 10% TCA.

The most common diluent is sodium phosphate-buffered saline (e.g., 0.01 to 0.05 M, pH 7.5). However, for membrane proteins, more complex buffer mixtures (containing nonionic or ionic detergents) are required to solubilize the proteins for use in a soluble RIA format. Furthermore, RIAs require the addition of a carrier protein at very large molar excess (e.g., 2% to 3% serum) over antigen and labeled tracer when working at low concentrations, to minimize losses due to adsorption to glass or plastic surfaces. In addition, the following should be checked: (1) the carrier protein concentration should prevent adsorption of radiolabeled antigen at the lowest concentration being assayed; (2) the carrier protein should be free of the antigen being assayed or any cross-reacting antigens; (3) the stability of the radiolabeled antigen in the presence of the carrier protein may be reduced, especially under prolonged incubation times at room temperature; and (4) a bacteriostatic agent (e.g., sodium azide at 0.1 g/liter or thimerosal at 0.01%, w/v) increases the stability of the assay by reducing inadvertent degradation of antigen or carrier protein by contaminating proteases.

Separation of bound from free tracer can be achieved physicochemically (via electrophoresis, chromatography, or gel diffusion; see Chapter 10) or by immunoprecipitation, as in (the so-called double-antibody method in which the antibody-tracer complex is immunoprecipitated with a secondary anti-immunoglobulin raised in another species; *UNIT 10.16*). In the double-antibody/PEG method described here, PEG is added to enhance the precipitation reaction. A perfect double-antibody separation system would show no tracer in the bound fraction in the absence of capture antibody and 100% of the tracer in the bound fraction after incubation with excess capture antibody.

As described by Hunter (1973), any separation system may affect the system in two discrete ways. First, antigen-antibody interactions are reversible, even if the experimental system is at equilibrium. Hence, some bound antigen may dissociate if the separation removes free antigen from the system. Such dissociation would only occur if the association and dissociation constants for the antigen-antibody interaction were equal. With antibodies of high avidity, this would not occur. Secondly, the separation system may disrupt the antigen-antibody complex. This could occur when nonpolar compounds are being assayed,

since the organic solvents used to extract unbound label could also extract free and bound compounds equally. This is not a problem with the RIAs of proteins (or peptides) using the double-antibody/PEG method, since organic solvents are not used.

Anticipated Results

As described by Hunter (1973), radioiodinated proteins (or peptides) are usually stable at 2° to 8°C for 30 days. High-specific-activity labeling of proteins (or peptides) can lead to a decrease in immunoreactivity due to radiochemical damage. Such damage can be differentiated from chemical damage by the fact that it is proportional to the amount of radioactivity reacted and should not vary with different batches of iodine. Chemical damage results from iodine's propensity to oxidize sulfhydryl groups and/or from denaturation by the organic solvents, if used to extract the unreacted iodine. Iodination may also alter the immunoreactivity of proteins (or peptides) if the iodinated tyrosine is contained within the antigenic site recognized by the antibody. Hence, to minimize this possibility, trace labeling should not exceed one atom of iodine per mole of protein (or peptide). Interestingly, such a decrease in the apparent immunoreactivity may be specific for a single antiserum and not others, so it may be beneficial to use several antisera during the development of an RIA.

Time Considerations

The solution RIA can be completed in 2 days or less. The incubation time for the assay using the double-antibody method is complete by 16 to 24 hr at 4° to 25°C. The separation of immunoprecipitated antigen requires different lengths of time depending on the number of samples being assayed, due to the time required to centrifuge the precipitate and to decant the supernatants (usually < 1 to 3 hr). The amount of time needed to count the samples with a γ counter depends on the specific activity of the labeled tracer, but is usually <5 min per tube.

CHAPTER 11

Immunology

INTRODUCTION

Certain technological advances in the field of molecular biology were made possible in part by earlier progress in the field of immunology. A review of the earlier chapters in this book documents the importance of immunological methods to the purification of proteins as well as to the identification of specific cDNA clones. Specific antibodies have greatly facilitated the purification of proteins by immunoaffinity chromatography (*UNIT 10.11*) and immunoprecipitation (*UNIT 10.16*). One limitation of immunoaffinity chromatography has been that the harsh dissociation conditions required to elute bound antigens from high-affinity antibodies sometimes denature the eluted antigens. *UNIT 11.18* presents a method to circumvent this problem by utilizing polyol-responsive antibodies that release their bound antigens under gentle dissociation conditions, employing a combination of various low molecular weight polyhydroxylated compounds (e.g., ethylene glycol) and nonchaotropic salts (e.g., ammonium sulfate). These polyol-responsive antibodies can be readily identified and isolated from typical fusions, prepared by standard hybridoma procedures. When pure protein has been unavailable for deducing the complementary oligonucleotide sequence, specific antibodies have been utilized to screen recombinant DNA libraries for the desired cDNA clones (*UNIT 6.7*) and selected mRNA for the translation of desired protein (*UNIT 6.8*). Specific antibodies have also been utilized to identify antigen by western blotting (*UNIT 10.8*).

Just as immunology has facilitated the advances made in the field of molecular biology, the latter in turn has contributed to a better understanding of the basis for antibody diversity. The clonal selection theory proposed by Sir Macfarlane Burnet in 1959 is now an accepted concept: each B cell differentiates into a plasma cell committed to the production of antibodies specific for one antigen—i.e., the antibodies are monoclonal in nature. “Clonal selection” refers to the fact that when an antigen binds to one of these antibodies on the membrane of the B cell, the cell is stimulated to proliferate (at which point some variation may be introduced in the “monoclonal” cell line). Generally, many clones respond to a single antigen, as most proteins carry multiple antigenic sites (called epitopes). The overall immune response is polyclonal, with specific recognition of multiple, discrete epitopes.

An understanding of the genetic mechanisms responsible for antibody (or immunoglobulin) diversity requires some knowledge of antibody structure. Man has five major immunoglobulin classes: IgG, IgA, IgD, IgE, and IgM, which share the same type of combining site for antigen. The immunoglobulin molecule is similar for the first four classes; it consists of four polypeptides—two heavy chains and two light chains—arranged in the shape of the letter “Y,” with a molecular weight of ~150,000. The IgM class, with a molecular weight of ~800,000, consists of five Y-shaped molecules arranged in a cyclic pentamer, with the antigen-binding sites facing outward. Although the different immunoglobulin classes can share the same κ or λ light chains, they are each distinguished by their unique heavy chains, designated γ (IgG), α (IgA), δ (IgD), ϵ (IgE), and μ (IgM). The heavy and light chains are each composed of constant and variable regions. The antigen-binding site, a cleft of about $15 \text{ \AA} \times 20 \text{ \AA} \times 10 \text{ \AA}$ deep formed by interactions of hypervariable regions of the heavy- and light-chain variable regions, is unique for each antibody.

Supplement 53

For many years it was assumed that the mammalian germ line must include a separate gene for every polypeptide that ultimately appears in an antibody; this model presupposes a vast number of immunoglobulin genes. In the past decade, however, recombinant DNA technology has shown that diversity in antigen-binding sites arises through genetic recombination in somatic cells—i.e., while B lymphocytes are maturing and differentiating in the bone marrow. Located on different chromosomes are approximately 50 genes coding for the “constant” **C** regions, the “variable” **V** regions, the “joining” **J** segments (which combine with the **C** and **V** regions to make up the antibody’s light chain) and the “diversity” **D** segments (which combine with **C**, **J**, and **V** regions to comprise the antibody’s heavy chain). Mouse germ cells have a few hundred **V** segments, approximately 20 **D** segments, and 4 **J** segments, which can be assembled in >10,000 combinations. Subsequent assemblage of heavy and light chains could yield >10 million specific antigen-binding sites. (For an excellent review of the molecular biology of the immune system, see Tonegawa, 1985.)

This chapter presents the methodologies for the preparation of both monoclonal and polyclonal antibodies. Section I describes the enzyme-linked immunosorbent assay (ELISA), a highly sensitive, versatile, and quantitative technique that requires little equipment and for which critical reagents are readily available. The preparation of enzyme-antibody conjugates, which forms the basis of this assay, is described in *UNIT 11.1*. The versatility of ELISAs is demonstrated by the six distinct ELISA protocols presented in *UNIT 11.2*. These provide general methods for the detection of specific antibodies, soluble antigens, or cell-surface antigens. Protocols for determining the isotype (i.e., serological class) of antibodies are described in *UNIT 11.3*.

The pioneering studies of Kohler and Milstein (1975) enable investigators to obtain milligram quantities of specific monoclonal antibodies after immunizing mice with relatively impure antigen. The spleen is removed from a previously immunized mouse that has a sufficient antibody titer. After separation into individual cells, B cells from the spleen are fused with myeloma cells of B cell origin to produce immortal antibody-secreting hybridoma cells of predetermined specificity. Each hybridoma cell is capable of producing an unlimited supply of a single, antigen-specific monoclonal antibody. Section II describes the preparation of these antigen-specific monoclonal antibodies in separate protocols that cover immunization of mice (*UNIT 11.4*), cell preparation and cell fusion for generating hybridoma cell lines (*UNITS 11.5-11.7*), cloning by limiting dilution to ensure the production of truly monoclonal antibodies derived from a single antibody-secreting cell (*UNIT 11.8*), freezing and recovery of hybridoma cell lines (*UNIT 11.9*), production of cell culture supernatants of monoclonal antibodies in ascites fluid (*UNIT 11.10*), and purification of these monoclonal antibodies by affinity chromatography (*UNIT 11.11*). Detection of antibody in serum, hybridoma supernatants (micrograms per milliliter), and ascites fluid (milligrams per milliliter) by ELISA is described in *UNIT 11.2*.

Although monoclonal antibodies can be made available in unlimited quantities and without the need to purify the antigen to homogeneity, the reliance upon only monoclonal antibodies for detection and identification of antigen and cDNA clones can produce equivocal results. Because monoclonal antibodies may be specific for short peptide sequences, there is a possibility of obtaining false positives, since unrelated proteins can share small regions of homology. One way in which this uncertainty can be minimized is to utilize several different monoclonal antibodies specific for different sites on the antigen. Another disadvantage of using a monoclonal antibody is that it may have a relatively low affinity for a given antigenic site.

These problems caused by the use of monoclonal antibodies may be circumvented by generating polyclonal antibodies, which consist essentially of numerous monoclonal

antibodies with different epitope specificities (Section III). When a purified antigen is available in sufficient amount for immunization, it is possible to obtain specific polyclonal antibodies with high affinity after repeated immunizations (*UNIT 11.12*; Klinman and Press, 1975). Choice of animal is determined by the amount of antiserum required for subsequent experiments. Although animals such as goats, sheep, or horses can provide larger volumes of antiserum, few institutions have adequate facilities for their care and maintenance. Mice, rats, and guinea pigs, on the other hand, may not yield sufficient volumes of antiserum. For these reasons, rabbits have become the animal of choice for the generation of polyclonal antibodies. *UNIT 11.12* describes the proper preparation of antigen as well as various routes of immunization in rabbits to optimize the antibody response. Although a schedule for immunization and boosting is provided, this procedure is only a recommendation of what has worked for the author; optimal conditions should be determined empirically. *UNIT 11.13* describes systems for in vitro antibody production, and subsequent measurement of secreted antibodies. *UNIT 11.14* discusses the purification from serum, ascites fluid, or hybridoma supernatant of the immunoglobulin G fraction, which becomes the predominant antibody class after the booster injection.

If purified antigen is in limited supply, polyclonal (as well as monoclonal) antibodies can still be raised by immunization with synthetic peptides whose sequences are based on that of the protein, which it is designed to mimic (Section IV). In this case, the selection of an immunogenic peptide is vital for obtaining a good antibody response. *UNIT 11.15* discusses the necessary parameters to consider in the selection of a particular peptide sequence that will elicit an antibody that recognizes the native form of the protein. To enhance the immunogenicity of the peptide, it can be chemically cross-linked to a carrier molecule (*UNIT 11.16*). Such cross-linking of the peptide has been demonstrated to be helpful in generating an antibody response to peptides that might not otherwise elicit antibody production.

The quantitation of specific antibody (as well as its isotypes) in polyclonal antisera, ascites fluid, or hybridoma supernatant by solid-phase radioimmunoassay (RIA) is described in *UNIT 11.17*. Although this method is more laborious than the nonradioactive ELISA described in *UNIT 11.2*, the disadvantages are offset by greater sensitivity and better reproducibility from assay to assay.

Antigen can be detected and quantitated using an enzyme-linked immunosorbent assay (ELISA). The direct and sandwich ELISAs discussed in *UNIT 11.2* are particularly useful for determining the presence or amount of antigen in samples ranging from crude bacterial lysates to highly purified protein antigen preparations. These assays require the preparation of enzyme-antibody conjugates. How these conjugates are prepared and what enzymes should be linked to the antigen-specific antibody in the conjugate are presented in *UNIT 11.1*.

UNIT 11.1

Conjugation of Enzymes to Antibodies

Conjugation of enzymes to antibodies involves the formation of a stable, covalent linkage between an enzyme [e.g., horseradish peroxidase (HRPO), urease, or alkaline phosphatase] and an antigen-specific monoclonal or polyclonal antibody in which neither the antigen-combining site of the antibody nor the active site of the enzyme is functionally altered. The chemistry of cross-linking HRPO or urease to immunoaffinity-purified monoclonal or polyclonal antibodies (IgG) is presented in Figures 11.1.1 and

Figure 11.1.1 Conjugation of horseradish peroxidase (HRPO) to antibody (IgG) using the periodate oxidation method. The method involves three chemical steps: (1) sodium periodate (NaIO_4) oxidation of the carbohydrate side chains of HRPO, (2) Schiff base formation between activated peroxidase and amino groups of the antibody, and (3) sodium borohydride (NaBH_4) reduction of the Schiff base to form a stable conjugate.

Figure 11.1.2 Conjugation of urease to antibody (IgG) with *m*-maleimidobenzoyl *N*-hydroxysuccinimide ester (MBS). The first step involves benzoylation of the amino groups of the antibody (IgG) oxidate oxidation method. The second step involves the thiolation of the maleimide moiety by the sulfhydryl groups of the urease enzyme.

11.1.2, respectively. The chemistry of cross-linking alkaline phosphatase to antibodies is presented in Figure 11.16.2.

CONJUGATION OF HORSERADISH PEROXIDASE TO ANTIBODIES

Horseradish peroxidase–antibody conjugates (Tijssen and Kurstak, 1984) can be used in ELISA (enzyme-linked immunosorbent assay; *UNIT 11.2*) and western blotting (*UNIT 10.8*).

Materials

1 mg/ml antibody solution (affinity-purified polyclonal or monoclonal antibodies; *UNIT 11.11*)

0.1 M phosphate buffer, pH 6.8

Horseradish peroxidase (HRPO; Sigma Type VI #P8375)

0.1 M carbonate buffer, pH 9.2

Sodium periodate (NaIO₄) solution, freshly prepared

Sodium borohydride (NaBH₄) solution, freshly prepared

Saturated ammonium sulfate [(NH₄)₂SO₄] solution

Tris/EDTA/NaCl (TEN) buffer, pH 7.2

Bovine serum albumin (BSA)

Glycerol

Dialysis membrane (see reagents and solutions and *APPENDIX 3*)

Pasteur pipet fitted with glass wool

Sephadex G-25, medium (size of gel matrix)

1. Dialyze 1 mg/ml antibody solution against 2 liters of 0.1 M phosphate buffer, pH 6.8, overnight at 4°C, stirring gently.

**BASIC
PROTOCOL**

Immunology

11.1.2

Antibody may be polyclonal or monoclonal, purified as described in UNIT 11.11.

A₂₈₀/1.44 = mg IgG/ml. Concentration of antibody should be at least 1 mg/ml.

Soak dialysis membrane 1 hr in 50% (v/v) aqueous ethanol, 1 hr in 10 mM NaHCO₃, and 1 hr in 1 mM EDTA. Then rinse twice in distilled water and store at 4°C in phosphate buffer containing 0.01% (w/v) sodium azide.

2. Dissolve 10 mg HRPO in 1 ml 0.1 M carbonate buffer, pH 9.2.
3. Mix 0.25 ml freshly prepared NaIO₄ solution with 0.25 ml of 10 mg/ml HRPO/carbonate mixture from step 2, cap tightly, and incubate at room temperature for 2 hr in the dark (NaIO₄ is light sensitive).
4. Into a Pasteur pipet fitted with glass wool and blocked at the tip with Parafilm, add 1 ml of the dialyzed 1 mg/ml antibody solution from step 1 to 0.5 ml of the 10 mg/ml HRPO solution from step 3. Add 0.25 g Sephadex G-25 to the antibody/HRPO mixture.

Addition of Sephadex increases the concentration of antibody and HRPO by absorbing water. This enhances the conjugation of enzyme to antibody.

5. Incubate 3 hr at room temperature in the dark.
6. Wash column with 0.75 ml carbonate buffer to elute conjugate.
7. Add 38 µl freshly prepared NaBH₄ solution to the eluate and incubate 30 min at room temperature in the dark.
8. Add 112 µl freshly prepared NaBH₄ and incubate 60 min in the dark.
9. Add 0.9 ml of saturated (NH₄)₂SO₄ solution and stir gently for 30 min at 4°C. Centrifuge 15 min at 10,000 × g, 4°C.
10. Decant, discard supernatant, and resuspend pellet in 0.75 ml TEN buffer.
11. Dialyze resuspended pellet overnight at 4°C against 2 liters TEN buffer. Change TEN solution in the morning and continue dialyzing for 4 hr.
12. Remove conjugate from dialysis membrane and add sufficient BSA to bring the conjugate solution to a final concentration of 20 mg BSA/ml.
13. Add an equal volume of glycerol and store at -20°C.

**ALTERNATE
PROTOCOL**

CONJUGATION OF UREASE TO ANTIBODIES

Urease conjugates can be used in ELISA (UNIT 11.2) but not western blotting (UNIT 10.8).

Additional Materials

- 20 mg/ml urease (Sigma Type VII #U0376; source is important) in 0.1 M phosphate buffer
- m*-Maleimidobenzoyl *N*-hydroxysuccinimide ester in dimethylformamide (MBS/DMF solution)
- 0.143 M 2-mercaptoethanol (prepare from 14.3 M stock)
- Phosphate-buffered saline (PBS; APPENDIX 2)
- 12 × 75-mm glass tubes
- 1.5 × 5-cm PD-10 column (Pharmacia)
- Nitrogen tank

1. Repeat step 1 of the basic protocol.
2. Dialyze 0.25 ml of 20 mg/ml urease in 0.1 M phosphate buffer against 2 liters 0.1 M phosphate buffer overnight at 4°C while stirring gently.
3. In the morning replace the phosphate buffer and continue to dialyze for 2 hr.
4. Remove antibody and urease solutions from dialysis membranes and place in separate glass tubes. Read A_{280} of antibody solution and dilute with phosphate buffer to 0.5 mg/ml.
5. Add 0.075 ml MBS/DMF solution to 1.5 ml of 0.5 mg/ml dialyzed antibody solution in a glass tube (MBS/antibody molar ratio, 120:1). Place a magnetic stir bar in the tube and stir gently at room temperature for 30 min.
6. Load on a PD-10 column (see support protocol, *UNIT 10.9*) preequilibrated with 100 ml phosphate buffer. Run column with phosphate buffer and collect 0.6-ml fractions. Read A_{280} of fractions and collect first peak that elutes.

The first peak contains activated antibody and the second peak contains free MBS.

7. Pool first peak (generally about 2.5 to 3.0 ml) and add 0.15 ml of 20 mg/ml urease in 0.1 M phosphatase buffer (urease/antibody weight ratio, 4:1).
8. Stir at room temperature under N_2 for 1.5 hr or until solution appears cloudy.
9. Add 0.143 M 2-mercaptoethanol to a final concentration of 2 mM (0.014 ml mercaptoethanol solution/ml urease-antibody conjugate) and stir at room temperature for 30 min.
10. Dialyze overnight at 4°C against 2 liters PBS. In the morning, replace PBS and dialyze 4 hr.
11. Add an equal volume of glycerol, divide into small aliquots, and store at -20°C (stable for 1 year).

CONJUGATION OF ALKALINE PHOSPHATASE TO ANTIBODIES

Alkaline phosphatase conjugates can be used in ELISA (*UNIT 11.2*) and western blotting (*UNIT 10.8*).

Additional Materials

- 5 mg/ml antibody solution (affinity-purified polyclonal or monoclonal antibodies, *UNIT 11.11*)
- 10 mg/ml alkaline phosphatase (enzyme immunoassay grade; Boehringer Mannheim; source is important)
- 25% glutaraldehyde in H_2O
- Tris/ovalbumin solution
- Sodium azide

1. Dialyze 5 mg/ml antibody solution as in step 1 of the basic protocol, except dialyze against PBS.
2. Remove antibody solution from dialysis membrane and place in a tube. Read A_{280} and dilute with PBS to 3 mg/ml.
3. Add 100 μ l dialyzed antibody solution to 90 μ l of 10 mg/ml alkaline phosphatase in a 1.5-ml microcentrifuge tube.

***ALTERNATE
PROTOCOL***

Immunology

11.1.4

4. Add 5 ml 25% glutaraldehyde and mix gently. Let stand at room temperature.
5. Remove 25- μ l samples at time 0, 5, 10, 15, 30, 60, and 120 min and place in separate 1.5-ml microcentrifuge tubes. Add 125 μ l PBS to each sample, then add 1.1 ml Tris/ovalbumin solution. Store each sample on ice until the time course is completed.
6. Dialyze the samples against PBS as described in step 1 of this protocol. Test each sample for alkaline phosphatase activity using a direct ELISA assay (*UNIT 11.2*) to determine which conjugation time yields the most active enzyme conjugate.
7. Repeat steps 1 to 4, but in step 4 allow the reaction to proceed for the optimal conjugation time, as determined in step 6.
8. Add sodium azide to 0.1% and store the conjugate protected from light at 4°C for up to 1 year. Alternatively, add an equal volume of glycerol and store the conjugates at -20°C for 1 year.

REAGENTS AND SOLUTIONS

0.1 M carbonate buffer, pH 9.2

1.36 g sodium carbonate
 7.35 g sodium bicarbonate
 950 ml H₂O
 Adjust pH to 9.2 with 1 M HCl or 1 M NaOH, if necessary
 Add H₂O to 1 liter

m-Maleimidobenzoyl N-hydroxysuccinimide ester in dimethylformamide (MBS/DMF solution)

Prepare 0.25% (w/v) solution by adding 2.3 mg MBS (Pierce #22310) to 0.92 ml DMF. Use within 1 hr of preparation.

MBS will deteriorate upon prolonged storage if repeatedly thawed, opened, and refrozen. Dispense into 10-mg aliquots and store desiccated at -20°C.

0.1 M phosphate buffer, pH 6.8

Stock A, 0.2 M: 31.2 g NaH₂PO₄ in 1 liter H₂O
 Stock B, 0.2 M: 28.39 g Na₂HPO₄ in 1 liter H₂O
 Mix 51 ml Stock A, 49 ml Stock B, and 100 ml H₂O

Saturated ammonium sulfate [(NH₄)₂SO₄] solution

Prepare 0.01 M Tris solution by adding 1.21 g Tris base to 990 ml water, adjust to pH 7.0, and bring to a final volume of 1 liter. Weigh 767 g (NH₄)₂SO₄ and dissolve in 1 liter 0.01 M Tris by stirring and gently warming. Adjust the pH to 7.0 and store at 4°C. (NH₄)₂SO₄ crystals should be seen at the bottom of the solution at 4°C.

Sodium borohydride (NaBH₄) solution

5 mg NaBH₄/ml 0.1 mM NaOH (use immediately)

Sodium periodate (NaIO₄) solution

1.71 mg NaIO₄/ml H₂O (use immediately)

Tris/EDTA/NaCl (TEN) buffer, pH 7.2

To 930 ml H₂O, add:
 6.06 g Tris base
 0.37 g Na₂EDTA
 8.77 g NaCl
 Adjust pH to 7.2 with HCl
 Add H₂O to 1 liter

Tris/ovalbumin buffer

0.05 M Tris·Cl, pH 8.0

5% ovalbumin

5 mM MgCl₂

0.5% NaN₃

0.5% mertiolate

COMMENTARY

Background Information

Direct conjugation of enzymes to antibodies has greatly simplified the development and performance of many different types of immunoassays. The conjugation of HRPO (Nakane and Kawaoi, 1974) to antibody is dependent on the generation of aldehyde groups by periodate oxidation of the carbohydrate moieties on HRPO. Combination of these active aldehydes with amino groups on the antibody forms Schiff bases that, upon reduction by sodium borohydride, become stable. Horseradish peroxidase (HRPO) conjugates are useful in all types of immunological assays, but are generally less stable than urease conjugates. In addition, endogenous peroxidases may cause false positive reactions. For urease conjugation (Healey et al., 1983), cross-linking the enzyme and antibody with MBS is achieved through benzoylation of free amino groups on antibody. This is followed by thiolation of the maleimide moiety of MBS by the cysteine sulfhydryl groups of urease. The advantages of urease conjugates are their stability in solution at normal working dilutions, the rapid turnover rate of the enzyme, the easily discernible color change when substrate is added, and the fact that urease is not found in most mammalian or bacterial systems. The disadvantage is that since no precipitable substrate is available, urease conjugates cannot be used for immunohistology or western blotting.

Alkaline phosphatase conjugates are useful for all types of immunological assays depending on the alkaline phosphatase substrate used (i.e., *p*-nitrophenyl phosphate in diethanolamine is the preferred substrate for ELISA with colorimetric detection, 4-methylumbelliferyl phosphate is useful for ELISA with fluorimetric detection, and nitroblue tetrazolium/5-bromo-4-chloro-3-indolyl phosphate is the preferred substrate for western blotting). Alkaline phosphatase conjugates are as stable as urease conjugates and more stable than HRPO conjugates. Endogenous phosphatases can cause false positive reactions. However, levamisole will inhibit alkaline phosphatase in many mammalian tissues but not the alkaline phosphatase (i.e., bovine intestinal) used in the conjugates,

and for this reason levamisole may be added to the substrate solution.

The one-step glutaraldehyde method (Voller et al., 1976) is the most simple available procedure for preparing alkaline phosphatase-antibody conjugates. Various alternative procedures for preparing alkaline phosphatase conjugates have been compared (Jeanson et al., 1988).

The sensitivity that can be achieved with either HRPO, urease, or alkaline phosphatase conjugates is comparable and between 1 ng/ml and 10 ng/ml of antigen can be detected.

Critical Parameters

The most critical parameters of both conjugation methods are the quality of enzyme and the cross-linking reagents. Several lots of these reagents should be tested as described in the protocol before conjugating to larger quantities of antibodies. It is imperative that the *m*-maleimidobenzoyl *N*-hydroxysuccinimide ester (MBS), sodium periodate (NaIO₄), and sodium borohydride (NaBH₄) be stored in a desiccator and that solutions containing these chemicals be prepared immediately prior to use. The method described is applicable to most antibodies and should produce conjugates that are useful for developing an ELISA for detecting sensitively and specifically a given antigen. However, not all antibodies conjugate in an identical manner. It may be necessary to vary the ratio of MBS/antibody or urease/antibody for the urease conjugation and the NaIO₄/HRPO and HRPO/antibody ratios for a given HRPO conjugation.

The quality and grade of alkaline phosphatase is crucial to the generation of effective conjugates. Immunoassay grade material is recommended over lower grades, and the enzyme should not be conjugated beyond its expiration date. In the case of polyclonal antisera, the specificity and titer of the antiserum will be reflected in the conjugate and any purification procedures that increase these values, such as immunoaffinity chromatography (UNIT 10.11) will enhance conjugate performance.

The selection of an optimal conjugation time

for preparing alkaline phosphatase–antibody conjugates varies for different antibodies, in particular when monoclonal antibodies are used. In contrast, polyclonal antibodies may be reliably conjugated in 120 min.

Troubleshooting

There are several factors that may contribute to the production of poor enzyme-antibody conjugates. It is important to determine first whether a poor conjugate is the result of inactivation of either the antibody or the enzyme (or both) or the result of insufficient or excessive cross-linking. The affinity of the antibody for substrate can be measured by determining the presence of bound antibody with another immunoassay employing anti-antibody conjugated to a different enzyme. Enzyme activity can be measured by cleavage of substrate at different enzyme concentrations. Precipitation of material in the conjugate solution or opaque solutions are indicative of excessive cross-linking. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (UNIT 10.2) is useful for monitoring the extent of cross-linking by determining the M_r of the cross-linked species.

Insufficient cross-linking usually results from the use of inactive or poor-quality cross-linking agents. Try using fresh reagents or different lots of reagent. Excessive cross-linking and inactivation of antibody or enzyme can be eliminated by either reducing the concentration of antibody and enzyme or by reducing the time of reaction.

It may not be possible to generate effective alkaline phosphatase conjugates with all antibodies using the one-step glutaraldehyde method. An alternative is to try a different conjugation technique (see Jeanson et al., 1988). Another alternative is to use an anti-species antibody–alkaline phosphatase conjugate to detect the antibody in question. These reagents may be purchased or prepared using the above technique.

Anticipated Results

Most monoclonal antibodies will couple to alkaline phosphatase very quickly, and a 5-min conjugation time will often be optimal. In general, polyclonal antibodies will take longer to conjugate, usually between 1 and 2 hr. The yield and titer of the resultant conjugate will depend on the original antibody's properties and spe-

cific application.

It is difficult to estimate the yield or working dilution of the conjugates, as it is dependent on numerous factors such as antibody affinity, type of ELISA, and quality of antigen. In general, the working dilutions range from 1:100 to 1:10,000.

Time Considerations

The total time for conjugation is 1 to 3 days, with working times of several hours per conjugation. The majority of time is spent dialyzing or stirring. Once started, a protocol should be completed as described because the reactant products and solutions are unstable.

Enzyme-Linked Immunosorbent Assays (ELISA)

This unit describes six different ELISA systems for the detection of specific antibodies, soluble antigens, or cell-surface antigens. In all six systems, soluble reactants are removed from solution after specifically binding to solid-phase reactants. Table 11.2.1 summarizes the different ELISA protocols, which are illustrated in Figures 11.2.1-11.2.6.

In the first four protocols, solid-phase reactants are prepared by adsorbing an antigen or antibody onto plastic microtiter plates; in the next two protocols, the solid-phase reactants are cell-associated molecules. In all protocols, the solid-phase reagents are incubated with secondary or tertiary reactants covalently coupled to an enzyme.

Table 11.2.1 Summary of ELISA Protocols

ELISA protocol	Uses	Required reagents	Comments
Indirect	Antibody screening; epitope mapping	Antigen, pure or semipure; test solution containing antibody; enzyme conjugate that binds Ig of immunized species	Does not require the use of preexisting specific antibodies; requires relatively large amounts of antigen
Direct competitive	Antigen screening; detect soluble antigen	Antigen, pure or semipure; test solution containing antigen; enzyme-antibody conjugate specific for antigen	Rapid assay with only two steps; excellent for measuring antigenic cross-reactivity
Antibody-sandwich	Antigen screening; detect soluble antigen	Capture antibody (purified or semi-purified specific antibody); test solution containing antigen; enzyme-antibody conjugate specific for antigen	Most sensitive antigen assay; requires relatively large amounts of pure or semi-pure specific antibody (capture antibody)
Double antibody-sandwich	Antibody-screening; epitope mapping	Capture antibody: (specific for Ig of immunized species); test solution containing antigen; enzyme-antibody conjugate specific for antigen	Does not require purified antigen; relatively long assay with five steps
Direct cellular	Screen cells for expression of antigen; measure cellular antigen expression	Cells that express antigen of interest; enzyme-antibody conjugate specific for cellular antigen	Sensitive assay for bulk screening; insensitive to heterogeneity of expression in mixed population of cells
Indirect cellular	Screen for antibodies against cellular antigens	Cells used for immunizing; test solution containing antibodies; enzyme conjugate that binds Ig of immunized species	May not detect antibodies specific for cellular antigens expressed at a low density

Unbound conjugates are washed out and a chromogenic or fluorogenic substrate is added. As the substrate is hydrolyzed by the bound enzyme conjugate, a colored or fluorescent product is generated. Finally, the product is detected visually or with a microtiter plate reader. The amount of product generated is proportional to the amount of analyte in the test mixture. The first support protocol can be used to optimize the different ELISAs. The second support protocol provides a method for preparing lysates for use as test antigen from bacterial cultures containing expressed protein.

BASIC PROTOCOL

INDIRECT ELISA TO DETECT SPECIFIC ANTIBODIES

This assay is useful for screening antisera or hybridoma supernatants for specific antibodies when milligram quantities of purified or semipurified antigen are available (1 mg of purified antigen will permit screening of 80 to 800 microtiter plates; Fig. 11.2.1). Antibodies are detected by coating the wells of microtiter plates with antigen, incubating the coated plates with test solutions containing specific antibodies, and washing away unbound antibodies. A solution containing a developing reagent, (e.g., alkaline phosphatase conjugated to protein A, protein G, or antibodies against the test solution antibodies) is then added to the plate. After incubation, unbound conjugate is washed away and substrate solution is added. After a second incubation, the amount of substrate hydrolyzed is assessed with a spectrophotometer or spectrofluorometer. The measured amount is proportional to the amount of specific antibody in the test solution. Visual inspection can also be used to detect hydrolysis.

Materials

Developing reagent: protein A–alkaline phosphatase conjugate (Sigma #P9650), protein G–alkaline phosphatase conjugate (Calbiochem #539304), or anti-Ig-alkaline phosphatase conjugate (*UNIT 11.1*)

Antigen solution

PBS (*APPENDIX 2*) containing 0.05% NaN₃ (PBSN)

Water, deionized or distilled

Blocking buffer

Test antibody samples

4-methylumbelliferyl phosphate (MUP) or *p*-nitrophenyl phosphate (NPP) substrate solution

0.5 M NaOH (optional)

Multichannel pipet and disposable pipet tips

Immulon 2 (Dynatech #011-010-3450), Immulon 4 (Dynatech #011-010-3850), or equivalent microtiter plates

Plastic squirt bottles

Microtiter plate reader (optional)—spectrophotometer with 405-nm filter or spectrofluorometer (Dynatech #011-970-1900) with 365-nm excitation filter and 450-nm emission filter

Determine developing reagent and antigen concentrations

1. Determine the optimal concentration of the developing reagent (conjugate) by criss-cross serial dilution analysis (see first support protocol).

Good conjugates of many specificities are available commercially. Choice of developing reagent (i.e., conjugate) is determined by the goals of the assay. If it is necessary to detect all antibodies that bind to antigen, conjugates prepared with antibodies specific for Ig κ and λ light chains should be used. Alternatively, protein A– or protein G–enzyme conjugates may be preferable when screening monoclonal antibodies. Specific monoclonal antibodies that bind protein A or protein G are easy to purify and characterize.

- Determine the final concentration of antigen coating reagent by criss-cross serial dilution analysis (see first support protocol). Prepare an antigen solution in PBSN at this final concentration. The final concentration of antigen is usually 0.2 to 10.0 $\mu\text{g/ml}$. Prepare ~ 6 ml antigen solution for each plate.

Pure antigen solution concentrations are usually ≤ 2 $\mu\text{g/ml}$. Although pure antigen preparations are not essential, $>3\%$ of the protein in the antigen solution should be the antigen. The total concentration of protein in the antigen solution should be increased for semipurified antigen preparations. Do not raise the total protein concentration in the antigen solution to >10 $\mu\text{g/ml}$, since this concentration usually saturates $>85\%$ of the available sites on Immulon microtiter plates. For some antigens, coating may occur more efficiently at different pHs.

Coat plate with antigen

- Using a multichannel pipet and tips, dispense 50 μl antigen solution into each well of an Immulon microtiter plate. Tap or shake the plate to ensure that the antigen solution is evenly distributed over the bottom of each well.

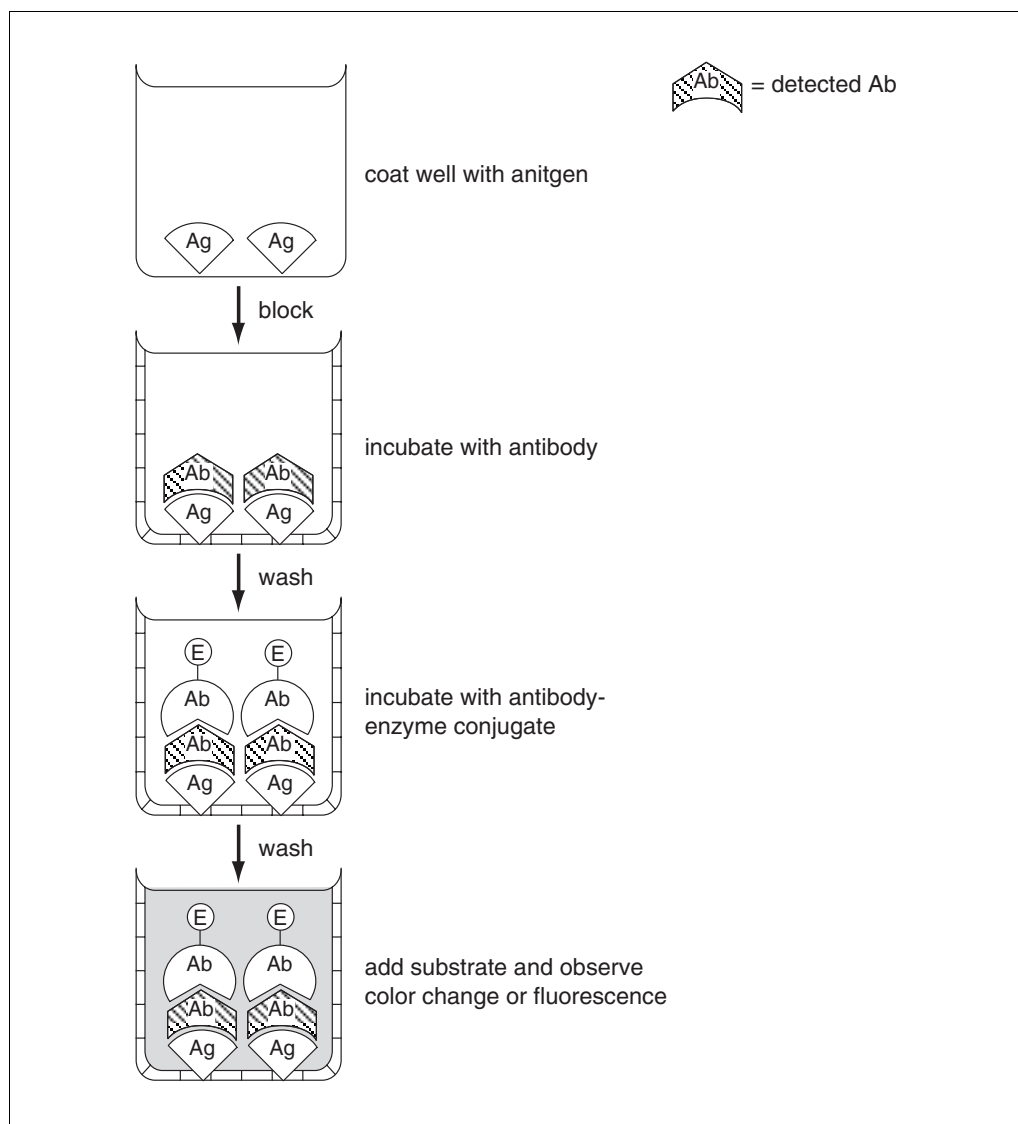

Figure 11.2.1 Indirect ELISA to detect specific antibodies. Ag = antigen; Ab = antibody; E = enzyme.

4. Wrap coated plates in plastic wrap to seal and incubate overnight at room temperature or 2 hr at 37°C.

Individual adhesive plate sealers are sold commercially but plastic wrap is easier to use and works as well. Sealed plates can be stored at 4°C with antigen solution for months.

5. Rinse coated plate over a sink by filling wells with deionized or distilled water dispensed either from a plastic squirt bottle or from the tap. Flick the water into the sink and rinse with water two more times, flicking the water into the sink after each rinse.

Block residual binding capacity of plate

6. Fill each well with blocking buffer dispensed as a stream from a squirt bottle and incubate 30 min at room temperature.

Residual binding capacity of the plate is blocked in this step. Tween 20 (0.05%) by itself is more effective at blocking than any protein tested, but because the combination of protein and Tween 20 may be more effective than Tween 20 alone in some cases, bovine serum albumin (BSA; 0.25%) is included in the blocking buffer.

7. Rinse plate three times in water as in step 5. After the last rinse, remove residual liquid by wrapping each plate in a large paper tissue and gently flicking it face down onto several paper towels laying on the benchtop.

Rinsing with water is cheaper and easier than rinsing with buffered solutions and is as effective.

Add antibody to plate

8. Add 50 µl antibody samples diluted in blocking buffer to each of the coated wells, wrap plate in plastic wrap, and incubate ≥2 hr at room temperature.

While enough antibody may be bound after 1 to 2 hr to generate a strong signal, equilibrium binding is generally achieved after 5 to 10 hr. Thus, the specific signal may be significantly increased by longer incubations.

For this and all steps involving the delivery of aliquots of many different solutions to microtiter plates with multichannel pipets, such as the primary screening of hybridoma supernatants, the same pipet tips can be reused for hundreds of separate transfers. Wash tips between transfers by expelling any liquid remaining in the tips onto an absorbent surface of paper tissues, rinsing tips five times in blocking buffer, and carefully expelling any residual liquid from tips onto the tissues. Avoid bubbles in the tips; any tip with intractable bubbles should be replaced.

Wash the plate

9. Rinse plate three times in water as in step 5.
10. Fill each well with blocking buffer, vortex, and incubate 10 min at room temperature.

Plates are vortexed to remove any reagent remaining in the corners of the wells.

11. Rinse three times in water as in step 5. After the final rinse, remove residual liquid as in step 7.

Add developing reagent to plate

12. Add 50 µl developing reagent in blocking buffer (at optimal concentration determined in step 1) to each well, wrap in plastic wrap, and incubate ≥2 hr at room temperature.

The strength of the signal may be increased by longer incubations (see annotation to step 8).

13. Wash plates as in steps 9 to 11.

After final rinsing, plates may be wrapped in plastic wrap and stored for months at 4°C prior to adding substrate.

Add substrate and measure hydrolysis

14. Add 75 µl MUP or NPP substrate solution to each well and incubate 1 hr at room temperature.
15. Monitor hydrolysis qualitatively by visual inspection or quantitatively with a microtiter plate reader (see below). Hydrolysis can be stopped by adding 25 µl of 0.5 M NaOH.
 - a. Visually, hydrolysis of NPP can be detected by the appearance of a yellow color. If using a microtiter plate reader to measure NPP hydrolysis, use a 405-nm filter.
 - b. Visually, hydrolysis of MUP can be monitored in a darkened room by illumination with a long-wavelength UV lamp. If using a microtiter plate spectrofluorometer to measure MUP hydrolysis, use a 365-nm excitation filter and a 450-nm emission filter.

The fluorogenic system using the MUP substrate is 10 to 100 times faster than the chromogenic system using NPP. Furthermore, the rate of spontaneous hydrolysis of MUP is much lower than that of NPP.

To detect bound antibodies that are present at low concentration, measure hydrolysis at a later time. To calculate when to measure hydrolysis the second time, remember that the amount of hydrolysis is almost directly proportional to the time of hydrolysis. For example, if the hydrolysis in the wells of interest reads 200 at 1 hr and a reading of 2000 is desired, incubate the plate ~10 hr before taking the second reading.

DIRECT COMPETITIVE ELISA TO DETECT SOLUBLE ANTIGENS

This assay is used to detect or quantitate soluble antigens and is most useful when both a specific antibody and milligram quantities of purified or semipurified antigen are available (Fig. 11.2.2). To detect soluble antigens, plates are coated with antigen and the binding of specific antibody-enzyme conjugates to antigen-coated plates is inhibited by test solutions containing soluble antigen. After incubation with mixtures of the conjugate and inhibitor in antigen-coated wells, unbound conjugate is washed away and substrate is added. The amount of antigen in the test solutions is proportional to the inhibition of substrate hydrolysis and can be quantitated by interpolation onto an inhibition curve generated with serial dilutions of a standard antigen solution.

The direct assay may also be adapted as an indirect assay by substituting specific antibody for specific antibody-enzyme conjugate. The amount of specific antibody bound is then detected using a species-specific or isotype-specific conjugate as a tertiary reactant.

Additional Materials

- Specific antibody–alkaline phosphatase conjugate (*UNIT 11.1*)
- Standard antigen solution
- Test antigen solutions
- Round- or cone-bottom microtiter plates

1. Determine the optimal concentration of coating reagent and antibody–alkaline phosphatase conjugate by criss-cross serial dilution analysis in which the concentrations of both the antigen (coating reagent) and the conjugate (developing reagent) are varied (see first support protocol). Prepare a 2× conjugate solution by diluting the

ALTERNATE PROTOCOL

Immunology

11.2.5

specific antibody–alkaline phosphatase conjugate in blocking buffer to twice the optimal concentration.

The final concentration is usually 25 to 500 ng antibody/ml. Prepare 3 ml antibody–alkaline phosphatase conjugate for each plate.

2. Coat and block wells of an Immulon microtiter plate with 50 μ l antigen solution as in steps 2 to 7 of the basic protocol.
3. Prepare six 1:3 serial dilutions of standard antigen solution in blocking buffer (see first support protocol for preparation of serial dilutions)—these antigen concentrations will be used in preparing a standard inhibition curve (see step 10).

Antigen concentrations should span the dynamic range of inhibition. The dynamic range of inhibition is defined as that range of inhibitor concentrations wherein changes of inhibitor concentration produce detectable changes in the amount of inhibition. The dynamic range of inhibition is empirically determined in an initial assay in which antigen concentration is typically varied from the micromolar (10^{-6} M) to the picomolar (10^{-12} M) range. For most protein antigens, initial concentration should be ~ 10 μ g/ml, followed by nine 1:4 serial dilutions in blocking buffer. These antigen dilutions are assayed for their ability to inhibit the binding of conjugate to antigen-coated plates under standard assay conditions. From this initial assay, six 1:3 antigen dilutions spanning the dynamic range of inhibition are selected for further use as standard antigen-inhibitor dilutions. Prepare ≥ 75 μ l of each dilution for each plate to be assayed.

Inhibitor curves are most sensitive in the region of the curve where small changes in inhibitor concentrations produce maximal changes in the amount of inhibition. This

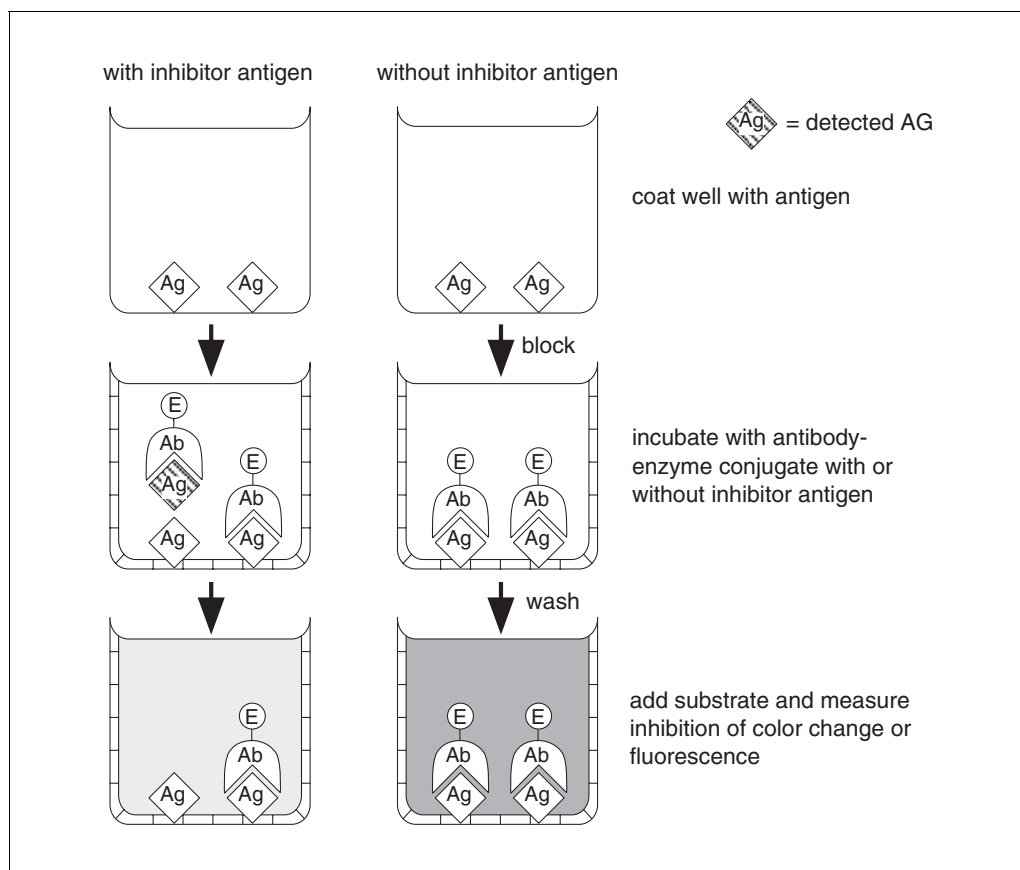

Figure 11.2.2 Direct competitive ELISA to detect soluble antigens. Ag = antigen; Ab = antibody; E = enzyme.

region of the curve normally spans 15% to 85% inhibition. In most systems, this range of inhibition is produced by concentrations of inhibitor between 1 and 250 ng/ml.

4. Mix and incubate conjugate and inhibitor by adding 75 μ l of 2 \times conjugate solution (from step 1) to each well of a round- or cone-bottom microtiter plate, followed by 75 μ l inhibitor—either test antigen solution or standard antigen solution (from step 3). Mix the conjugate and inhibitor solutions by pipetting up and down in the pipet tip three times (see annotation to step 8 in the basic protocol) and incubate \geq 30 min at room temperature.

For accurate quantitation of the amount of antigen in the test solutions, test antigen solutions should inhibit conjugate binding between 15% to 85%. It may be necessary to assay two or three different dilutions of the test solutions to produce inhibitions within this range.

5. Prepare uninhibited control samples by mixing equal volumes of 2 \times conjugate solution and blocking buffer.
6. Transfer 50 μ l of the mixture of conjugate plus inhibitor (from step 4) or conjugate plus blocking buffer (from step 5) to an antigen-coated plate (from step 2) and incubate 2 hr at room temperature.

If samples are to be assayed in duplicate, the duplicates should be in adjacent columns on the same plate. Reserve column 11 for uninhibited control samples (step 5) and column 12 for substrate alone without any conjugate. If the concentration of antigen in the test samples is to be accurately quantitated, dilutions of homologous antigen solutions (step 3) should be included on each plate.

7. Wash plate as in steps 9 to 11 of the basic protocol.
8. Add 75 μ l of MUP or NPP substrate solution to each well and incubate 1 hr at room temperature.
9. Read plates on the microtiter plate reader after \geq 1 hr, at which time enough substrate has been hydrolyzed in the uninhibited reactions to permit accurate measurement of the inhibition.
10. Prepare a standard antigen-inhibition curve constructed from the inhibitions produced by the dilutions of the standard antigen solutions from step 3. Plot antigen concentration on the x axis, which is a log scale, and fluorescence or absorbance on the y axis, which is a linear scale.
11. Interpolate the concentration of antigen in the test solutions from the standard antigen-inhibition curve.

The dynamic range of the inhibition curve may deviate from linearity if the specific antibodies are heterogeneous and possess significantly different affinities or if the standard antigen preparation contains heterogeneous forms of the antigen. Antigen concentration in test samples can be accurately interpolated from the inhibition curve as long as the test antigen is antigenically identical to the standard antigen and the concentration of test antigen falls within the dynamic range of inhibition.

ANTIBODY-SANDWICH ELISA TO DETECT SOLUBLE ANTIGENS

Antibody-sandwich ELISAs may be the most useful of the immunosorbent assays for detecting antigen because they are frequently between 2 and 5 times more sensitive than those in which antigen is directly bound to the solid phase (Fig. 11.2.3). To detect antigen, the wells of microtiter plates are coated with specific (capture) antibody followed by incubation with test solutions containing antigen. Unbound antigen is washed out and a different antigen-specific antibody conjugated to enzyme (i.e., developing reagent) is added, followed by another incubation. Unbound conjugate is washed out and substrate is added. After another incubation, the degree of substrate hydrolysis is measured. The amount of substrate hydrolyzed is proportional to the amount of antigen in the test solution.

Additional Materials

Specific antibody or immunoglobulin fraction from antiserum or ascites fluid, *or* hybridoma supernatant (UNIT 11.10), *or* bacterial lysate (second support protocol)

Figure 11.2.3 Antibody-sandwich ELISA to detect antigen. Ag = antigen; Ab = antibody; E = enzyme.

1. Prepare the capture antibody by diluting specific antibody or immunoglobulin fraction in PBSN to a final concentration of 0.2 to 10 $\mu\text{g/ml}$.

The capture antibodies can be monoclonal or polyclonal.

If the immunoglobulin fraction from an antiserum or ascites fluid is used, the concentration of total protein may need to be increased to compensate for the lower content of specific antibody. Little advantage is gained by increasing the total protein concentration in the capture antibody solution beyond 10 $\mu\text{g/ml}$.

2. Determine the concentration of capture antibody and conjugate necessary to detect the desired concentration of antigen by criss-cross serial dilution analysis (see first support protocol). Prepare a capture antibody solution in PBSN at this concentration.
3. Coat wells of an Immulon plate with capture-antibody solution as in steps 3 to 5 of the basic protocol.
4. Block wells as in steps 6 and 7 of the basic protocol.
5. Prepare a standard antigen-dilution series by successive 1:3 dilutions of the homologous antigen stock in blocking buffer (see first support protocol).

In order to measure the amount of antigen in a test sample, the standard antigen-dilution series needs to span most of the dynamic range of binding. This range typically spans from 0.1 to 1000 ng antigen/ml. The dynamic range of binding is defined as that range of antigen concentrations wherein small, incremental changes in antigen concentration produce detectable differences in the amount of antigen bound (see annotation to step 3, in the preceding alternate protocol). In most assay systems, the amount of antigen in a test solution is most accurately interpolated from the standard curve if it produces between 15% to 85% of maximal binding.

NOTE: While standard curves are necessary to accurately measure the amount of antigen in test samples, they are unnecessary for qualitative “yes/no” answers.

6. Prepare dilutions of test antigen solutions in blocking buffer.

It may be necessary to assay one or two serial dilutions of the initial antigen test solution to ensure that at least one of the dilutions can be accurately measured. For most assay systems, test solutions containing 1 to 100 ng/ml of antigen can be accurately measured.

7. Add 50- μl aliquots of the antigen test solutions and the standard antigen dilutions (from step 5) to the antibody-coated wells and incubate ≥ 2 hr at room temperature.

For accurate quantitation, samples should be run in duplicate or triplicate, and the standard antigen-dilution series should be included on each plate (see step 5). Pipetting should be performed rapidly to minimize differences in time of incubation between samples.

8. Wash plate as in steps 9 to 11 of the basic protocol.
9. Add 50 μl specific antibody-alkaline phosphatase conjugate and incubate 2 hr at room temperature.

The conjugate concentration is typically 25 to 400 ng specific antibody/ml.

When the capture antibody is specific for a single determinant, the conjugate must be prepared from antibodies which recognize different determinants that remain available after the antigen is bound to the plate by the capture antibody.

10. Wash plate as in steps 9 to 11 of the basic protocol.
11. Add 75 μl of MUP or NPP substrate solution to each well and incubate 1 hr at room temperature.

12. Read the plate on a microtiter plate reader.

To quantitate low-level reactions, the plate can be read again after several hours of hydrolysis.

13. Prepare a standard curve constructed from the data produced by serial dilutions of the standard antigen (step 5). Plot antigen concentration on the x axis which is a log scale, and fluorescence or absorbance on the y axis which is a linear scale.
14. Interpolate the concentration of antigen in the test solutions from the standard curve.

ALTERNATE PROTOCOL

DOUBLE ANTIBODY–SANDWICH ELISA TO DETECT SPECIFIC ANTIBODIES

This assay is especially useful when screening for specific antibodies in cases when a small amount of specific antibody is available and purified antigen is unavailable (Fig. 11.2.4). Additionally, this method can be used for epitope mapping of different monoclonal antibodies that are directed against the same antigen. Plates are coated with capture antibodies specific for immunoglobulin from the immunized species. The test antibody solution is incubated on the plates coated with the capture antibodies. Plates are then washed, incubated with antigen, washed again, and incubated with specific antibody conjugated to an enzyme. After incubation, unbound conjugate is washed out and substrate is added. Wells that are positive for hydrolysis may contain antibodies specific for the antigen.

Additional Materials

Capture antibodies specific for immunoglobulin from the immunized species
Specific antibody–alkaline phosphatase conjugate

1. Coat wells of an Immulon microtiter plate with 50 μ l of 2 to 10 μ g/ml capture antibodies as in steps 2 to 5 of the basic protocol.

NOTE: Capture antibodies must not bind the antigen or conjugate antibodies. When analyzing hybridoma supernatants or ascites fluid, coat plates with 2 μ g/ml capture antibody. When analyzing antisera, coat plates with 10 μ g/ml capture antibody.

2. Block wells as in steps 6 and 7 of the basic protocol.
3. Prepare dilutions of test antibody solutions in blocking buffer. Add 50 μ l to coated wells and incubate ≥ 2 hr at room temperature.

Hybridoma supernatants, antisera, or ascites fluid can be used as the test samples. Dilute hybridoma supernatants 1:5 and antisera or ascites fluid 1:200.

4. Wash plate as in steps 9 to 11 of the basic protocol.
5. Prepare an antigen solution in blocking buffer containing 20 to 200 ng/ml antigen.

Although purified antigen preparations are not essential, the limit of detectability for most protein antigens in this type of system is 2 to 20 ng/ml. A concentration of 20 to 200 ng antigen/ml is recommended.

6. Add 50- μ l aliquots of the antigen solution to antibody-coated wells and incubate ≥ 2 hr at room temperature.
7. Wash plate as in steps 9 to 11 of the basic protocol.
8. Add 50 μ l specific antibody–alkaline phosphatase conjugate to the wells and incubate 2 hr at room temperature.

The conjugate antibodies must not react with the capture antibody or the test antibody. The conjugate concentration is typically between 25 to 500 ng specific antibody/ml, and should be high enough to result in ~0.50 absorbance units/hr at 405 nm when using NPP as a substrate or a signal of 1000 to 1500 fluorescence units/hr when using MUP as a substrate. If no specific antibodies from the appropriate species are available to serve as a positive control, then a positive control system should be constructed out of available reagents. Such reagents can be found in Linscott's Directory of Immunological and Biological Reagents.

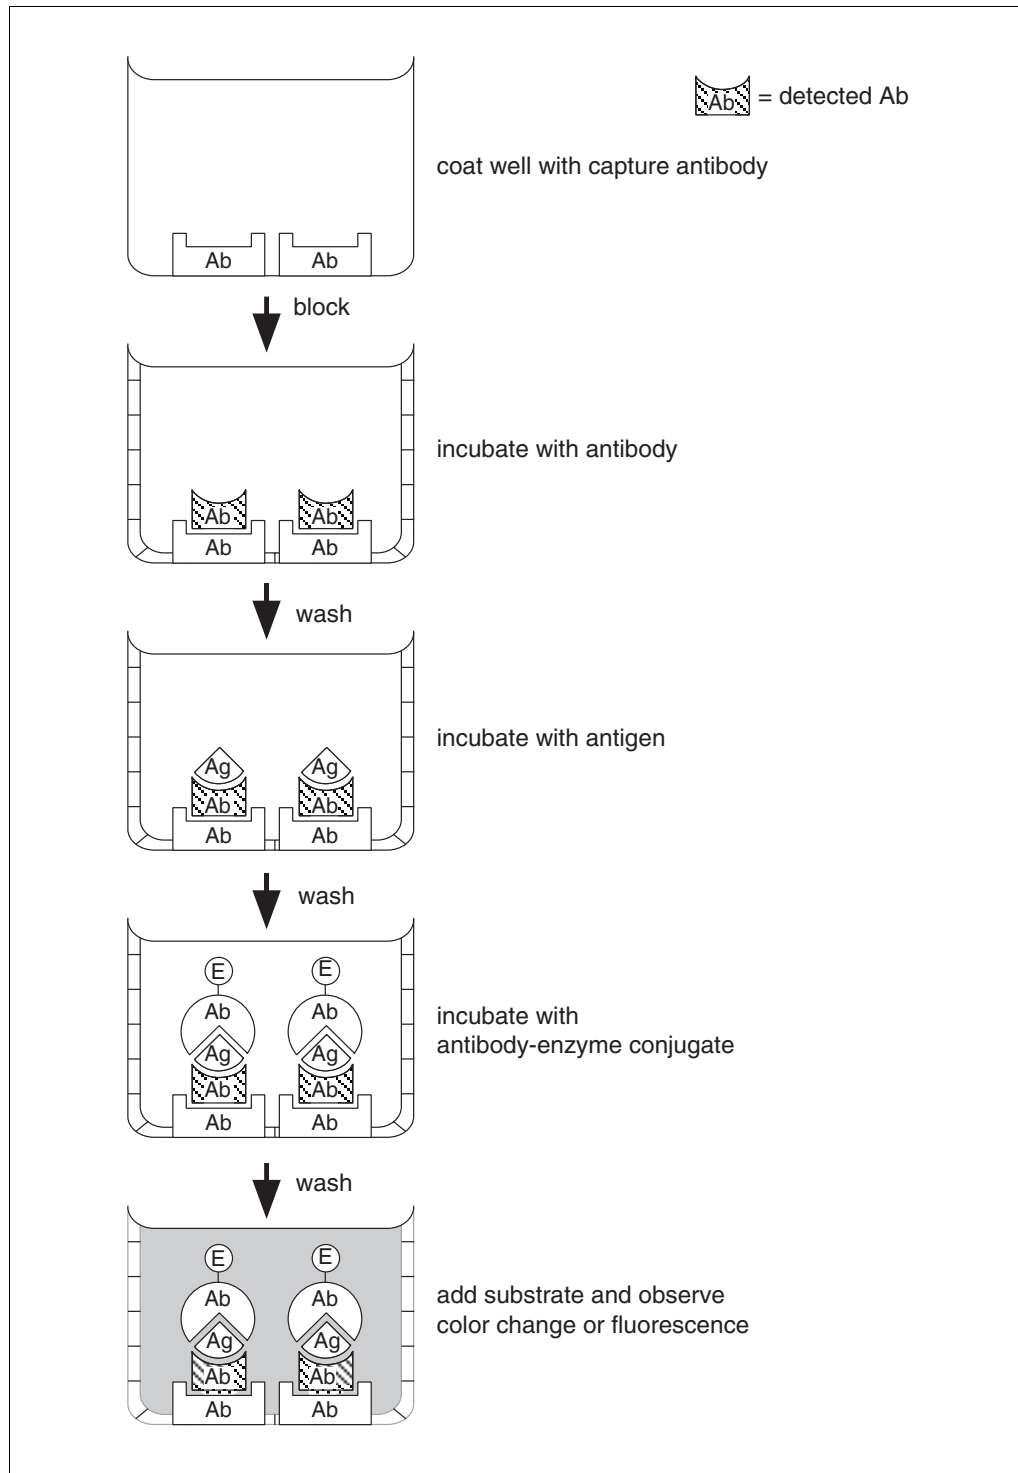

Figure 11.2.4 Double antibody-sandwich ELISA to detect specific antibodies. Ag = antigen; Ab = antibody; E = enzyme.

9. Wash plate as in steps 9 to 11 of the basic protocol.
10. Add 75 μ l of MUP or NPP substrate solution to each well and incubate 1 hr at room temperature. After 1 hr, examine hydrolysis visually or spectrophotometrically (see step 15 of the basic protocol).

In order to detect low-level reactions, the plate can be read again after several hours or days of hydrolysis.

11. Check for false positives by rescreening samples that test positive for antigen-specific antibody. For each positive sample, coat four wells with capture antibody and arm the capture antibody with test antibody (steps 1 to 4). Incubate two of the wells with antigen (steps 5 to 7) and two of the wells with blocking buffer. Add conjugate and substrate to all four wells (steps 8 to 10) and measure hydrolysis after 1 hr.

This procedure will eliminate false positives resulting from test antibodies that react with the enzyme-antibody complex.

ALTERNATE PROTOCOL

DIRECT CELLULAR ELISA TO DETECT CELL-SURFACE ANTIGENS

The expression of cell-surface antigens or receptors is measured using existing antibodies or other ligands specific for cell-surface molecules (Fig. 11.2.5). Cells are incubated with enzyme conjugated to antibodies that are specific for a cell-surface molecule. Unbound conjugate is washed away and substrate is added. The level of antigen expression is proportional to the amount of substrate hydrolysis. This procedure can be as sensitive as flow cytometry analysis in quantitating the level of antigen expression on a population of cells (Coligan et al., 1991). Unlike the flow cytometry analysis, however, this method is not sensitive for mixed populations. This assay can be converted to an indirect assay by substituting biotinylated antibody for the enzyme-antibody conjugate, followed by a second incubation with avidin-alkaline phosphatase.

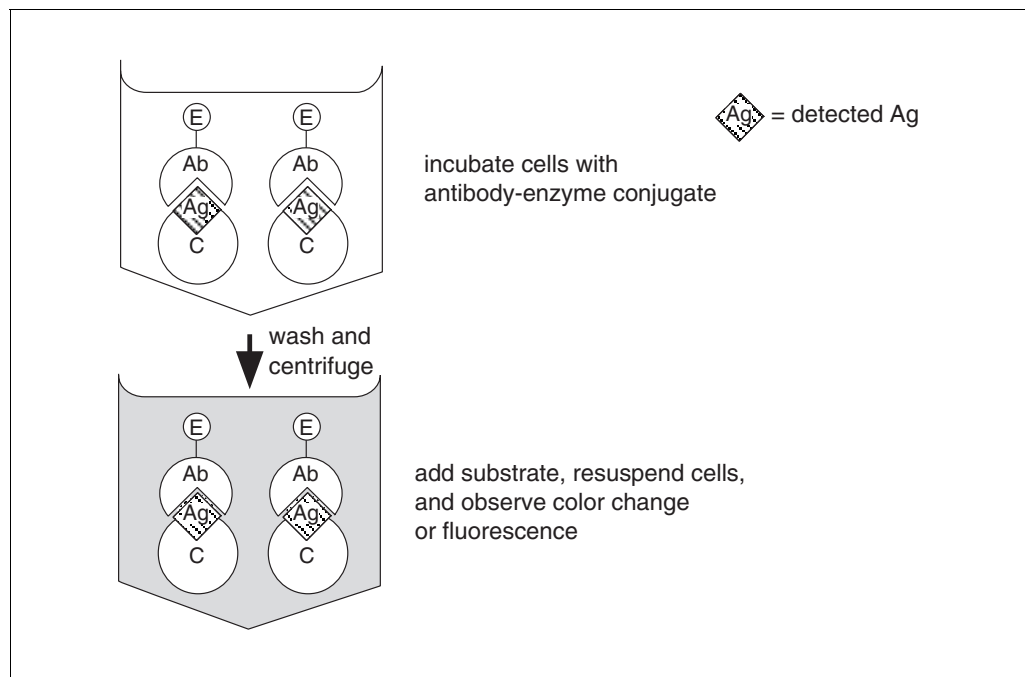

Figure 11.2.5 Direct cellular ELISA to detect cell-surface antigens. Ab = antibody; E = enzyme; C = cell.

Additional Materials

Cell samples
Specific antibody–alkaline phosphatase conjugate (see second support protocol)
Wash buffer, ice-cold

Cone- or round-bottom microtiter plates
Sorvall H-1000B rotor (or equivalent)

1. Determine the optimal number of cells per well and the antibody-conjugate concentration by criss-cross serial dilution analysis (see first support protocol) using variable numbers of positive- and negative-control cell samples and varying concentrations of antibody-biotin conjugate.

Titrate cells initially at $1-5 \times 10^5$ /well and conjugate at 0.5 to 10 $\mu\text{g/ml}$. For preparation and handling of cells, consult steps 2 to 5.

Because eukaryotic cells express variable amounts of alkaline phosphatase, test cells must be assayed in a preliminary experiment for alkaline phosphatase by incubation with substrate alone. If the test cells express unacceptable levels of alkaline phosphatase, another enzyme conjugate such as β -galactosidase should be used. Both chromogenic and fluorogenic substrates are available for β -galactosidase.

2. Centrifuge cell samples in a table-top centrifuge 5 min in Sorvall H-1000B rotor at 1500 rpm ($450 \times g$), 4°C , in a 15- to 50-ml centrifuge tube. Count cells (APPENDIX 3) and resuspend in ice-cold wash buffer at $1-5 \times 10^6$ cells/ml.

If the surface antigen retains its antigenicity after fixation, cells may be fixed at the beginning of the experiment—but do not fix cells unless it can be demonstrated that the antigenicity is retained after fixation. Fix cells by suspending in glutaraldehyde (0.5% final; from a 25% stock, EM grade Sigma #G5882), and incubating 30 min at room temperature. Pellet cells, resuspend in PBSLE (see second support protocol), and incubate for 30 min at 37°C . Wash twice in PBSLE and resuspend in wash buffer. Cells can be kept for months at 4°C after fixation.

3. Dispense 100 μl of cell suspension ($1-5 \times 10^5$ cells) into wells of cone- or round-bottom microtiter plates, and centrifuge 1 min at $450 \times g$, 4°C . Remove supernatant by vacuum aspiration, and disrupt pellet by briefly shaking microtiter plate on a vortex mixer or microtiter plate shaker.
4. Resuspend pellet in 100 μl of conjugate in ice-cold wash buffer at the optimal concentration (see step 1). Incubate 1.5 hr at 4°C , resuspending cells by gently shaking at 15-min intervals.

Be careful not to splash cell suspensions out of wells.

5. Centrifuge cells 1 min at $450 \times g$, 4°C , remove supernatant by vacuum aspiration, briefly vortex pellet, and resuspend in 200 μl ice-cold wash buffer. Repeat three times.
6. Add 100 μl MUP or NPP substrate solution. Incubate 1 hr at room temperature, resuspending cells by gently shaking at 15-min intervals during hydrolysis.
7. Determine extent of hydrolysis by visual inspection or using a microtiter plate reader.

INDIRECT CELLULAR ELISA TO DETECT ANTIBODIES SPECIFIC FOR SURFACE ANTIGENS

This assay is designed to screen for antibodies specific for cell-surface antigens (Fig. 11.2.6). Antibodies against surface antigens are detected by incubating whole cells with a test solution containing the primary antibody. The unbound antibody is washed away and the cells are then incubated with an enzyme conjugated to antibodies specific for the primary antibody. Unbound enzyme conjugate is washed away and substrate solution added. The level of bound primary antibody is proportional to the amount of substrate hydrolysis.

Additional Materials

Positive-control antibodies (i.e., those that react with the experimental cells and are from the immunized species)

Negative-control antibodies (i.e., those that do not react with the experimental cells)

Test antibody solution

Antibody or $F(ab')_2$ (against immunoglobulin from the immunized species) conjugated to alkaline phosphatase

Cone- or round-bottom microtiter plates

Figure 11.2.6 Indirect cellular ELISA to detect antibodies specific for surface antigens. Ab = antibody; E = enzyme; C = cell.

1. Centrifuge and resuspend cell samples as in step 2 of the previous alternate protocol at $1-5 \times 10^6$ cells/ml.

Because this technique detects antibodies against uncharacterized epitopes, fixation prior to analysis is not recommended. Fixation may destroy the antigenicity of the epitope. All steps must be performed at 4°C in physiological buffers containing NaN₃.

Because eukaryotic cells express variable amounts of alkaline phosphatase, test cells must be assayed for alkaline phosphatase activity. If the endogenous alkaline phosphatase level is too high, another enzyme should be substituted for alkaline phosphatase in the antibody-enzyme conjugate (see annotation to step 1 of the previous alternate protocol).

2. In preliminary assays, determine the optimal number of cells per well and conjugate concentration by criss-cross serial dilution analysis using positive- and negative-control antibodies instead of test antibodies (see first support protocol). In adapting the criss-cross serial dilution analysis, whole cells replace the solid-phase coating reagent; see techniques for handling cells are outlined in steps 3 to 8. Set up titrations by varying the number of cells between 1×10^5 and 5×10^5 /well, the concentration of positive- and negative-control antibodies between 0.1 and 10 µg/ml, and the concentration of antibody-enzyme conjugate between 0.1 and 10 µg/ml.
3. Dispense 100 µl of cell suspension ($1-5 \times 10^5$ cells) into wells of round- or cone-bottom microtiter plates. Centrifuge 1 min at 1500 rpm, 4°C, remove supernatant by vacuum aspiration, and disrupt pellet by briefly shaking microtiter plate on the vortex mixer.
4. Resuspend cells in 100 µl solutions containing 1 to 10 µg/ml test antibody or control antibodies in ice-cold wash buffer. Incubate 1.5 hr at 4°C, resuspending cells by gently shaking at 15-min intervals.

Be careful not to splash cell suspensions out of wells.

5. Centrifuge cells 1 min at 1500 rpm, 4°C, remove supernatant by vacuum aspiration, briefly vortex pellet, and resuspend in 200 µl ice-cold wash buffer. Repeat twice.
6. Resuspend pellet in 100 µl enzyme-antibody conjugate or F(ab')₂-enzyme conjugate diluted in ice-cold wash buffer. The optimal concentration of antibody, determined in step 2, is usually 100 to 500 ng/ml. Incubate 1.5 hr at 4°C, resuspending cells by gently shaking at 15-min intervals.

When working with cells that may express Fc receptors, it is best to use enzyme conjugated to F(ab')₂ fragments. F(ab')₂ fragments have had the Fc portion of the antibody enzymatically removed and no longer bind to Fc receptors.

7. Wash cells as in step 5. Repeat three times.
8. Add 100 µl MUP or NPP substrate solution. Allow hydrolysis to proceed until the signal has reached the desired levels; resuspend cells by gently shaking at 15 min intervals during hydrolysis. If desired, stop hydrolysis by adding 25 µl of 0.5 M NaOH.
9. Determine extent of hydrolysis by visual inspection or spectrophotometrically using a microtiter plate reader.

**CRISS-CROSS SERIAL DILUTION ANALYSIS TO DETERMINE
OPTIMAL REAGENT CONCENTRATIONS**

Serial dilution titration analyses are performed to determine optimal concentrations of reagents to be used in ELISAs. In this protocol, all three reactants in a three-step ELISA—a primary solid-phase coating reagent, a secondary reagent that binds the primary reagent, and an enzyme-conjugated tertiary developing reagent that binds to the secondary reagent—are serially diluted and analyzed by a criss-cross matrix analysis (Fig 11.2.7). Once the optimal concentrations of reagents to be used under particular assay conditions are determined, these variables are kept constant from experiment to experiment. The coating (primary), secondary, and developing (tertiary) reagents will vary depending upon which of the previous protocols needs to be optimized.

Additional Materials

- Coating reagent
- Secondary reagent
- Developing reagent
- 17 × 100–mm and 12 × 74–mm test tubes

		Secondary reactant												Rows
		homologous (antigen)						heterologous (antigen)

	Columns													

Figure 11.2.7 Results of a criss-cross serial dilution analysis (for optimization of secondary and tertiary reactant concentrations) of an antibody-sandwich ELISA to detect antigen. The numbers in columns 1 to 11 and rows B to G represent relative fluorescence units observed for each well on a 96-well microtiter plate.

Plates were coated overnight with the capture antibody at 2 μg/ml. The secondary reactants, 4-fold serial dilutions of the homologous antigen and a non-cross-reactive heterologous antigen, were incubated on the plate 2 hr. The tertiary reactant, 2-fold serial dilutions of specific antibody-alkaline phosphatase conjugates, were incubated on the plate 2 hr. After 1 hr of incubation with the substrate MUP, the fluorescence was read in a microtiter plate spectrofluorometer.

Reagent concentrations depend upon individual assay variables that are set by the investigator. If the time of hydrolysis is set at 1 hr, the relative fluorescence at ~1000 relative fluorescence units, and the sensitivity at 780 pg/ml of homologous antigen, then 500 ng/ml of enzyme-antibody conjugate must be used in the ELISA. If, however, the assay has to detect only 3.12 ng/ml of homologous antigen, then the concentration of conjugate can be reduced to 125 ng/ml. It should be noted by comparing the homologous with the heterologous reactions (wells B5 versus B11 and D4 versus D10) that both the specificity and the signal-to-noise ratio for this assay are excellent.

Prepare coating-reagent dilutions

1. Place four 17 × 100–mm test tubes in a rack and add 6 ml PBSN to the last three tubes. In tube 1, prepare a 12-ml solution of coating reagent at 10 µg/ml in PBSN. Transfer 6 ml of tube 1 solution to tube 2. Mix by pipetting up and down five times. Repeat this transfer and mix for tubes 3 and 4; the tubes now contain the coating reagent at 10, 5, 2.5, and 1.25 µg/ml.
2. Using a multichannel pipet, dispense 50 µl of the coating reagent solutions into wells of four Immulon microtiter plates (i.e., each plate is filled with one of the four dilutions). Incubate overnight at room temperature or 2 hr at 37°C.
3. Rinse and block plates with blocking buffer as in steps 5 to 7 of the basic protocol.

Prepare secondary-reagent dilutions

4. Place five 12 × 75–mm test tubes in a rack and add 3 ml blocking buffer to the last four tubes. In tube 1, prepare a 4-ml solution of secondary reagent at 200 ng/ml in PBSN. Transfer 1 ml of tube 1 solution to tube 2. Pipet up and down five times. Repeat this transfer and mix for tubes 3 to 5; the tubes now contain the secondary reactant at 200, 50, 12.5, 3.125, and 0.78 ng/ml. If possible, prepare and test serial dilutions of a nonreactive heterologous form of the secondary reactant in parallel (Fig. 11.2.7).

If the assay is especially insensitive, it may be necessary to increase the secondary reactant concentrations so the tube-1 solution is 1000 ng/ml.

5. Dispense 50 µl of the secondary reagent solutions into the first five columns of all four coated plates. The most dilute solution is dispensed into column 5, while solutions of increasing concentration are added successively into columns 4, 3, 2, and 1. Thus, the fifth column contains 0.78 ng/ml and the first column 200 ng/ml. Incubate 2 hr at room temperature.
6. Wash plates as in steps 9 to 11 of the basic protocol.

Prepare developing-reagent dilutions

7. Place five 17 × 100–mm test tubes in a rack and add 3 ml blocking buffer to the last four tubes. In tube 1, prepare a 6-ml solution of developing reagent at 500 ng/ml in blocking buffer. Transfer 3 ml of tube 1 solution into tube 2 and mix. Repeat this transfer and mixing for tubes 3 and 4—the tubes now contain the developing reagent at 500, 250, 125, 62.5, and 31.25 ng/ml.
8. Dispense 50 µl of the developing reagent solutions into the wells of rows 2 to 6 of each plate, dispensing the most dilute solution into row 6 and solutions of increasing concentration successively into rows 5, 4, 3, and 2. Incubate 2 hr at room temperature.
9. Wash plates as in steps 9 to 11 of the basic protocol.

Measure hydrolysis

10. Add 75 µl MUP or NPP substrate solution to each well, incubate 1 hr at room temperature, and measure the degree of hydrolysis visually or with a microtiter plate reader. An appropriate assay configuration results in 0.50 absorbance units/hr at 405 nm when using NPP as a substrate or 1000 to 1500 fluorescence units/hr when using MUP as a substrate.

These results can be used to adjust optimal concentrations in the basic and alternate protocols.

PREPARATION OF BACTERIAL CELL LYSATE ANTIGENS

A culture of *E. coli* containing proteins expressed from cloned genes is lysed for use as test antigen in any of the first three protocols of this unit. For more extensive discussion on protein expression for antigen production, see *UNITS 16.4-16.7* (expression by fusion protein vectors).

Materials

Escherichia coli culture in broth or agar (*UNITS 1.2 & 1.3*)

Cell resuspension buffer

Lysozyme solution

Tris/EDTA/NaCl (TEN) buffer (*UNIT 11.1*)

10% sodium dodecyl sulfate (SDS)

8 M urea (optional)

Nylon-tipped applicator (Falcon #2069, Becton Dickinson)

1. For liquid culture, centrifuge 5 ml of cells at 2500 rpm in a tabletop centrifuge for 10 min. Decant supernatant and resuspend pellet in 5 ml cell resuspension buffer by vortexing gently. For agar culture, remove about 10 colonies from the plate using a nylon-tipped applicator and resuspend in 2 ml cell resuspension buffer. Press swab against side of tube to remove as much liquid as possible.

Yield of expressed protein may vary with growth phase. Samples should be taken for analysis at various periods of growth (e.g., mid-log and stationary phases). If samples are taken from agar plates, the culture should be grown overnight at 37°C.

2. Place 1 ml of resuspended cells in a microcentrifuge tube on ice.
3. Add 0.2 ml lysozyme solution to the tube and leave 5 min on ice.
4. Microcentrifuge 5 min. Decant supernatant and save. Resuspend pellet in 1.2 ml TEN buffer.

Since many expressed proteins are insoluble, it is worthwhile to assay both the pellet and supernatant for activity.

5. Add 0.065 ml of 10% SDS solution to each sample. Incubate 10 min at 37°C. Samples are ready for ELISA at this point. Store frozen if not used within several hours.

Alternatively, add urea to a final concentration of 8 M (4.8 g to a final volume of 10 ml) to denature and solubilize proteins.

REAGENTS AND SOLUTIONS

Borate-buffered saline (BBS)

0.017 M Na₂B₄O₇·10H₂O

0.12 M NaCl

Adjust to pH 8.5 with NaOH

Blocking buffer

BBS (see above) containing:

0.05% Tween 20

1 mM EDTA

0.25% bovine serum albumin (BSA)

0.05% NaN₃

Store at 4°C

Gelatin may be substituted for BSA; 5% instant milk has been successfully used but may interfere nonspecifically with antibody binding.

Cell resuspension buffer (10 mM HEPES)

2.38 g HEPES

Add H₂O to 1 liter

Lysozyme solution

5 mg chicken egg white lysozyme (Sigma Grade VI #L2879)

1 ml TEN buffer (UNIT 11.1)

Make fresh immediately before use

MUP substrate solution

0.2 mM 4-methylumbelliferyl phosphate (MUP; Sigma #M8883)

0.05 M Na₂CO₃

0.05 mM MgCl₂

Store at room temperature

NPP substrate solution

3 mM *p*-nitrophenyl phosphate (NPP; Sigma #104-0)

0.05 M Na₂CO₃

0.05 mM MgCl₂

Store at 4°C

Test antibody solution

Hybridoma supernatants (UNIT 11.10) can usually be diluted 1:5 and ascites fluid and antisera (UNIT 11.12) diluted 1:500 in blocking buffer and still generate a strong positive signal. Dilutions of nonimmune ascites or sera should be assayed as a negative control. Prepare antibody dilutions in cone- or round-bottom microtiter plates before adding them to antigen-coated plates.

Sources of appropriate antibodies and conjugates can be found in Linscott's Directory of Immunological and Biological Reagents.

Test antigen solution

0.2 to 10 µg/ml antigen, purified or partially purified in PBSN; store at 4°C

Wash buffer

Hanks balanced salt solution (HBSS; APPENDIX 2)

1% fetal calf serum (FCS; heat-inactivated 60 min, 56°C)

0.05% NaN₃

Store at 4°C

COMMENTARY

Background Information

Since their first description in 1971 (Engvall and Perlman), ELISAs have become the system of choice when assaying soluble antigens and antibodies. Factors that have contributed to their success include their sensitivity, the long shelf-life of the reagents (alkaline phosphatase conjugates typically lose only 5% to 10% of their activity per year), the lack of radiation hazards, the ease of preparation of the reagents, the speed and reproducibility of the assays, and the variety of ELISA formats that can be generated with a few well-chosen reagents. Additionally, no sophisticated equipment is necessary for many ELISA applications, including

screening hybridoma supernatants for specific antibodies and screening biological fluids for antigen content.

The ELISAs described here combine the special properties of antigen-antibody interactions with simple phase separations to produce powerful assays for detecting biological molecules. The multivalency of antibodies can result in the formation of long-lived antigen-antibody complexes, thus allowing long periods of time during which such complexes can be measured. By designing an assay so that a capture reagent initiates the binding of antigen-antibody complexes and enzyme conjugates onto a solid phase, the unbound reagents can be easily and

rapidly separated from the solid phase. The solid phase is washed and the amount of bound conjugate is visualized by incubating the solid phase with a substrate that forms a detectable product when hydrolyzed by the bound enzyme. ELISAs are similar in principle to radioimmunoassays, except that the radioactive label is replaced by an enzyme conjugate.

A number of different enzymes have been successfully used in ELISAs, including alkaline phosphatase, horseradish peroxidase, β -galactosidase, glucoamylase, and urease. Alkaline phosphatase—perhaps the most widely used conjugated enzyme—is recommended because of its rapid catalytic rate, excellent intrinsic stability, availability, ease of conjugation, and resistance to inactivation by common laboratory reagents. Additionally, the substrates of alkaline phosphatase are nontoxic and relatively stable. Solutions of *p*-nitrophenyl phosphate (NPP) are stable for months at 4°C, while solutions of 4-methylumbelliferyl phosphate (MUP) can be kept for months at room temperature without any significant spontaneous hydrolysis. The biggest disadvantage of alkaline phosphatase is that if NPP is used as a substrate, the yellow color of the nitrophenyl product is relatively difficult to detect visually. Using the substrate MUP instead of NPP can greatly enhance the sensitivity of the assay. The fluorogenic system using MUP is 10 to 100 times faster than the chromogenic system using NPP, and appears to be as sensitive as an enhanced chromogenic assay in which alkaline phosphatase generates NAD⁺ from NADP (Macy et al., 1988). The disadvantage of using fluorogenic substrates is that they require a microplate fluorometer costing twice as much as a high-quality microtiter plate spectrophotometer.

Cellular ELISAs have been shown to be as sensitive as flow cytometry analysis in detecting some cell-surface antigens (Bartlett and Noelle, 1987) and are potentially of great value in rapidly screening hybridoma supernatants for antibodies against surface molecules (Feit et al., 1983). Using ELISAs for screening large numbers of hybridoma supernatants has been hindered by the large number of cells required and high background signal. The increased sensitivity of the fluorogenic system should reduce the number of cells needed by a factor of 5, making the system more useful as a screening assay.

In addition to the methods described here, hundreds of other ELISA applications have been described, including the determination of

antibody affinities (Beatty et al., 1987; Schots et al., 1988), the detection of antibodies specific for hormone receptors (Quinn et al., 1988; Wang and Leung, 1985), expression cloning of lymphokine receptors (Harada et al., 1990), and homogeneous assays in which a solid phase is not needed because the antigen-antibody interaction itself modifies the enzymatic activity (Rubenstein et al., 1972). A number of books are devoted to ELISAs and can be consulted for further discussion (Maggio, 1981; Kurstak, 1986).

Critical Parameters

Sensitive ELISAs require antibodies of high affinity and high specificity. Since the sensitivity of an ELISA depends upon the affinity of the antibodies involved, antibodies with the highest affinities should be used when setting up ELISAs. Antibodies should be screened for unwanted cross-reactions. For instance, capture antibodies must not bind conjugate antibodies and vice versa. There are many commercial sources of reliable reagents. *Linscott's Directory of Immunological and Biological Reagents* is an excellent source book for locating reagents used in ELISAs. If reagents from one source are inadequate, try another.

When screening for expressed proteins in *E. coli*, it is important to utilize conjugates with antibodies that recognize nonnative and native molecules. Many foreign proteins expressed in *E. coli* will not assume their native conformation, and expression of such proteins will not be detected if antibody specific for the native form is used. It is also important to test enzyme-antibody conjugates for cross-reactivity or non-specific binding to host cell molecules. This potential problem can be eliminated by incorporating these as control antigens in the screening procedures used to select the original antibodies in the basic protocol.

When coating plates with antigen, the antigen preparation need not be pure, but should generally comprise >3% of the protein in the coating solution. In some situations, dilution of the antigen solution with BSA has greatly improved the sensitivity of the ELISA (Jitsukawa et al., 1989).

All steps after coating the microtiter plates should be carried out in solutions containing 0.05% Tween 20 and a carrier protein (0.25% BSA or gelatin).

When using ELISAs for quantitative determinations of antigen or antibody concentrations, four guidelines should be followed.

First, it is essential that all experimental conditions up to the final wash after incubation with conjugate—including incubation times, wash times, reagent concentrations, and temperature—be kept constant between experiments. This is especially important in assays using polyvalent antibodies and complex mixtures of antigens. The optimal concentrations of all reagents for each system should be determined in an initial criss-cross serial dilution experiment (see first support protocol). Second, because the efficiency of binding and other micro-environmental conditions can vary from plate to plate, a standard curve should be included on each plate. Third, all samples must be analyzed at least in duplicate. Fourth, the concentration of the reagent being quantitated must lie within the dynamic range of the standard curve.

Anticipated Results

Antibody-sandwich assays are generally the most sensitive ELISA configuration and can detect concentrations of protein antigens between 100 pg/ml and 1 ng/ml. ELISAs in which antigen is directly bound to plates are usually an order of magnitude less sensitive than sandwich techniques.

Either the direct or sandwich ELISA may be used to detect and quantitate a bacterially expressed antigen or a purified or partially purified antigen in the range of 1 ng/ml to 1 μ g/ml. A major disadvantage of the direct ELISA is that when an impure antigen preparation like a bacterial lysate is coated directly onto the surface of the microtiter well, the antigen must compete with all the other macro-molecules in the lysate for binding to the plastic and very little of the desired antigen may be bound. The sandwich ELISA bypasses this problem by relying on selective adsorption of an antigen to an antigen-specific antibody-coated surface.

Time Considerations

These assays are designed to take ~6 hr, but the incubation times may be abbreviated or expanded as needed. Since equilibrium binding between the soluble and solid phases frequently takes 5 to 10 hr, stronger specific signals can usually be obtained by longer incubations.

Fluorogenic ELISAs are generally 10 to 100 times faster than assays using chromogenic substrates.

Isotype Determination of Antibodies

UNIT 11.3

Frequently it is necessary to know the amount and serological class of antibodies made by an immunized animal, produced by hybridomas, or present in the serum of patients with inflammatory or neoplastic conditions. The immunologist's approach to such a problem is to consider the antibody or immunoglobulin molecules themselves as antigens and to use anti-immunoglobulin antibodies as the specific and sensitive agents of detection. This unit describes two methods for measurement and classification of supernatant or serum immunoglobulins—an ELISA (first basic protocol) and a method employing electrophoresis and immunofixation (second basic protocol).

SANDWICH ELISA FOR ISOTYPE DETECTION

The speed and sensitivity of sandwich ELISAs make them the assays of choice for isotype determination. The antibody-sandwich ELISA to measure soluble antigen (UNIT 11.2; Fig. 11.2.3) is adapted in this unit for isotype detection. Microtiter wells are coated with isotype-specific capture antibodies followed by incubation with test solutions containing the antibodies to be isotyped. After test antibodies have been bound to the plate by reacting with capture antibodies, unbound test antibodies are washed out. Developing reagent is added to the wells, followed by another incubation. Unbound conjugate is washed out and substrate is added. Substrate hydrolysis indicates that the test solution contained the appropriate isotype. A lack of hydrolysis indicates that the test solution did not contain the appropriate isotype. UNIT 11.2 should be consulted for additional information.

**BASIC
PROTOCOL**

Materials

Capture anti-isotype antibodies: heavy-chain class-specific antibodies (anti- μ , - α , - γ , - δ , - ϵ), heavy-chain subclass-specific antibodies (anti- γ 1, - γ 2a, - γ 2b, - γ 3, - γ 4), or light-chain isotype-specific antibodies (anti- κ , - λ)

PBS (APPENDIX 2) containing 0.05% NaN_3 (PBSN)

Test antibodies: hybridoma supernatants, ascites fluid, or antisera

Blocking buffer (UNIT 11.2)

Standard isotype antibodies (i.e., purified antibodies of known isotypes)

Developing reagent: anti-Ig antibody (specific for all heavy-chain classes)—alkaline phosphatase conjugate (see UNIT 11.1; Southern Biotechnology or *Linscott's Directory*)

MUP or NPP substrate solution (UNIT 11.2)

Immulon 2 or 4 microtiter plates (or equivalent; UNIT 11.2)

Additional reagents and equipment for ELISA (UNIT 11.2)

1. Prepare the capture anti-isotype antibodies by diluting in PBSN to 2 $\mu\text{g}/\text{ml}$ final.

Capture antibodies can be monoclonal or polyclonal.

When screening hybridoma supernatants for IgG (anti- γ), it is advisable to initially use a capture-antibody preparation that recognizes all IgG isotypes. Subsequent analysis using subclass-specific capture antibodies can determine which IgG subclass is expressed. It is crucial that the capture antibodies do not bind to the antibodies in the developing reagent.

2. Coat each well of an Immulon microtiter plate with 50 μl capture antibody solution as in steps 3 to 5 of the basic protocol in UNIT 11.2.
3. Block wells as in steps 6 and 7 of the basic protocol in UNIT 11.2.
4. Prepare dilutions of the test antibodies in blocking buffer—typically, hybridoma supernatants are diluted 1:5 while sera are diluted 1:500.

Immunology

Supplement 18

5. Prepare the standard isotype antibodies at ~500 ng/ml to serve as positive controls.
6. Transfer 50- μ l aliquots of test or standard isotype antibodies into the antibody-coated wells and incubate >2 hr at room temperature.

Specificity controls consisting of wells coated with capture antibodies and a series of standard antibodies of different isotypes should be included on each plate. Negative controls should be included on each plate and consist of wells coated with capture antibodies but receive no test or control antibodies.

7. Wash plate as in steps 9 to 11 of the basic protocol in *UNIT 11.2*.
8. Prepare the developing reagent so that the final conjugate solution contains ~200 ng anti-Ig/ml.

Crucial that antibodies in developing reagent do not bind to capture antibodies.

9. Add 50 μ l developing reagent to each well and incubate 2 hr at room temperature.

All test wells, positive-control wells, and negative-control wells should receive the developing reagent.

10. Wash as in steps 9 to 11 of the basic protocol in *UNIT 11.2*.

11. Add 75 μ l MUP or NPP substrate solution to each well and incubate at room temperature. Periodically check the plate for substrate hydrolysis.

Hydrolysis of NPP results in liberation of a yellow product that can be detected by visual inspection in ambient light. Hydrolysis of MUP results in the liberation of a fluorescent product that can be detected by visual inspection under a long-wavelength UV lamp in a darkened room. For more quantitative estimates of isotype concentrations, plates can be read with microtiter plate reader. Positive-control wells give strong signals by 1 hr. Weaker reactions can be detected by incubation for many hours or overnight.

BASIC PROTOCOL

DETECTING AND ISOTYPING ANTIBODIES BY ELECTROPHORESIS AND IMMUNOFIXATION

Qualitative identification and quantitative determination of serum (and other biological fluid) proteins provide useful information concerning pathologic conditions of the lymphoid system. High-resolution zone electrophoresis is a simple method to separate serum proteins based on their classification defined by five electrophoretic zones: albumin, α 1-globulin, α 2-globulin, β -globulin, and γ -globulin. Following electrophoresis, the proteins can be detected by staining with amido black, or immunofixation can be performed first to achieve more precise identification. In immunofixation procedure described below, immunoglobulins within separated protein bands are identified, and clonality is established, using antisera to the α , γ , μ , ϵ , and δ heavy chains and κ and λ light chains of immunoglobulins. Other serum proteins—including glycoproteins, transferrin, and C3—can be identified in electrophoresed sample by same technique.

The serum (or other fluid) is loaded on an agarose gel-covered microscope slide and electrophoresed. Proteins are detected after zone electrophoresis and can be identified by immunofixation.

Materials

- Serum (or other biological fluid)
- Normal saline
- 95% methanol/5% acetic acid
- 1% amido black (1 g in 100 ml of 2.5% acetic acid)
- 2.5% (v/v) acetic acid

Figure 11.3.1 Normal serum protein electrophoretic pattern obtained by agarose gel zone electrophoresis demonstrating the five protein zones.

2 × 2-cm cellulose acetate strip
 Monospecific anti-Ig, heavy-chain-specific (α , γ , μ , ϵ , or δ) or
 light-chain-specific (κ or λ)
 0.85% (w/v) NaCl
 Agarose gel-covered microscope slides
 Plexiglas electrophoresis cell with two agarose bridges
 Electrophoresis power supply (e.g., Pharmacia EPS 500/400)

Electrophorese the sample

1. Cut a narrow slit with a razor blade in the middle of an agarose gel-covered microscope slide. For standard fixation and staining (steps 3 and 4), place 1.5 μ l undiluted serum in the slit. For immunofixation (steps 5 to 8), dilute serum in normal saline to generate 1 to 2 mg/ml of the specific protein being evaluated (e.g., IgG, IgA, or IgM) and place in the slit.
2. Place the slide in an electrophoresis cell with two agarose bridges having the same composition as the gel on the slide. Electrophorese 12 min at 140 V. Proceed to steps 3 and 4 for standard fixation and staining. Proceed to steps 5 to 8 for immunofixation.

Standard fixation and staining

3. Fix slides by submerging in 95% methanol/5% acetic acid 15 min. Air dry with filter paper placed on the gel.
4. Stain agarose gel by submerging in 1% amido black 10 min. Destain in 2.5% acetic acid until the background clears, then rinse in water. Dry 5 min at 60°C in a drying oven for visual inspection (Fig. 11.3.1).

Immunofixation

5. Transfer the *unstained* and *unfixed* gel (from step 2) to a petri dish containing damp filter paper. Overlay the γ -globulin zone of the gel with a cellulose acetate strip impregnated with a monospecific anti-Ig.

The γ -globulin zone is that nearest the cathode (Fig. 11.3.1).

The cellulose acetate strip is cut from any commercial membrane and dipped into the appropriate antibody solution (see critical parameters). The concentration of the antibody solution provided by supplier (usually 0.5 to 1 mg/ml) is suitable.

6. Allow the antibody to diffuse into the gel 15 min at room temperature.
7. Remove the slides and immerse in 0.85% NaCl for 2 hr to wash out unfixed proteins. Air dry with filter paper placed on the gel.
8. Stain as described in step 4 and visually inspect for immunoprecipitated protein bands (Fig. 11.3.2).

REAGENTS AND SOLUTIONS

Agarose gel-covered microscope slides

Add 0.5 g agarose (Seakem agarose HE, FMC Bioproducts) to 100 ml of 0.05 M barbital buffer (Sigma #B0500); store at room temperature and heat to 100°C. Stir until agarose has dissolved and allow to cool to 70°C. Pour 2.5 ml of the agarose solution on each microscope slide and allow to gel 2 to 3 min at room temperature. Store the prepared slides at 4°C in a humidified chamber. Set up a chamber by half-filling a petri dish with the above agarose solution. Allow to cool and place in a refrigerator. This humidified chamber can be used to store agarose slides up to 2 weeks.

COMMENTARY

Background Information

Sandwich ELISA

Antibodies are heteromeric molecules consisting of heavy and light chains, each of which contains a variable and a constant region. Heavy-chain constant regions include μ , α , $\gamma 1$, $\gamma 2a$, $\gamma 2b$, $\gamma 3$, $\gamma 4$, δ , or ϵ , depending upon the species; light-chain constant regions include κ and λ . Immunoglobulin constant regions, commonly referred to as isotypes, determine many of the biological and immunochemical properties of the antibody molecule including complement fixation, binding to Fc receptors, and binding to proteins A and G. Because the iso-

type may influence the method of purification (Andrew and Titus, 1991), it is routine to determine the isotypes of monoclonal antibodies or other specific antibody preparations as part of their initial characterization. The identification of antibody isotypes can easily be performed with an ELISA employing commercially available anti-isotype reagents. Alternatively, isotypes can be determined using electrophoresis/immunofixation (second basic protocol) or a double-immunodiffusion assay (Hornbeck, 1991).

See UNIT 11.2 for a full discussion of the ELISA technique.

Figure 11.3.2 Agarose gel zone electrophoresis of patient serum demonstrating a monoclonal band in the γ -globulin zone (A; arrow). Immunofixation electrophoresis with anti- μ (B) and anti- κ (C) demonstrate that the band is a μ - κ monoclonal immunoglobulin. There is no reactivity with the antisera to the other heavy (α , γ , δ , ϵ) and light (λ) chains (data not shown).

Electrophoresis and immunofixation

Zone electrophoresis is based on the principle that charged particles migrate at different rates in an electric field based on the net charge of the particle. The application of this method to the evaluation of serum proteins was first described in a seminal paper by Tiselius (1937). In this paper it was shown that serum proteins were separable into defined zones (albumin, α -globulins, β -globulins, and γ -globulins). While protein separation by zone electrophoresis is excellent, protein quantitation using this method is poor. To overcome these shortcomings, various support media have been employed, including cellulose acetate, agar gel, and, more recently, agarose gel. Agarose gel provides improved stability and clarity, as well as greater sensitivity than other materials (Papadopoulos et al., 1982).

Immunofixation electrophoresis combines the high resolution of agarose gel zone electrophoresis and the unique specificity of an antigen-antibody reaction (Johnson, 1982). After electrophoretic separation, the antigen of interest is reacted with an overlaid, monospecific antibody to form an immunoprecipitate, which can be easily detected. The location of the immunoprecipitate depends on the electrophoretic migration of the specific protein antigen. The unreacted proteins and antibody reagents are washed out of the agarose gel and the precipitin band is stained for visualization. Using this method, polyclonality, oligoclonality, or monoclonality can be ascertained (Fig. 11.3.2). Commercial sources for complete immunofixation electrophoresis setups are available. Immunoelectrophoresis, a classic method in which diffusion of antibody into the gel is combined with electrophoresis, is an alternative method for evaluation of protein clonality. However, this approach is less sensitive and more difficult to interpret as compared with immunofixation (Johnson, 1986).

Critical Parameters and Troubleshooting

Sandwich ELISA

Sources of isotype-specific antibodies can be found in *Linscott's Directory of Immunological and Biological Reagents* (see key references, UNIT 11.2). Isotype-specific antibodies should have no detectable cross-reactivity against other isotypes and should not cross-react with other antibodies that might be used in the assay. Check isotype-specific reagents against standard isotype proteins to confirm

their specificity. Sources of purified isotypes from the species of interest, to be used as experimental standards, can also be found in *Linscott's Directory*. Alternatively, standard isotype proteins can be prepared from myeloma and hybridoma lines of known isotypes using standard techniques (UNIT 11.8). Many myelomas and hybridomas of defined isotypes and specificities are available from ATCC and other sources; see full listing in Knapp et al. (1991).

The concentration of the developing reagent should be adjusted so that the positive control gives a strong signal by 1 hr. Since the hydrolysis of MUP is at least 10-fold easier to detect than the hydrolysis of NPP, assays using MUP can be significantly faster than those using NPP. Test solutions should be scored as positive only when they give 3-fold higher signals than the negative controls.

While this assay is designed to qualitatively determine the presence or absence of a given isotype in the test solution, it can be easily modified to quantitate the concentration of isotype by including serial dilutions of standard isotype proteins (for details of quantitation using a standard curve, see UNIT 11.2 protocol for antibody-sandwich ELISA to measure soluble antigen).

Electrophoresis and immunofixation

Antigen and antibody interaction at or near the point of equivalence results in the formation of immune complexes that produce an insoluble precipitate. In the case of a monoclonal (homogeneous) protein, this precipitate is found in a very narrow band, while a polyclonal protein will generate a broad band. Immunoprecipitation is optimal at antigen/antibody equivalence. It is often useful to quantitate total immunoglobulin levels in the sample to allow for the dilution of the serum (see step 1 of basic protocol). Antigen excess will result in clear spots (lack of detectable immunoprecipitate) in the location where the band(s) are anticipated. If this occurs, dilute the sample and repeat immunofixation electrophoresis.

Failure to see a clearly discernible electrophoretic protein pattern after step 4 suggests a technical problem at some point during steps 1 through 4. Immunofixation should not be performed and the initial electrophoresis procedure should be repeated.

Absence of a detectable immunoprecipitate after step 8 (in the presence of a gamma globulin band after step 4) suggests antigen excess. Quantitate immunoglobulins, dilute serum accordingly, and repeat entire experiment.

Anticipated Results

Sandwich ELISAs are typically sensitive to 0.5 to 2.0 ng/ml of antibody isotype.

During electrophoresis and immunofixation, the specific bands observed in immunofixation electrophoresis are dependent on both the presence of particular proteins and the appropriate antisera being used in the detection process. In the case of normal immunoglobulins, all three major isotypes should be observed. Monoclonal or oligoclonal immunoglobulins produce single or multiple darker (clonal) bands (Fig. 11.3.2). The detection limit for a specific protein using this immunofixation technique is 5 to 10 $\mu\text{g/ml}$.

Time Considerations

The sandwich ELISA requires 6 to 8 hr. However, the times allotted for the various incubation steps can usually be reduced by half, so results can be obtained in 3 to 4 hr.

For electrophoresis and immunofixation, running and developing the gel takes 2 to 3 hr. Additional time (10 to 15 min) is needed to prepare and titrate the serum sample if immunoglobulin levels are increased.

PREPARATION OF MONOCLONAL ANTIBODIES

The preparation of monoclonal antibodies should be undertaken carefully, since the production of monoclonal antibodies is expensive and time-consuming. Figure 11.4.1 summarizes the experimental procedures that must be carried out to prepare monoclonal antibodies. The various procedures are presented in individual protocols and described in sufficient detail to allow an individual with no prior experience to carry out a cell fusion, to produce monoclonal antibodies in ascites fluid, and to purify antigen-specific monoclonal antibodies.

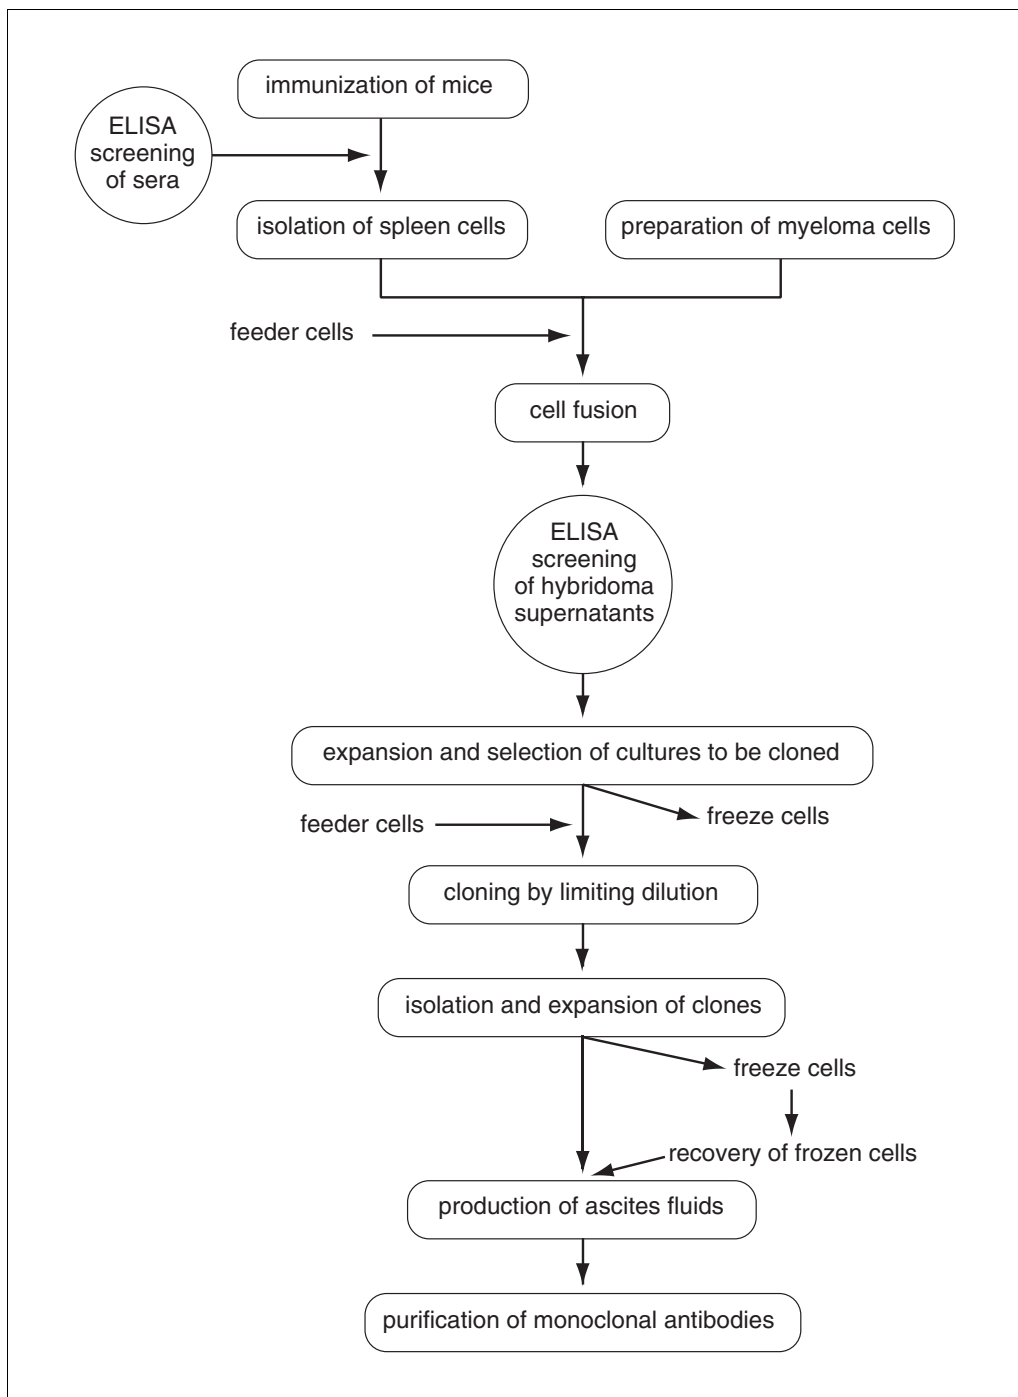

Figure 11.4.1 Flow chart for preparation of monoclonal antibodies.

Immunization of Mice

Antigen is prepared for injection either by emulsifying an antigen solution with Freund's adjuvant or by homogenizing a polyacrylamide gel slice containing the protein antigen. Mice are immunized at 2- to 3-week intervals. Test bleeds are collected 7 days after each booster immunization to monitor serum antibody levels. Mice are chosen for hybridoma fusions when a sufficient antibody titer is reached.

BASIC PROTOCOL

PRODUCTION OF IMMUNE SPLEEN CELLS: IMMUNIZATION WITH SOLUBLE ANTIGEN

Materials

Phosphate-buffered saline (PBS; *APPENDIX 2*)

Antigen

Complete Freund's adjuvant

Any strain mice, 6 to 8 weeks old

Incomplete Freund's adjuvant

22-G needles

3-ml syringes with locking hubs (Luer-Lok, Becton Dickinson)

Double-ended locking hub connector (Luer-Lok, Becton Dickinson)

Sterile sharp scissors

Sterile razor blades or scalpel blades

Wooden applicator sticks

200- μ l pipettor

Additional reagents and equipment for ELISA (*UNITS 11.2 & 11.3*) and western blotting (optional; *UNIT 10.8*)

1. Prepare an emulsion (200 to 400 μ l/mouse) of equal volumes PBS containing 25 to 100 μ g antigen and complete Freund's adjuvant. Using a 22-G needle, inject mice intraperitoneally. For each antigen, 3 to 5 mice are immunized.

Complete Freund's adjuvant contains mycobacteria—incomplete Freund's does not.

An emulsion is most readily prepared by linking two locking syringes, one loaded with antigen and the other loaded with adjuvant, using a double-ended locking connector (see Fig. 11.4.2). Press syringe barrels back and forth, transferring contents from one syringe to the other, for 5 to 10 min until a stable emulsion is produced. For best antibody production, inject antigen in as small an emulsion volume as practicable.

A stable emulsion is an oil-in-water emulsion which will not disperse when dropped into water. This is a useful check for the emulsification endpoint. Further, at the endpoint the emulsion will thicken noticeably.

Mice may be restrained for immunization in the following manner: Place mouse on gridded cage top. Lift mouse by the tail (generally, when mice are lifted by the tail they will grab the bars of the cage top with their front feet, thus stabilizing themselves for restraint). Immobilize the mouse's head by pinching together the skin at the base of the skull between thumb and forefinger. Turn hand over so that mouse is lying with its back against the palm. Wrap fourth finger around tail and stretch mouse over arched palm for intraperitoneal injection.

CAUTION: *Handle Freund's adjuvant carefully, since self-injection can cause a positive TB test and lead to a granulomatous reaction.*

2. Boost mice 3 weeks later by intraperitoneally injecting an emulsion (200 to 400 μ l) of equal volumes PBS containing 10 to 50 μ g antigen and incomplete Freund's adjuvant. The emulsion is prepared and injected as in step 1.

Figure 11.4.2 Double-syringe device for preparation of antigen-adjuvant emulsions.

- Bleed mice 7 days after second immunization by cutting off 0.5 cm of the tail with sterile sharp scissors or a razor blade. Collect 100 to 200 μl blood into a 1.5-ml microcentrifuge tube. After clot formation, rim the clot with a wooden applicator stick to dislodge the clot from the surface of the tube, but do not break up the clot. After clot retraction, transfer the serum into another microcentrifuge tube with a 200- μl pipettor. If test bleeds are collected more than three times, it will be necessary to cut the tail vein to obtain further samples rather than cutting off additional lengths of the tail itself. This is done by nicking one of the lateral tail veins with a razor blade.

The collection of blood may be facilitated by using a heat lamp to warm the mouse for 30 sec to 1 min prior to cutting of the tail. Additionally, if blood flow from the cut tail is slow, the tail may be "milked" from base to the cut tip with thumb and forefinger.

- Determine the antibody titer in the serum by ELISA (UNITS 11.2 & 11.3). If desired, further characterize the antibody specificity by western blotting (UNIT 10.8).

Antibody titer is operationally defined as that dilution of serum that results in 0.2 absorbance units above background in the ELISA procedure.

- If the antibody titer is considered too low ($\geq 1/1000$) for cell fusion, mice can be boosted every 2 weeks until an adequate response is achieved. Bleed the mice and test the serum with an ELISA.
- When the antibody titer is sufficient ($> 1/1000$), boost mice by injecting 10 to 50 μg antigen in PBS intraperitoneally (200 to 400 μl), or intravenously (50 to 100 μl) via the tail veins, 3 days before fusion but >2 weeks after previous immunization.

In general, the higher the serum antibody titer, the more antigen-specific antibody-producing hybridomas are obtained per fusion.

If an antibody against a nonimmunodominant epitope is desired, the cell fusion may be done at an earlier or later time, since the percentage of antibody-producing cells in the spleen directed at these less immunogenic regions of the antigen may vary with time in an unpredictable fashion.

- Perform cell fusion (UNIT 11.7) 3 days after the immunization (step 6).

**ALTERNATE
PROTOCOL**

**IMMUNIZATION WITH COMPLEX ANTIGENS (MEMBRANES, WHOLE
CELLS, AND MICROORGANISMS)**

1. Prime the mice and boost intraperitoneally with adjuvant (i.e., complete Freund's for priming and incomplete Freund's for booster immunizations) as described for soluble antigen (see basic protocol, steps 1 and 2) or suspend antigen in PBS and inject. Use 1 to 2×10^7 cells for mammalian species or 10^8 to 10^9 bacterial or yeast cells.
2. Bleed the mice and determine the antibody titer of the serum as described for soluble antigen (see basic protocol, steps 3 to 6).
3. Perform cell fusion (UNIT 11.7) 3 days after final immunization.

**ALTERNATE
PROTOCOL**

IMMUNIZATION WITH ANTIGEN ISOLATED BY ELECTROPHORESIS

In some instances the antigen under investigation can be purified most conveniently by gel electrophoresis (UNIT 10.2). Mice can be immunized with protein antigens still contained in a polyacrylamide gel slice, as described in this protocol.

Additional Materials

0.1 M KCl, cold

Tissue grinder

Additional reagents and equipment for denaturing (SDS) discontinuous gel electrophoresis (UNIT 10.2)

1. Apply a protein mixture containing 10 to 50 μg of the desired protein antigen to an appropriate denaturing (SDS) discontinuous gel electrophoresis system (e.g., the Laemmli gel system) and complete the electrophoresis as described in UNIT 10.2.
2. Soak gel 5 to 15 min in cold 0.1 M KCl. Protein bands will appear as white precipitates against a clear gel background.
3. Cut out the appropriate bands from the gel with a razor blade or scalpel blade.
4. Prepare gel suspension by homogenizing the gel slice in a minimum volume of PBS using a tissue grinder. Minimum volume is defined by adding successive 100- μl volumes of PBS until the homogenized gel is liquid.

Alternatively, the gel may be air dried for 1 to 2 hr, smashed with a glass rod, and suspended in a minimum volume of PBS.

5. Immunize each mouse with 200 to 400 μl gel suspension containing 10 to 50 μg antigen via an intraperitoneal injection.

Amount of antigen is estimated from prior observation of the proportion of desired protein antigen to other antigens in the sample as determined by the relative intensity of stained bands on the polyacrylamide gel (see UNIT 10.6 for staining procedures).

6. Boost mice after 3 weeks with 200 to 400 μl gel suspension containing 10 to 25 μg antigen.
7. Bleed the mice and determine the antibody titer of the serum as described for soluble antigen (see basic protocol).

Mice immunized repeatedly with polyacrylamide tend to form adhesions that can make aseptic removal of the spleen difficult.

8. Perform cell fusion (UNIT 11.7) 3 days after final immunization.

COMMENTARY

Background Information

The stimulation of an effective humoral immune response in mice is critical to the production of monoclonal antibodies directed at a particular antigen. The variety and quality of the monoclonal antibodies prepared is generally directly proportional to the serum antibody titer in the particular mouse used for cell fusion. Any means of antigen preparation, antigen delivery, or immunization schedule that increases antibody titer in the serum of the immunized mouse will potentiate the isolation of hybridomas secreting monoclonal antibodies of interest. We have described two methods of antigen preparation: (1) antigen emulsified in Freund's adjuvants (probably the most common technique used) and (2) antigen isolated in a polyacrylamide gel slice and homogenized. Other preparation methods (e.g., adsorption of antigen to supports such as aluminum hydroxide or aluminum phosphate, polystyrene beads, or nitrocellulose paper, and alternate sites of injection such as footpads) are discussed in the key references.

Critical Parameters

It is desirable to use antigen of the highest available purity for immunizations, particularly for primary immunizations. Contaminants may be more immunogenic than the antigen of interest and as such may result in a low specificity antibody. Mice given primary immunizations of highly pure antigen may be boosted with less pure material (containing as little as one-third specific antigen in a complex protein mixture).

Troubleshooting

Poor success in raising an adequate antibody titer to an antigen of interest can be attributed to several factors. Improperly prepared emulsion when using Freund's adjuvant (i.e., the aqueous and oil phases separate upon standing) is ineffective in stimulation of an immune response. Contaminants in an antigen preparation may be more immunogenic, necessitating a more homogeneous preparation of the desired antigen. Other parameters that can be varied in an effort to produce a higher antibody titer and increased specificity include presentation of antigen (Freund's adjuvant emulsion versus

polyacrylamide gel slice), site of immunization (intraperitoneal versus footpad or tail vein), antigen dose, and frequency of immunization. Alternate immunization protocols are presented in the key references below.

Anticipated Results

Isolation of high-quality monoclonal antibodies correlates with high-serum antibody titers. A serum ELISA titer of $1/1000$ is the minimum level before attempting a cell fusion. Titers for most antigens (particularly from animals injected with highly purified antigen) will range from $1/1000$ to $1/100,000$ after 3 to 4 immunizations. Occasional serum samples will titer at greater than 10^6 . The proportion of monoclonal antibodies of IgG class rather than IgM class generally increases proportionally to the duration of the immunization schedule, although this can vary dramatically among different antigens. [In general, IgG class antibodies are more suitable for immunoassays, western blotting (UNIT 10.8), immunoaffinity chromatography (UNIT 10.11), and immunoprecipitation (UNIT 10.16)].

Time Considerations

A primary immunization followed by two booster immunizations and test bleeds will occupy 6 weeks. For many antigens, however, an adequate antibody response in the mice is achieved only after several months and multiple immunizations.

Preparation of Myeloma Cells

BASIC PROTOCOL

Myeloma cells are cultured with 8-azaguanine to ensure their sensitivity to the HAT selection medium (see UNIT 11.6) used after cell fusion (UNIT 11.7). One week prior to cell fusion, myeloma cells are grown in medium without 8-azaguanine. Cell culture conditions are adjusted such that the Sp2/0 cells are in the log phase of growth and exhibit high viability at the time of collection for fusion (UNIT 11.7).

Materials

Sp2/0 murine myeloma cell line (ATCC #CRL 1581)
Complete culture medium
20 µg/ml 8-azaguanine

Tissue culture flasks, 25 cm² or 75 cm²
8% CO₂-in-air gas mixture
Humidified 37°C, 8% CO₂ incubator
Inverted microscope

1. Recover frozen cells from liquid N₂ storage, as described in UNIT 11.9.
2. Grow Sp2/0 cells overnight in complete medium in tissue culture flasks at 37°C in a CO₂ incubator in 8% CO₂-in-air atmosphere with 98% relative humidity.
3. Determine that the cells are growing by examining the cell cultures in the flasks with an inverted microscope and return culture flask to CO₂ incubator for continuation of cell growth.
4. To ensure that the Sp2/0 cells remain aminopterin sensitive for the selection process following fusion, supplement the complete culture medium with 8-azaguanine at 20 µg/ml during maintenance. One week prior to fusion, culture cells in medium *without* 8-azaguanine.

A seeding cell density of 2.5 to 5 × 10⁴ cells/ml works well with Sp2/0 cells.

Sp2/0 cells will grow to a maximum density of 6 to 9 × 10⁵ cells/ml, with a doubling time of 10 to 15 hr. When this density is reached, there is a rapid decline in cell viability. The Sp2/0 cultures are split every 2 to 3 days either by discarding an appropriate volume from the old flask and replacing with fresh medium or by transferring an appropriate volume of cells to a new flask and adding fresh medium. A 1-in-10 or 1-in-20 split is recommended.

5. A total of 1 × 10⁷ Sp2/0 cells (i.e., 1:10 ratio to immune spleen cells) is used for fusion. Cell viability at the time of collection should be greater than 95%. To ensure that cells are collected in log phase of growth, adjust the cell density to 2 × 10⁵ cells/ml the day before the fusion by adding fresh medium. Determine cell viability using the trypan blue exclusion method (see support protocol, below) on cells suspended in serum-free medium or PBS.

SUPPORT PROTOCOL

CELL VIABILITY TEST BY TRYPAN BLUE EXCLUSION

This procedure is used to determine the number of viable cells present in the cell culture. A non-viable cell will have a blue cytoplasm; a viable cell will have a clear cytoplasm.

Additional Materials

Phosphate-buffered saline (PBS; APPENDIX 2) or serum-free
complete culture medium
0.4% trypan blue solution

Binocular microscope
Hemocytometer

1. Centrifuge 1 ml cell suspension at $100 \times g$ for 5 min.
2. Resuspend the cell pellet in 1 ml PBS or serum-free complete culture medium.

Serum proteins stain with trypan blue and can produce misleading results. Determinations must be made in serum-free solution.

3. Mix 1 part of trypan blue solution and 1 part cell suspension ($\frac{1}{2}$ dilution).
4. Using a binocular microscope, count the unstained (viable) and stained (dead) cells separately in a hemacytometer. Each of the four corner squares (composed themselves of 16 smaller squares) have 1 mm sides and are 0.1 mm deep (0.1 mm^3). Count all cells within each of the four corner squares, including those that lie on the bottom and left-hand perimeters, but not those that lie on the top and right-hand perimeters. Count any clumps of cells as one cell. Calculate the mean number of cells per 0.1-mm^3 volume. Multiply by 10^4 to obtain the number of cells/ml (i.e., cells/ cm^3). Apply dilution factor for trypan blue ($2\times$) to obtain the number of cells per milliliter of culture.
5. Calculate the percentage of viable cells as follows:

$$\text{Viable cells (\%)} = \frac{\text{Number of viable cells}}{\text{Total number of cells (dead and viable)}} \times 100$$

REAGENTS AND SOLUTIONS

Complete culture medium

Dulbecco modified Eagle medium (DMEM), high-glucose formula (4.5 g glucose/liter; GIBCO/BRL #430-2100) supplemented to the indicated concentrations with the following additives:

- 2.8 g/liter sodium bicarbonate (33.3 mM)
- 4.8 g/liter HEPES (20 mM)
- 10% fetal calf serum (v/v)
- 10 ml/liter L-glutamine (2 mM)
- 10 ml/liter sodium pyruvate (1 mM)
- 10 ml/liter penicillin (50 IU/ml) and streptomycin (50 $\mu\text{g/ml}$)

The last four additives are available as $100\times$ solutions from GIBCO/BRL and other major suppliers of cell culture media. Penicillin and streptomycin are combined in one solution.

Samples of fetal calf serum lots should be tested for ability to support efficient cell growth and cloning before a large purchase because there is much variability between lots of a given supplier. The fetal calf serum must be mycoplasma free. If low volume usage of fetal calf serum precludes testing of serum lots, purchase of mycoplasma-free, virus-free, low endotoxin sera from suppliers such as GIBCO/BRL, Flow Laboratories, or Sigma will generally provide satisfactory results. Horse or bovine serum is not an adequate substitute!

COMMENTARY

Background Information

The Sp2/0 cell line was chosen as the fusion partner for immune spleen cells because of its good rate of growth, the efficiency with which hybridomas are obtained after fusion, and, most importantly, because it does not synthesize or secrete any immunoglobulin heavy or light chains itself. The Sp2/0 myeloma cell line was developed by Schulman et al. (1978). Other commonly used cell lines are P3X63-Ag8.653 (Kearney et al., 1979), which does not secrete immunoglobulins, and NS-1 (Kohler and Milstein, 1976), which produces only κ light chains.

Critical Parameters

Optimal growth of myeloma cells is density dependent. Cultures should be split at regular intervals to maintain >95% viability. Do not culture Sp2/0 cells longer than 1 month to avoid genetic drift and development of antibiotic-resistant contaminants. Maintain several aliquots of Sp2/0 cells in liquid nitrogen storage.

Anticipated Results

Proper care yields a healthy log phase

myeloma cell culture able to sustain good production of hybridomas upon fusion.

Time Considerations

Depending on culture conditions, 10^5 cells can be expanded to the 10^7 cells required for fusion in 4 to 6 days.

Preparation of Mouse Feeder Cells for Fusion and Cloning

UNIT 11.6

**BASIC
PROTOCOL**

Chilled sucrose solution is injected intraperitoneally into mice. When withdrawn, the solution contains feeder cells (macrophages and other cells) that are placed in the wells of microtiter plates 1 day prior to seeding of hybridomas from cell fusion (UNIT 11.7) or cloning (UNIT 11.8) procedures.

Materials

- 0.34 M sucrose solution, sterile and chilled
- Mice (any strain)
- 70% ethanol
- HAT medium, chilled
- Sterile phosphate-buffered saline (PBS; APPENDIX 2)
- 10-ml syringe, sterile
- 18-G needle, sterile
- 50-ml conical centrifuge tube, sterile
- Dissecting board
- Forceps, sterile
- Scissors, sterile
- 96-well microtiter plates
- 8% CO₂-in-air gas mixture
- Humidified CO₂ incubator
- Additional reagents and equipment for estimating cell viability by trypan blue exclusion (support protocol, UNIT 11.5)

1. Just prior to sacrificing a mouse, fill a 10-ml syringe with 8 ml chilled sucrose solution and attach 18-G needle.

To avoid macrophages adhering to plastic surfaces, it is important to use chilled solutions to optimize cell harvest.

2. Chill the 50-ml conical centrifuge tube in ice.
3. Kill mouse by cervical dislocation.

This is accomplished by firmly holding a thick pencil or similar rod-shaped object to the neck of the mouse just behind the skull and quickly and firmly pulling the tail.

4. Immerse the mouse in a 100-ml beaker containing 70% ethanol.
5. Lay out mouse on dissecting board.
6. Snip skin at diaphragm level and pull skin back, exposing the lower part of the rib cage and abdomen.

With forceps pull skin from underlying tissue at the diaphragm level and snip with a scissors. With forceps or sterile gloved hands, pull skin back at both sides of the incision to expose the lower part of the rib cage and abdomen.

Care must be taken not to tear or cut the peritoneal membrane.

7. Insert the needle into the peritoneal cavity at the base of the sternum and rest the tip of the needle over the liver. Inject sucrose solution. Gently squeeze the abdomen two or three times.
8. Harvest the peritoneal feeder cells by withdrawing as much solution as possible into the syringe.

Care must be taken not to puncture the digestive organs, which may lead to fecal contamination of the feeder cells.

Enough peritoneal feeder cells can usually be isolated from one mouse to seed ~100 to 300 wells. However, some mice do not yield effective feeder cells. Depending on the total number of wells that must be seeded with mouse feeder cells, an appropriate number of mice must be killed. Peritoneal exudate feeder cells can be prepared up to 3 days prior to use.

9. Transfer the feeder cell-containing sucrose solution into the 50-ml centrifuge tube.
10. In a sterile fume hood, add 20 ml chilled HAT medium.
11. Centrifuge at $100 \times g$ for 5 min at room temperature.
12. Resuspend the pellet in 1 ml chilled HAT medium and perform cell viability test by trypan blue exclusion as described in the support protocol, *UNIT 11.5*.
13. Suspend the cell pellet in chilled HAT medium at 1×10^5 cells/ml.
14. Add 100 μ l cell suspension to each of the 60 inner wells of the 96-well plates. The peripheral 36 wells are filled with sterile PBS.

Plates having 24 wells may be used. If this is the case, add 1 ml cell suspension/well.
15. Incubate plates overnight at 37°C in a CO₂ incubator in 8% CO₂-in-air with 98% relative humidity.

REAGENTS AND SOLUTIONS

The following solutions are sterilized by filtration through a 0.22- μ m membrane. A suitable sterilization system is a disposable filter unit (e.g., Nalgene #120-0020). Glass-distilled water should be used for all preparations.

0.34 M sucrose solution

58.2 g sucrose

H₂O to 500 ml

Filter sterilize and store at 4°C in 100-ml aliquots

HAT (hypoxanthine/aminopterin/thymidine) medium

Complete culture medium (see reagents and solutions, *UNIT 11.5*) supplemented to the indicated concentrations with the following additives:

20% (v/v) fetal calf serum

0.1 mM nonessential amino acids

100 μ M hypoxanthine

0.4 μ M aminopterin

16 μ M thymidine

These additives may be purchased in concentrated and sterile solutions from the major suppliers of cell culture media and reagents. Concentrated solutions of hypoxanthine and thymidine (HT) and aminopterin may also be prepared in the laboratory (see following recipes).

100 \times HT solution

Weigh 340.3 mg hypoxanthine and 96.9 mg thymidine; add water to 250 ml. Heat to 70°C to dissolve. Filter sterilize and store in 20-ml aliquots at -20°C. Thaw at 70°C for 10 to 15 min.

1000 \times aminopterin solution

Weigh 17.6 mg aminopterin. Add 60 ml water and dissolve by adding 0.1 M NaOH dropwise. Titrate with HCl to pH ~8.5. Adjust volume to 100 ml and filter sterilize. Make 100 \times working solution by diluting stock in complete culture medium. Store in 5-ml aliquots at -20°C.

Aminopterin precipitates at low pH and is light sensitive.

COMMENTARY

Background Information

To maximize the yield of hybrids from the fusion and cloning procedures, feeder cells are required to be cocultured with the hybrids, while hybrid cell density is low. Mouse peritoneal cells, most of which are macrophages, have been found to be convenient and effective feeder cells which are a source of soluble growth factors for hybridoma cells.

Critical Parameters

Feeder cells such as peritoneal cells provide best support of hybridoma growth when used 1 to 3 days after harvest. Use of chilled solutions is necessary for optimum cell harvest, to prevent macrophages adhering to plastic surfaces.

Anticipated Results

From 1 to 3×10^6 peritoneal feeder cells are harvested from one mouse. The number of feeder cells will be enough to seed 100 to 300 wells.

Time Considerations

Peritoneal feeder cells from one mouse can be processed in 1 hr or less.

Fusion of Myeloma Cells with Immune Spleen Cells

BASIC PROTOCOL

Freshly harvested spleen cells and myeloma cells are copelleted by centrifugation and fused by addition of polyethylene glycol solution to the pellet. Cells are centrifuged again and the PEG solution diluted by slow addition of medium. Fused cells are centrifuged, resuspended in selection medium, and aliquoted into 96-well microtiter plates. Hybridomas are grown to 10 to 50% confluence and then assayed for production of antigen-specific antibody.

Materials

- Any strain immunized mouse (*UNIT 11.3*)
- Sp2/0 murine myeloma cells in active log phase (Am. Type Culture Collection #CRL 1581; *UNIT 11.5*)
- Diethyl ether
- 70% ethanol
- Dulbecco modified Eagle medium (DMEM) with supplements
- Sterile polyethylene glycol (PEG) solution
- HAT medium (*UNIT 11.6*)
- HT medium
- Phosphate-buffered saline (PBS; *APPENDIX 2*)
- 15- and 50-ml centrifuge tubes
- Glass desiccator or metal can with lid
- Dissecting board
- 10.5-cm scissors (Irex #IR-105), sterile
- 10.5-cm forceps (Irex #IR-1393), sterile
- 60- and 100-mm petri dishes
- Stainless-steel strainer (Collector; GIBCO #1985-8500), sterile
- 3-cc glass syringes with 26-G needle
- 5-ml serological pipets
- 37° C water bath
- Stopwatch
- 8% CO₂-in-air gas mixture
- Humidified CO₂ incubator
- Polyvinyl or polystyrene 96-well microtiter plates
- Inverted microscope
- Additional reagents and equipment for estimating cell viability by trypan blue exclusion (*UNIT 11.5*) and for detection of antibodies (*UNIT 11.4*)

Preparation of myeloma and spleen cells

1. Just prior to sacrificing the mouse, transfer 1×10^7 Sp2/0 murine myeloma cells (prepared as described in *UNIT 11.5*) to a 50-ml centrifuge tube. Check the percentage of viable cells using the trypan blue exclusion method (support protocol, *UNIT 11.5*).
2. Sacrifice the mouse by anesthetizing with diethyl ether in a closed container (e.g., a glass desiccator or a metal can with a lid).

At this point, a blood sample may be collected from the mouse by severing the blood vessels of one forelimb. Collect the blood with a Pasteur pipet and place the blood in a microcentrifuge tube.
3. Immerse the mouse in a beaker containing 70% ethanol and lay out on a dissecting board.

4. Using sterile forceps, lift skin over the thorax area and snip with sterile scissors. Peel skin over both sides to expose left side of the rib cage.
5. Using another set of sterile forceps and scissors, remove the spleen from the left upper abdomen of the mouse. The spleen is a small dark red organ.
6. Place the spleen in a 60-mm petri dish containing 3 ml supplemented DMEM.
7. Take spleen in petri dish to sterile hood and carefully dissect away surface fat and other adhering tissue by using a sterile forceps and scissors.
8. Transfer spleen to sterilized, stainless-steel strainer in 100-mm petri dish with 10 ml DMEM.
9. Fill the 3-cc syringe with 2 ml supplemented DMEM. Using a 26-G needle, fill the spleen with DMEM by injecting at several sites.
10. With sterile scissors, cut the supplemented DMEM-filled spleen in 3 or 4 places.
11. Using circular movements, press the spleen against the screen of the stainless-steel strainer with the glass syringe plunger of the 3-cc syringe until only fibrous tissue remains on top of the strainer screen. The tissue that is forced through the strainer is collected in a sterile petri dish underneath.
12. Rinse the screen with 2 ml supplemented DMEM.
13. Transfer the suspension of spleen cells to a 15-ml centrifuge tube. Using a 5-ml serological pipet, disperse the clumps by drawing up and expelling several times.
14. Let suspension stand for 3 min at room temperature.
15. Transfer the top 95% of the cell suspension to a 15-ml centrifuge tube.
16. Perform a viable cell count using the trypan blue exclusion procedure (support protocol, *UNIT 11.5*); record the percentage of viable cells.
Ignore red blood cells that are substantially smaller than the nucleated cells.
17. Transfer 1×10^8 viable spleen cells into a 15-ml centrifuge tube.
18. Wash myeloma cells (from step 1) twice with supplemented DMEM followed by centrifugation at $200 \times g$ for 5 min and resuspend the cells in 5 ml supplemented DMEM.
19. Add spleen cells to myeloma cells in the 50-ml tube and fill the tube with DMEM.
20. Centrifuge the suspension at $200 \times g$ for 5 min at room temperature.
21. Resuspend the cell pellet in 50 ml supplemented DMEM and centrifuge as above.
22. Warm the cell pellet by placing the tube in a 37°C water bath in a beaker for 2 min.
23. Loosen the pellet by flicking the tip of the tube gently.

Cell fusion

24. Fuse spleen and Sp2/0 cells with sterile PEG solution:

Over the first 1 min—Add 1 ml PEG solution at 37°C. Mix gently.

Over the next 2 min—Spin at $100 \times g$ (2 min, total time).

Over the next 3 min—Add 4.5 ml supplemented DMEM.

Over the next 2 min—Add 5 ml supplemented DMEM.

Fill the tube with supplemented DMEM.

Timing is critical and should be monitored with a stopwatch.

25. Centrifuge at $100 \times g$ for 5 min at room temperature.
26. Aspirate supernatant.
27. Resuspend the cell pellet in 35 ml HAT medium.
Do not force the dispersion of small cell clumps.
28. Incubate cell suspension at 37°C in a CO_2 incubator in 8% CO_2 -in-air with 98% relative humidity for a minimum of 30 min.

Plating and culture of fused cells

29. Add 100 μl cell suspension to each of the 60 inner wells of six 96-well plates. Peripheral 36 wells are filled with sterile PBS.

Twenty-four (24) hr prior to use, the 60 inner wells are conditioned with 1×10^4 mouse peritoneal macrophages per well in 100 μl HAT medium.

30. Incubate plates at 37°C in CO_2 incubator in 8% CO_2 -in-air with 98% relative humidity. (This is day 1 of the culture).
31. On day 5 of the culture, add 100 μl HAT medium to each well.
32. On day 7 of the culture, remove 100 μl from each well and add 100 μl fresh HAT medium.
33. Repeat step 32 every other day until hybrid cell growth covers 10% to 50% of the surface area of the wells. This is monitored by examining the bottom of the wells with an inverted microscope. At this time, the wells should be screened for antibody (UNIT 11.4).
34. Grow the hybrids in HAT medium for 2 weeks after fusion.
35. After 2 weeks, change the medium to HT medium.
36. The hybrids are grown in the HT medium until the completion of two cloning procedures (as described in the protocol for cloning of hybridoma cells by limiting dilution, UNIT 11.8).

REAGENTS AND SOLUTIONS

Dulbecco modified Eagle medium (DMEM), high-glucose formula (GIBCO/BRL #430-2100), supplemented to the indicated concentrations with the following additives:

- 2.8 g/liter sodium bicarbonate (33.3 mM)
- 4.8 g/liter HEPES (20 mM)

HT medium

Prepare as described in UNIT 11.6 for HAT medium but without aminopterin solution.

PEG (polyethylene glycol) solution

Weigh 10 g PEG 4000 (Merck) into a 100-ml glass bottle. Autoclave PEG for 10 min at 121°C . Cool the molten PEG to 50°C . Mix with 10 ml prewarmed supplemented DMEM (50°C) that contains 5% (v/v) dimethylsulfoxide (DMSO). Aliquot the mixture into small glass bottles (3 ml/bottle). Store at 4°C in the dark.

PEG 4000, Merck's gas chromatography grade, appears to be the best PEG for cell fusions using Sp2/0 myeloma cells regardless of lot number. Remove PEG from the autoclave as soon as the pressure is down in order to avoid prolonged heating of PEG. Incubate PEG solution at 37°C for 24 hr prior to use to test its sterility.

Alternatively, if the temperature control of the autoclave is uncertain, melt the PEG at 65°C on the day of fusion. Mix the PEG with supplemented DMEM to make a 45% PEG solution and sterilize by filtration through a 0.22- μ m membrane filter.

COMMENTARY

Background Information

Murine spleen cells, some of which are involved in production of the desired antibodies, are fused with a murine myeloma cell line to form a stable antibody-producing hybridoma cell line. The myeloma cells (Sp2/0) are hypoxanthine–guanine phosphoribosyltransferase deficient (HGPRT⁻) and therefore are unable to use the purine salvage pathway when de novo purine synthesis is blocked by aminopterin, which is included in the HAT selection medium. See discussion of selectable markers in *UNIT 9.5*. Hypoxanthine and thymidine in the HAT selection medium allow HGPRT⁺ cells, the spleen cell–myeloma hybrids, to survive and grow. Unfused spleen cells eventually die.

Literature Review

Kohler and Milstein (1975) first demonstrated that somatic cell fusion could be used to generate a hybridoma cell line producing a monoclonal antibody of predetermined specificity. Cell fusion was initially accomplished by addition of Sendai virus. The fusion procedure used in this protocol is a modification of the method of Gefer et al. (1977), which uses polyethylene glycol (PEG) as the fusogen. A similar procedure is presented by Oi and Herzenberg (1980). Each protocol encompasses careful timing of the PEG addition to the cell pellet and its subsequent dilution after fusion.

Critical Parameters

The choice and use of PEG in the fusion protocol is the most critical factor. PEG can vary dramatically in efficiency between manufacturers and among lots of a particular manufacturer. The suggested source (Merck) has provided the most consistent lots of PEG. Care must be taken to autoclave the PEG at 121°C for only 10 min in order to minimize the production of toxic aldehydes. In the fusion procedure itself, it is important to adhere carefully to the time schedule established. Extended incubation of the cells with PEG results in decreased cell viability. Dilution of the PEG by medium must be done carefully to avoid lysis of the cells.

Troubleshooting

When poor fusion results (i.e., poor hybridoma growth) are obtained despite close adherence to the protocol, the likely causes are the PEG, the myeloma cells used as fusion partner, or the culture conditions. Most critical is the PEG (see critical parameters). The quality of the fusion partner (i.e., the myeloma culture; see *UNIT 11.5* for details) is also very important. The CO₂ incubator must provide a stable temperature, pH, and humidity for optimal hybridoma growth.

Anticipated Results

Hybridoma growth should be observed with the aid of an inverted microscope in nearly all wells after a few days in culture. For wells with viable cells, generally 10 to 50% will contain antigen-specific antibody. Results can vary widely, of course, and it has been observed that 0 to 99% of the supernatants in the wells will contain specific antibody.

Time Considerations

The fusion procedure requires 3 to 4 hr to complete. For best results, it should be accomplished without interruption. Wells with hybridoma growth can be assayed for specific antibody 7 to 12 days after fusion.

Cloning of Hybridoma Cell Lines by Limiting Dilution

BASIC PROTOCOL

Hybridomas to be cloned are diluted to 0.8 cells/well. This dilution provides 36% of wells with 1 cell/well by Poisson statistics. When cultures are 10 to 50% confluent, antibody is assayed by ELISA. Two or more cloning procedures are carried out until >90% of the wells containing single clones are positive for antibody production.

Materials

HAT medium (UNIT 11.6)
HT medium (UNIT 11.7)
Complete culture medium (UNIT 11.5)

Polyvinyl or polystyrene 96-well microtiter plates
6- and 24-well culture plates
8% CO₂-in-air gas mixture
Humidified CO₂ incubator
Cryotubes (Nunc #3-63401)
2-, 5-, and 10-ml serological pipets
Multichannel pipet and tips
Inverted microscope

Additional reagents and equipment for preparing mouse feeder cells for fusion and cloning (UNIT 11.6), for ELISA screening (UNIT 11.4), and for estimating cell viability by trypan blue exclusion (UNIT 11.5)

1. *The day before cloning*, isolate mouse feeder cells and prepare 96-well plates with feeder cells in appropriate medium, as described in UNIT 11.6.

Choice of medium depends on the current stage of the cloning process. The first cloning uses HAT medium, and the second cloning uses HT medium. Any other clonings use complete culture medium.

2. Transfer all of the cells from each well containing antigen-specific antibody in its hybridoma supernatant (as determined by an ELISA, UNIT 11.4) into a separate well of a 24-well plate that has been preincubated with 0.5 ml of an appropriate culture medium (see note in step 1) and culture overnight at 37°C, 8% CO₂-in-air, and 98% humidity in a CO₂ incubator.

If there are greater than 40 to 50 positive wells, it is difficult to manage conveniently the cloning procedure. The ELISA assays (UNIT 11.4) or western blotting (UNIT 10.8) can be performed using the 24-well culture supernatants in order to select the most promising samples to be cloned. The remaining positive samples can be transferred to cryotubes and frozen, as described in UNIT 11.9.

Cloning efficiency is always improved when hybrid cells are grown to log phase in 24-well plates. The efficiency is still better if the 24 wells are preconditioned with feeder cells prior to transferring the hybrids.

3. Perform cell viability count using trypan blue exclusion method (support protocol, UNIT 11.5) on the overnight cultures in 24-well plates.
4. Using a 6-well plate, make dilutions of cells from overnight cultures in HT or complete medium. In the first well, make a 1:100 dilution in a total of 3 ml; in the second well, dilute an aliquot of the first dilution to 80 cells/ml in 5 ml; in the third well, prepare 8 cells/ml in 10 ml (i.e., a 1:10 dilution from the second well).

Choice of medium is discussed in step 1. Using 6-well plates is far easier for preparing cell dilutions than using tubes. However, using 6-well plates is expensive.

5. With a multichannel pipet, fill the upper 50 wells of the inner 60 wells of the 96-well plate from step 1 with 100 µl of 8 cells/ml dilution (i.e., 0.8 cells/well)

and the 10 wells of the bottom row with 100 μ l of 80 cells/ml dilution (i.e., 8 cells/well).

6. Incubate at 37°C in a CO₂ incubator in 8% CO₂-in-air with 98% relative humidity (day 1).

As a precaution, the hybridoma cells remaining in the 24-well plate can be transferred to cryotubes and frozen, as described in UNIT 11.9.

7. On day 6, feed the culture with the addition of 100 μ l/well of fresh medium, using a multichannel pipet. Thereafter, if necessary, refeed the culture every other day by removing 100 μ l media from each well and adding 100 μ l fresh media.
8. When cell growth in the bottom of the wells is 10 to 50% confluent (as monitored using an inverted microscope), assay for specific antibody in the hybridoma supernatants using an ELISA (UNIT 11.4).
9. Transfer 2 to 3 selected positive subclones from each plate into a 24-well plate (as for step 2) and incubate overnight.

Expand the subclones and freeze one aliquot for each subclone in a cryotube. This is done as a precaution in case one fails to recover positive clones.

10. Repeat cloning procedure from the beginning until a stable and single hybridoma cell line is established.

Hybridomas that yield >90% antibody-positive cultures upon recloning are considered to be stable. Those that yield <90% positive cultures are subjected to further cloning. When clones become stable, reduce the 20% fetal calf serum level in the HT medium to 10%, gradually reduce HT level, and finally remove HT from the medium entirely. Some clones are more sensitive to this HT weaning process than others.

11. Once established as stable cell lines, hybridomas are maintained in complete culture medium in a similar manner to the myeloma cell line (UNIT 11.5). Cells are then propagated for liquid N₂ storage (UNIT 11.9) and for antibody production in ascites fluid (UNIT 11.10).

Recloning of established hybridoma lines may become necessary when they are cultured for longer than 30 days. Somatic mutation or chromosome loss may occur during an extended culturing, which could lead to a loss of antibody production.

COMMENTARY

Background Information

Cloning by limiting dilution is a method based on the Poisson distribution. Dilution of cells to an appropriate number per well can maximize the proportion of wells that contain one single clone. The cloning protocol presented here is a modification of the method of Galfre and Milstein (1981).

Critical Parameters

Accurate cell counting is necessary to obtain the proper dilution of 0.8 cells/well at step 5. Clone as soon as antibody-positive hybridomas are identified in order to avoid overgrowth by nonsecreting hybrids.

Anticipated Results

Depending on accuracy of cell counts and growth characteristics of each hybridoma, 20 to 50% of wells seeded at 0.8 cells/well can be expected to

exhibit growth. Normally, all wells at 8 cells/well will exhibit growth. Upon ELISA screening of the first cloning, some hybridomas will have lost production of specific antibody. The proportion of hybridomas that lose antibody production generally decreases at each successive cloning.

Time Considerations

Two to three clonings require 4 to 6 weeks.

FREEZING OF CELL LINES

Hybridoma cells are suspended in dimethyl sulfoxide/fetal calf serum and frozen rapidly in a dry ice–ethanol and glycerol bath followed by transfer to liquid nitrogen storage. Cells are recovered by thawing rapidly at 37°C, with immediate replacement of freezing medium by culture medium.

Materials

Freezing medium

95% ethanol

10% glycerol

Cryotubes (Nunc #3-63401)

15-ml plastic centrifuge tubes

Liquid N₂ freezer

Additional reagents and equipment for estimating cell viability by trypan blue exclusion (UNIT 11.5)

Ideally, hybridoma cells to be frozen should be in the log phase of growth (as described for the Sp2/0 myeloma cells, UNIT 11.5, step 5).

1. Perform a cell viability count using the trypan blue exclusion procedure (support protocol, UNIT 11.5).
2. Using a pencil, label cryotubes with identification and date.
3. Centrifuge cell suspension at 100 × g for 5 min at room temperature.
4. Aspirate the supernatant.
5. Resuspend cell pellet in freezing medium to give a cell density of 1 × 10⁷ viable cells/ml.
6. Aliquot 0.5 ml/cryotube (i.e., 5 × 10⁶ cells/tube).
7. Freeze in dry ice/ethanol and glycerol bath for 60 min (see Fig. 11.9.1).

For optimal cell viability, it is important that the time interval between steps 5 and 7 is not less than 15 min or greater than 30 min.

Alternatively, place the tubes in a styrofoam box, then place the box in a –70°C freezer overnight. The styrofoam box slows the rate of freezing of the medium in the tubes.

8. Transfer cryotubes to liquid nitrogen freezer.

RECOVERY OF FROZEN CELL LINES**Materials**

Complete culture medium (as described for Sp2/0 cells, UNIT 11.5)

37°C water bath

Alcohol swabs

15-ml centrifuge tubes

25-cm² tissue culture flask (Costar or Falcon)

1. Thaw cryotubes completely in 37°C water bath.

Thawing should be completed within 1 min. Immerse tubes only to level of contents.

2. Wipe top of cryotube with alcohol swab, transfer cells to 15-ml centrifuge tube and add 5 ml of complete culture medium warmed in a 37°C water bath.

Figure 11.9.1 Apparatus for freezing of hybridoma cell lines in dry ice-ethanol and glycerol bath.

3. Centrifuge at $100 \times g$ for 5 min.
4. Aspirate supernatant.
5. Resuspend cell pellet in 5 ml warm complete culture medium (37°C).
6. Transfer suspended cells to a 25-cm^2 tissue culture flask.
7. Incubate overnight at 37°C in a CO_2 incubator in $8\% \text{CO}_2$ -in-air with 98% humidity. Keep flask upright.
8. Add 5 ml warm complete culture medium (37°C). Lay flask flat.
9. Propagate cells in complete culture media as described in *UNIT 11.10*, step 3.

REAGENTS AND SOLUTIONS

Freezing medium

10% (v/v) dimethyl sulfoxide, analytical grade

90% (v/v) fetal calf serum

Medium is prepared on day of use and chilled to 4°C before use.

COMMENTARY

Background Information

Liquid nitrogen storage is the method of choice for long-term safekeeping of hybridoma cell lines. Frozen aliquots of originally isolated hybridomas provide insurance against loss of antibody production and vigor during culture. There are many variations of cell freezing methods in use. However, for freezing hybridomas and lymphoid cells in general, this protocol is simple and has been successful.

Critical Parameters

Cell viability in the freezing and recovery protocols is drastically affected by the length of time spent in liquid freezing medium prior to and after frozen storage. Adhere carefully to time limits of the protocols.

Anticipated Results

Viability upon recovery of frozen aliquots ranges from 50% to 95%. Any recovery less than 50% viable is considered substandard.

Time Considerations

Freezing of cells can be accomplished in 1.5 to 2 hr. Recovery of hybridoma cell lines should require less than 10 min.

Production of Monoclonal Antibody Supernatant and Ascites Fluid

UNIT 11.10

A major advantage of using monoclonal antibodies over polyclonal antisera is the potential availability of large quantities of the specific monoclonal antibody. In general, preparations containing the monoclonal antibody include a hybridoma supernatant, ascites fluid from a mouse inoculated with the hybridoma, and purified monoclonal antibody. Hybridoma supernatants are easy to produce, especially for large numbers of different monoclonal antibodies, but are relatively low in monoclonal antibody concentration. Ascites fluid contains a high concentration of the monoclonal antibody but the fluid is not a pure monoclonal antibody preparation. To obtain a purified preparation of the monoclonal antibody, affinity chromatography (UNITS 10.9 & 10.10) of culture supernatants or ascites fluid can be performed; however, this obviously requires more effort (see commentary).

Procedures detailing the production of monoclonal antibody supernatants (first basic protocol), including the production of larger amounts (liters; first alternate protocol) are presented here. The second alternate protocol for large-scale production of hybridomas or cells (e.g., for isolation of cellular proteins) involves a similar procedure. A method for producing and obtaining ascites fluid containing the monoclonal antibody is presented in the second basic protocol.

PRODUCTION OF A MONOCLONAL ANTIBODY SUPERNATANT

**BASIC
PROTOCOL**

There are a variety of methods for producing monoclonal antibody supernatants. In the easy version presented here, the hybridoma is grown and split 1:10. The cells are then overgrown until cell death occurs. The supernatant is harvested and the titer determined. If the titer is high, the hybridoma can be used for large-scale production in anticipation of purification or ascites production.

Materials

- Hybridoma of interest (UNIT 11.7)
- Complete DMEM-10 medium (APPENDIX 3F)
- 175-cm² tissue culture flasks
- 50-ml conical centrifuge tubes, sterile
- Beckman TH-4 rotor (or equivalent)

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator.

1. Place hybridoma in a 175-cm² tissue culture flask in complete DMEM-10 medium. Incubate until vigorously growing and ready to split.

Most cell lines need to be split into new medium or new flasks when cell density reaches 1-2 × 10⁶ cells/ml. Tissue culture flasks can be inspected with an inverted microscope and cell viability and density determined. In addition, the culture can be monitored for contamination. Cells should never be allowed to become so crowded that cell death occurs because this crisis phase increases the likelihood of phenotypic change. With experience, most investigators will be able to determine whether or not to split the cells by their macroscopic appearance and the color of the medium—i.e., cells may need to be split when the medium in the flask becomes turbid and more yellow than medium in the DMEM bottle (macroscopic turbidity in the absence of a color change is often a sign of bacterial contamination). The density can then be confirmed by microscopic examination.

2. Split cells 1:10 in a new 175-cm² flask. Fill the flask with complete DMEM-10 to

Immunology

11.10.1

Supplement 18

100 ml total and incubate until cells are overgrown, medium becomes acidic (yellow), and cells die (~5 days).

Alternatively, add hybridoma cells at high density ($1-2 \times 10^6$ cells/ml) in fresh medium to a tissue culture flask. Incubate 2 to 3 days, at which time the cells will die and the supernatant can be collected (step 3).

3. Transfer flask contents to sterile 50-ml conical centrifuge tubes. Centrifuge 10 min in a TH-4 rotor at 2700 rpm ($1500 \times g$), room temperature. Collect the supernatant and discard the pellet.
4. Assay titer of MAb supernatant by appropriate method (see commentary).
5. Store the supernatant under sterile conditions; it is generally stable at 4°C for weeks to months, at -20°C for months to years, and indefinitely at -70°C. Minimize thawing and refreezing by storing several aliquots.

ALTERNATE PROTOCOL

LARGE-SCALE PRODUCTION OF MONOCLONAL ANTIBODY SUPERNATANT

The first step in monoclonal antibody purification by affinity chromatography (*UNIT 11.11*) is the production of large amounts of the culture supernatant. The procedure described below utilizes readily available equipment and supplies and a special tissue culture roller apparatus. Cells are first grown in smaller flasks, then gradually expanded into large-volume roller flasks. The supernatant is harvested and stored until needed.

Additional Materials

Complete DMEM-10 medium (*APPENDIX 3F*) with 5 to 10 mM HEPES, pH 7.2 to 7.4

70% ethanol

850-cm² roller flask

Roller apparatus in 37°C room or incubator

250-ml conical centrifuge tubes, sterile

Beckman JS-5.2 rotor (or equivalent)

1. Repeat step 1 of the first basic protocol and split 1:10 in complete DMEM-10/HEPES to 100 ml total.

Each 175-cm² flask will ultimately seed 2.35 to 2.5 liters of culture medium. Scale up the experiment as desired. If the supernatant will be used for MAb purification by affinity chromatography, the yield will be 1 to 10 mg MAb/liter. It is usually not necessary to adapt and grow cells in serum-free media (which frequently decreases yield); however, if the supernatant will be used for MAb purification by protein A-affinity chromatography, test the culture medium with FCS alone for contaminants (i.e., other proteins) that may co-purify with the MAb. Bovine newborn serum frequently contains significant amounts of Ig that will bind to protein A and should not be used as a medium supplement.

2. When cells are ready to split, transfer contents of the 175-cm² flask (100 ml) to an 850-cm² roller flask. Add an additional 150 ml complete DMEM-10/HEPES (250 ml total volume). Cap tightly, place on roller apparatus in 37°C room or incubator and grow 1 to 2 days.

Timing of the split will depend on the cell line (see step 1 of the first basic protocol).

3. Wipe cap and neck of roller flask with a sterile gauze sponge soaked in 70% ethanol.
4. Open roller flask and add 250 ml complete DMEM-10/HEPES (500 ml total volume). Cap tightly and incubate on roller apparatus 1 to 2 days at 37°C.

- Repeat wiping as in step 3.
- Open roller flask and add ~2 liters complete DMEM-10/HEPES until flask is almost full (~2.5 liters total volume depending on capacity of flask). Cap tightly and incubate on roller apparatus at 37°C until the medium turns yellow (~ 5 days).

Avoid foaming by first pouring in growth medium without FCS followed by FCS to 10% final.

Avoid prolonged rolling, as cell fragmentation will occur and the debris will be difficult to pellet with the large centrifuge tubes.

- Pour the culture into sterile 250-ml conical centrifuge tubes. Harvest the supernatant by centrifuging 20 min in JS-5.2 rotor at 1000 rpm (250 × g), room temperature. Collect the supernatant and discard the pellet. Freeze the supernatant in aliquots.

If the supernatant will not be used in a bioassay, add 10% sodium azide to 0.02% final. If the supernatant will undergo affinity chromatography or salt fractionation, sterile filtration through a 0.45- μ m filter is recommended to eliminate debris.

LARGE-SCALE PRODUCTION OF HYBRIDOMAS OR CELL LINES

The following procedure is used to produce large amounts of cells which can be used to isolate cellular components such as membrane proteins. Individual small flasks are grown, then each is used to inoculate a larger roller flask. The cells are gradually expanded by addition of fresh medium, and are harvested when the cells are near saturation densities.

- Follow steps 1 to 6 for large-scale production of MAb supernatants (first alternate protocol) but harvest when the density is appropriate or if the cell growth plateaus.

Estimate the amount of cells needed. This procedure will yield ~10⁶ cells/ml. More cells can be obtained with faster-growing cell lines or lines that can tolerate higher densities, but we usually grow 80 liters (33 flasks) and obtain 10¹⁰ to 10¹¹ cells.

Seed (introduce cells into) the number of 175-cm² flasks necessary to produce the amount of cells required (one 175-cm² flask for every 2.4 liters of medium). Each flask should be treated as an independent culture. Thus, if there is contamination at any time after the 175-cm² flasks are initially seeded, the contamination should spread vertically (i.e., stay in the flask and roller bottle seeded by the contaminated flask) and not horizontally (i.e., not involve any other flasks or roller bottles).

Estimate the time of harvesting by macroscopic inspection for medium color and turbidity and by taking daily cell counts and checking viability on several flasks. When the cell concentration reaches a plateau, harvesting is indicated. Do not allow cells to overgrow or cell viability will drop precipitously.

- Pour cells into sterile 250-ml conical centrifuge tubes, centrifuge 15 min in JS-5.2 rotor at 1000 rpm (250 × g), 4°C, and discard supernatant.

Each tube can be used for two spins. Harvesting 80 liters of cells requires at least three centrifuges to spin four to six tubes (1 to 1.5 liters) each, two or three people, and nearly one day. Conical centrifuge tubes are recommended because pellets in the flat-bottom bottles are harder to work with.

- Place cell pellets on ice. Pool 10 cell pellets into one tube by resuspending cells in 250 ml of 4°C PBS. Centrifuge at 250 × g, 4°C, and discard supernatant.
- Repeat and further consolidate tubes into one tube. After three washes, the cells are ready for further processing (i.e., cell lysis, radiolabeling, or other procedures).

Alternatively, lyse smaller cell pellets as they become ready after three washes.

ALTERNATE PROTOCOL

PRODUCTION OF ASCITES FLUID CONTAINING MONOCLONAL ANTIBODY

High-titer monoclonal antibody preparations can be obtained from the ascites fluid of mice inoculated intraperitoneally with monoclonal antibody-producing hybridoma cells. The fluid is collected several times after injection of the cells. It is heat-inactivated, titered, and stored.

Materials

Nude mice, 6 to 8 weeks old and specific-pathogen free, *or* syngeneic host if mouse-mouse hybridomas are injected

Pristane (2,6,10,14-tetramethylpentadecane; Aldrich)

Hybridoma of interest (UNIT 11.7)

Complete DMEM-10 medium (APPENDIX 3F) with 10 mM HEPES and 1 mM sodium pyruvate

PBS (APPENDIX 2) *or* HBSS, sterile and without FCS

20- or 22-G needle and 18-G needle

175-cm² tissue culture flask

Beckman TH-4 rotor (or equivalent)

50- and 15-ml polypropylene conical centrifuge tubes, sterile

56°C water bath

Additional reagents and equipment for ELISA (UNIT 11.2) and counting cells (UNIT 11.5)

1. Using a 20- or 22-G needle, inject mice intraperitoneally with 0.5 to 1 ml Pristane per mouse 1 week prior to inoculation with cells (Donovan and Brown, 1991).

Alternatively, the injections can be done at the same time, but the week interval is recommended to avoid leakage through two needle sites. Mice should be maintained in specific-pathogen free (spf) facility (see commentary).

2. Grow hybridoma cells in a 175-cm² tissue culture flask in complete DMEM-10/HEPES/pyruvate under conditions that promote log-phase growth.

Before injecting mice (step 7), test the supernatants for MAb activity by ELISA or appropriate assay, preferably before the cells are expanded.

To minimize the risk of introducing a pathogen into the rodent colony, screen cells for pathogens by antibody-production assay (Donovan and Brown, 1991).

3. Transfer the culture to 50-ml conical centrifuge tubes. Centrifuge 5 min in TH-4 rotor at 1500 rpm (500 × g), room temperature, and discard supernatant.

4. Wash cells by resuspending in 50 ml sterile PBS or HBSS without FCS, then centrifuging 5 min at 500 × g, room temperature, and discarding supernatant. Repeat twice and resuspend cells in 5 ml PBS or HBSS.

Avoid washing in FCS-containing medium because the mouse will produce antibodies to the FCS.

5. Count cells and determine viability by trypan blue exclusion.

Cells should be nearly 100% viable.

6. Adjust cell concentration to 2.5×10^6 cells/ml with PBS or HBSS without FCS.

7. Draw up cells in 10-ml sterile syringe. Using a 22-G needle, inject nude mouse intraperitoneally with 2 ml cells. Wait for ascites to form (1 to 2 weeks).

Typically, three mice are injected at one time. In most cases, at least one and frequently all of the mice will develop ascites.

8. Harvest ascites by grasping and immobilizing the mouse in one hand in such a way as to stretch the abdominal skin taut. With the other hand, insert an 18-G needle 1 to 2 cm into the abdominal cavity. Enter either the left or right lower quadrants to avoid the vital organs in the upper quadrants and the major vessels in the midline. Allow the ascites to drip into a sterile 15-ml polypropylene conical centrifuge.

If the mouse has a large amount of ascites and the fluid stops dripping from the 18-G needle, it may be necessary to reposition the needle tip by withdrawing it slowly and reinserting it in a different plane. If no ascites fluid accumulates, the mouse may be reinjected (see commentary).

Occasionally, the ascites is under such high pressure that a large amount squirts out as soon as the needle is inserted. For this reason, be sure that the hub of the needle is pointed into a tube before inserting the needle into the peritoneal cavity.

Rather than tapping the mouse as soon as the ascites is apparent, allow the fluid to build up (3 to 7 days) to obtain the highest yield. Frequently, 5 to 10 ml (sometimes >40 ml) of ascites can be collected from each mouse.

9. Centrifuge the ascites 10 min in TH-4 rotor at 2700 rpm (1500 × g), room temperature. Harvest supernatants and discard pellet. Store ascites fluid at 4°C until all collection is completed (<1 week).

If the fluid clots, “rim” the clot by passing with a wooden applicator stick around its edge (between clot and tube) before centrifugation. The clot may adhere to the applicator stick and thus may be discarded or it will remain in the tube and become part of the cell pellet after centrifugation.

10. Allow the mouse to reaccumulate ascites (2 to 3 days) before reharvesting as in step 8. Process the ascites as in step 9. Repeat this process until no further ascites accumulate, the fluid cannot be collected, or the mouse becomes ill. The mouse should be euthanized at this point (Donovan and Brown, 1991).

11. Pool ascites fluid collected on different days and heat-inactivate 45 min in a 56°C water bath. If a clot reforms, remove it by rimming and centrifuge as in step 9.

12. Assay the titer of MAb-containing ascites by the appropriate method (see commentary).

Saturating concentration (maximal activity) of the MAb should be apparent at 0.5% or higher dilutions. Lower titers usually are the result of unstable hybridomas that stop producing MAb or too many (>2) in vivo serial passes of the hybridomas.

13. Dilute >1:10 and filter sterilize through a 0.45-μm filter. Aliquot and freeze at -70°C, avoiding repeated freezing and thawing (Yokoyama, 1991a). Shelf life should be several years.

Add sodium azide to 0.02% final if the ascites will not be used for bioassay.

It is possible that ascites fluid will not form. If the mice die without any ascites forming, particularly within 2 weeks of inoculation, try fewer cells. If the mice do not form ascites after 2 weeks and they appear healthy, inject those mice—as well as naive, Pristane-primed mice—with more cells. If solid tumors form, tease cells into suspension and inject tumor cells into another Pristane-primed mouse. Even if a little ascites forms, the fluid can be transferred to another mouse (~0.5 ml/mouse), and large amounts of ascites should accumulate. Once the ascites is formed, the mouse-adapted cells can be frozen and used to reinoculate mice in the future.

COMMENTARY

Background Information

Production of MAb supernatant

There are three basic preparations that contain monoclonal antibodies: supernatant from a MAb-producing hybridoma, ascites from a mouse inoculated with the hybridoma, or purified MAb. In the first protocol, a MAb-containing supernatant is produced. The hybridoma continues to secrete MAb into the culture fluid until cell death occurs. Because the MAb is not metabolized, it accumulates in the culture supernatant. Hybridoma supernatants are advantageous because small amounts (<100 ml) can be easily obtained in a few days (<1 week), and from multiple hybridomas with relatively little effort. Such small quantities of the MAb can be used in preliminary experiments to determine if the MAb has the desired property before expending the effort required to produce ascites or purified MAb.

The first step in MAb purification, usually by affinity chromatography, is the production of large amounts of the MAb. For the noncommercial laboratory, several liters of culture supernatant are adequate for most MAb-purification protocols. The use of bioreactors or large spinner flasks would require expensive, somewhat fragile equipment. The alternate protocol described here involves the use of sealed roller bottles that can be rotated on a roller apparatus in any 37°C room, as the pH of the medium is maintained by the HEPES instead of a bicarbonate-based buffer system and a CO₂ atmosphere.

Production of ascites containing MAb

A convenient source of large concentrations of the desired MAb is the ascites fluid of mice inoculated with the appropriate hybridoma cells. These fluids often have a titer >100-fold more than culture supernatants and thus can be diluted significantly. Frequently, high-titer ascites preparations will have saturating MAb concentrations of 10⁻³ to 10⁻⁴ by flow cytometry analysis of cell-surface-antigen binding (Holmes and Fowlkes, 1991). This high titer minimizes the nonspecific functional effects (e.g., in proliferation assays) of equivalent concentrations of MAb in spent culture supernatants. However, ascites used at concentrations >0.5% may also have significant nonspecific effects. In addition to the appropriate

isotype control MAb ascites, ascites harvested from mice inoculated with the nonsecretory partner cell line (i.e., SP2/0) also provides a useful nonspecific control.

The general procedure involves the elicitation of nonspecific inflammation in the peritoneal cavity of an appropriate host mouse, usually with Pristane, and injection of the hybridoma cells. The tumor cells then grow as an ascites tumor and should continue to secrete the MAb. Eventually, the mouse develops a monoclonal gammopathy similar to the human disease, multiple myeloma, in that a monoclonal protein reaches high titer in the serum. Since the combination of the ascites tumor and Pristane results in an inflammatory exudate in the peritoneal cavity, the ascites should contain concentrations of the MAb similar to that in serum.

Critical Parameters

Monoclonal antibody production by hybridomas is an unstable phenotype. Hybridoma cells always should be grown under log-phase growth conditions. Prolonged *in vitro* culture and *in vivo* passage should be avoided. Thus, the most critical parameter is whether the hybridoma of interest is secreting a high titer of the MAb. This should be checked before a major effort is made to grow large amounts of supernatant or to produce ascites fluid. The MAb titer can be determined by serial dilution of the culture supernatant in the assay appropriate for that MAb, such as ELISA (UNIT 11.2) or flow cytometry (Holmes and Fowlkes, 1991; Yokoyama, 1991b). Titers of ≥1:10 should be saturating if spent culture supernatants are examined. If necessary, the hybridoma can be recloned by limiting dilution (UNIT 11.8) to find high-producing clones. If cells are known to produce MAb at high titers, aliquots frozen immediately after cloning (Yokoyama, 1991a) will retain this phenotype.

The most critical parameter in the large-scale production of cell lines and hybridomas is the adaptation of the cells to roller flasks. Most hybridomas and other nonadherent cells that grow in suspension can be easily adapted. If the cells (particularly adherent cells) cannot be adapted, other methods should be tried. For example, large-scale production of cells for use in isolating cellular components can be performed using multiple 175-cm² flasks instead of roller flasks. Unfortunately, the

relative surface area is small, and therefore the number of flasks required can become prohibitive. Adherent cell lines are less easily adaptable to growth in roller flasks. The surface area for growing adherent cells can be increased by the use of dextran beads (e.g., Cytodex beads from Pharmacia). These beads can increase the surface area of a culture flask severalfold.

If there is any suspicion that the cells may be mycoplasma contaminated, diagnosis and treatment are indicated (Fitch et al., 1991). Mycoplasma-contaminated lines will produce a much poorer yield of final cell numbers because they do not grow to as high a cell density as normal cells.

Supernatants frequently contain 1 to 10 $\mu\text{g/ml}$ of MAb, but the concentration is cell-line dependent. The supernatants could be concentrated by salt precipitation, but this is not generally recommended because large volumes of culture supernatants have to be concentrated to derive the amount of MAb in small amounts of ascites. Moreover, the FCS in the supernatant will also be concentrated. While the hybridoma could be adapted to culture in serum-free medium, this requires additional testing and yields may decrease. Affinity purification of the culture supernatants would take a similar amount of effort and produce purified MAb at high concentrations. Thus, instead of concentrating supernatants (if high concentrations of MAb are desired), it is recommended to produce purified MAb by first growing hybridomas at a larger scale (liters) or to produce ascites.

For ascites production, it is important to consider the appropriate host for the hybridoma since an injection of allogeneic or xenogeneic cells may result in rejection. For most mouse-mouse hybridomas, an F1 hybrid—between the BALB/c strain (origin of the commonly used SP2/0 fusion partner) and the strain from which the normal cells were obtained—could be used. For xenogeneic hybridomas, nude mice or low-dose irradiated normal mice are potential hosts. Outbred nude mice are somewhat more expensive than normal mice but do not require irradiation. It is not necessary to use the prohibitively expensive inbred nude mouse strains.

Because the level of normal immunoglobulin in mouse serum is in the same range as ascites fluid (mg/ml), ascites fluid can be only partially purified by salt fractionation or anti-mouse-Ig- or protein A–affinity chromatography (UNIT 2.7). However, it is a convenient source of raw material from which to affinity purify rat MAb with a mouse anti-rat κ MAb (e.g., MAR 18.5) column (Andrew and Titus, 1991).

Troubleshooting

It is possible that ascites fluid will not form. The reasons for this are unclear but are probably related to a property of the individual hybridoma. If the mice die without any ascites forming, particularly within 2 weeks of inoculation, try fewer cells. If the mice do not form detectable ascites after 2 weeks and they appear healthy, inject those mice—as well as naive, Pristane-primed mice—with more cells. If solid tumors form, tease cells into suspension and inject the tumor cells into another Pristane-primed mouse. Even if a little ascites forms, the fluid can be transferred to another mouse (~ 0.5 ml/mouse), and large amounts of ascites should accumulate. Once the ascites is formed, the mouse-adapted cells can be frozen and used to reinoculate mice in the future.

Anticipated Results

Most culture supernatants will have saturating MAb titers of $\geq 1:10$ when tested at 100 μl for 10^6 cells. If the spent culture supernatant is used for MAb purification by affinity chromatography (UNITS 10.9 & 10.10; Andrew and Titus, 1991), 1 to 10 mg of purified MAb/liter can be anticipated. If a much lower titer or yield is achieved, recloning of the hybridoma line may be indicated. Hamster-mouse hybridomas are particularly notorious for instability.

Most hybridomas can be grown as ascites tumors. The saturating concentration of the MAb in such fluids should be detected at dilutions of 1:500. If MAb titers are significantly lower, the hybridoma may be a poor producer. If ascites do not form, see troubleshooting above.

Most tumor cells that grow in suspension should be amenable to growth in roller flasks and densities of $>10^6$ cells/ml should be attained. Careful work should result in no contamination.

Time Considerations

For high-titer and large-scale production of MAb supernatants, a flask split 1:10 will be overgrown, with cell viability definitely decreasing by day 5 to 6, at which time the supernatants can be harvested. If several liters of supernatant are required, ~ 10 days are required to expand a 25-cm² flask (10 ml) to 2.4 liters.

For production of ascites fluid containing MAb, 4 to 6 weeks are necessary for growth of the cells for inoculation, ascites accumulation, tapping the fluid, centrifugation, and determination of the MAb titer.

Once the 175-cm² flasks are seeded for large-scale production of hybridomas and cell lines, <2 weeks are required to reach saturating cell densities in the roller bottles.

Purification of Monoclonal Antibodies

UNIT 11.11

PURIFICATION USING PROTEIN A–SEPHAROSE

BASIC
PROTOCOL

Ascites fluid is diluted in high pH buffer and loaded onto protein A–Sepharose. The column is washed and bound antibody is eluted with a succession of buffers of decreasing pH. The procedure for other affinity columns is similar, except that only one eluting buffer is used. Antibodies are concentrated by ultrafiltration.

Materials

Protein A–Sepharose CL-4B (Pharmacia)

Tris buffer, pH 8.6

Ascites fluid (UNIT 11.10)

Citrate buffer, pH 5.5

Acetate buffer, pH 4.3

Glycine-Cl buffer, pH 2.3

Neutralizing buffer, pH 7.7

2.5-cm (inner diameter) glass chromatography column

UV flowthrough detector or UV spectrophotometer and cuvette

Ultrafiltration cells and XM50 membranes (Amicon)

Additional reagents and equipment for ELISA screening (UNIT 11.4)

1. Fully swell protein A–Sepharose in Tris buffer (50-fold excess, vol/vol) in a beaker. Pour the protein A–Sepharose into a 2.5-cm glass chromatography column and equilibrate protein A–Sepharose with Tris buffer at room temperature (see UNIT 10.11A; Figure 10.11A.1).

The size of the protein A–Sepharose column and the volume of ascites used are subject to the requirements of the researcher. A column of 10-ml bed volume (~3 g dry weight protein A–Sepharose) is sufficient to purify antibody from 10 to 20 ml of ascites.

2. Dilute ascites fluid in 3 vol Tris buffer and apply to column at a flow rate of 1 to 5 ml/min.

Ascites can be applied directly to the top of the column by a Pasteur pipet or a flow adapter.

3. Wash column with Tris buffer until entire unbound proteins are eluted. This can be monitored by measuring the column effluent at A_{280} using a UV flowthrough detector or a UV spectrophotometer and cuvette.
4. Collect unbound protein and successively eluted protein peaks by fraction collector or by pooling an entire buffer elution volume.
5. Elute bound proteins successively with 2 to 3 column volumes of citrate, acetate, and glycine-Cl buffers directly into test tubes in a fraction collector containing neutralizing buffer in an amount equal to one-quarter of the collected volume.

Alternatively, bound material may be eluted in one step using glycine-Cl buffer only.

Collecting individual buffer fractions provides a better separation of monoclonal antibody from nonspecific antibody.

6. Eluted fractions or pools may be assayed for antigen-specific monoclonal antibody by ELISA (UNIT 11.4).

Supplement 37

7. Concentrate appropriate eluates containing monoclonal antibodies to 1 to 5 mg/ml using an ultrafiltration cell with an XM50 ultrafiltration membrane. Store at -20°C .

Antibody concentration may be estimated by measuring absorbance at 280 nm. A mouse IgG solution at 1 mg/ml = 1.44 absorbance units.

ALTERNATE PROTOCOL

ALTERNATIVE BUFFER SYSTEM FOR PROTEIN A-SEPHAROSE

Pharmacia recently suggested another buffer system that results in higher binding capacity for certain monoclonal antibodies. The protocol was as described above; however, the buffers used were different. These alternative buffers are as listed below.

1. Glycine-OH buffer. Replaces Tris buffer in the basic protocol.
2. Elution buffers (0.04 M sodium citrate/0.02 M NaCl at pH 6.0, 5.0, 4.0, and 3.2). These buffers replace those in the basic protocol as follows:

Elution buffers, pH 6.0 and pH 5.0. Replace citrate buffer.

Elution buffer, pH 4.0. Replaces acetate buffer.

Elution buffer, pH 3.2. Replaces glycine·Cl buffer.

ALTERNATE PROTOCOL

PURIFICATION BY ANTIGEN-SEPHAROSE AND ANTI-MOUSE IMMUNOGLOBULIN-SEPHAROSE

This protocol describes the preparation of other affinity columns for purification of monoclonal antibodies if protein A-Sepharose will not bind the antibody (e.g., IgM or some IgG1 antibodies). It is useful for coupling protein antigens or anti-mouse immunoglobulin antibodies to commercially available CNBr-activated Sepharose 4B (see support protocol, *UNIT 10.16* for alternate procedure). Columns to which antigen or anti-mouse immunoglobulin antibody are attached may be used as immunoadsorbents to isolate specific antibody (antigen-Sepharose) or all mouse immunoglobulins (anti-mouse immunoglobulin-Sepharose) from ascites fluid.

Additional Materials

CNBr-activated Sepharose 4B (Pharmacia)
1 mM HCl
Coupling buffer
Protein antigen (previously purified; see Chapter 10) or anti-mouse immunoglobulin antibody (commercially available)
1 M ethanamine, pH 8.0
Phosphate-buffered saline (PBS; *APPENDIX 2*)
Washing buffer
60- or 150-ml sintered glass funnel, medium porosity
50-ml conical plastic centrifuge tube

1. Allow required amount of CNBr-activated Sepharose 4B to swell in 1 mM HCl.
One gram of dry gel swells to about 3 ml. It is convenient to use 5 to 10 mg of ligand per milliliter of gel. The remainder of the protocol assumes that 10 ml of gel is being prepared.
2. Transfer to sintered glass funnel and wash successively with (a) 1 mM HCl, 200 to 500 ml, and (b) coupling buffer, 200 to 500 ml (wash over a period of 0.5 hr).
3. Transfer swollen gel to a 50-ml conical plastic centrifuge tube. Add 50 to 100 mg of ligand at a concentration of 2 to 5 mg/ml.
4. Mix gel and ligand on rocker platform or end-over-end mixer overnight at 4°C .

5. Centrifuge at $250 \times g$ for 10 min.
6. Fill the tube with coupling buffer. Centrifuge as in step 5.
7. Incubate with 20 to 40 ml of 1 M ethanolamine, pH 8.0, on rocker platform for 4 to 5 hr at 4°C .
8. Centrifuge at $250 \times g$ for 10 min. Wash gel successively by filling the tube with PBS and washing buffer followed by centrifugation.
9. Transfer gel to a 2.5-cm glass column and equilibrate with 100 ml PBS.
10. Ascites fluid is diluted with 3 vol PBS and applied to the column at a flow rate of 1 to 5 ml/min at room temperature.
11. Wash unbound protein from the column with 30 ml PBS.
12. Elute bound protein using glycine-Cl buffer from the basic protocol (p. 11.11.1, step 5).
13. Concentrate eluate containing monoclonal antibodies to 1 to 5 mg/ml using ultrafiltration cell and XM50 ultrafiltration membrane. Store at -20°C .

Antibody concentration may be estimated by measuring absorbance at 280 nm. A mouse IgG solution at 1 mg/ml = 1.44 absorbance units.

REAGENTS AND SOLUTIONS

Acetate buffer, pH 4.3

To 900 ml H_2O , add:

6.80 g sodium acetate (trihydrate) (0.05 M)

8.77 g NaCl (0.15 M)

Titrate with acetic acid to pH 4.3

Add H_2O to 1 liter

Citrate buffer, pH 5.5

2.45 g citric acid (anhydrous) } (0.05 M citrate)

10.96 g trisodium citrate dihydrate }

8.77 g NaCl (0.15 M)

Add H_2O to 1 liter

Coupling buffer, pH 8.3 (0.125 M phosphate)

Solution A: 17.75 g Na_2HPO_4 (anhydrous)

Add H_2O to 1 liter

Solution B: 1.95 g $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$

Add H_2O to 100 ml

Titrate solution A with solution B to pH 8.3

Elution buffers (0.04 M sodium citrate/0.02 M NaCl at pH 6.0, 5.0, 4.0, and 3.2)

To 900 ml H_2O , add:

11.76 g trisodium citrate dihydrate

1.17 g NaCl

Titrate with HCl to pH 6.0, 5.0, 4.0, or 3.2

Add H_2O to 1 liter

1 M ethanolamine, pH 8.0

61.1 ml ethanolamine

Titrate with HCl to pH 8.0

Add H_2O to 1 liter

Glycine-Cl buffer, pH 2.3

To 900 ml H₂O, add:
3.75 g glycine (0.05 M)
8.77 g NaCl (0.15 M)
Titrate with HCl to pH 2.3
Add H₂O to 1 liter

Glycine-OH buffer

To 700 ml H₂O, add:
108.9 g glycine (1.45 M)
175.3 g NaCl (3 M)
Titrate with NaOH to pH 8.9
Add H₂O to 1 liter

Neutralizing buffer, pH 7.7 (0.5 M phosphate)

Solution A: 70.98 g Na₂HPO₄ (anhydrous)
Add H₂O to 1 liter
Solution B: 7.80 g NaH₂PO₄·2H₂O
Add H₂O to 100 ml
Titrate solution A with solution B to pH 7.7

Tris buffer, pH 8.6

To 900 ml H₂O, add:
6.06 g Tris-Cl (0.05 M)
8.77 g NaCl (0.15 M)
0.2 g NaN₃ (0.02%)
Titrate with HCl to pH 8.6
Add H₂O to 1 liter

Washing buffer

To 900 ml H₂O, add:
13.6 g sodium acetate (trihydrate) (0.1 M)
29.2 g NaCl (0.5 M)
Titrate with acetic acid to pH 4.0
Add H₂O to 1 liter

COMMENTARY

Background Information

The uses of monoclonal antibodies as enzyme conjugates and as immunoaffinity reagents require their purification from the crude ascites fluid. Protein A–Sepharose chromatography and affinity chromatography are superior to ammonium sulfate precipitation, gel filtration, or ion-exchange chromatography for the preparation of contaminant-free antibody.

Literature Review

Staphylococcal protein A is known to bind immunoglobulins of several mammalian species. Ey et al. (1978) were able to use protein A–Sepharose to fractionate murine IgG antibodies using a stepwise pH elution. This protocol uses the buffer systems described by Oi and Herzenberg (1980), which allow efficient

purification of most IgGs and occasional IgM monoclonal antibodies at room temperature. The alternate protocol for preparation of specific affinity columns is a modification of the procedure suggested by Pharmacia.

Critical Parameters

Low-pH buffer elutions should be collected into vessels containing neutralizing buffer to avoid undue loss of antibody activity because of denaturation.

Anticipated Results

For most antibodies bound by the affinity columns, yield will be quantitative. Protein A–Sepharose will bind some IgM, most IgG₁, and nearly all IgG_{2a}, IgG_{2b}, and IgG₃ monoclonal antibodies. Yield of other affinity tech-

niques depends on the antibody-ligand interaction.

Time Considerations

The time involved in affinity chromatography depends largely on sample size and column dimensions. Research scale procedures (less than 20 ml of ascites on a 1 × 10 cm column) can be accomplished in 2 to 4 hr.

Production of Polyclonal Antisera

UNIT 11.12

Antibodies are serum immunoglobulins with binding specificity for particular antigens. Although antibodies can be identified in the serum of individuals or patients that have been exposed to particular pathogens, the usual methods for eliciting antibodies involve immunization with purified or partially purified antigen preparations. Antigens used are most commonly proteins or peptides, but carbohydrates, nucleic acids, small organic molecules (haptens) conjugated to appropriate protein carriers, cells, and cell and tissue extracts can also be employed.

The first consideration is usually whether polyclonal or monoclonal antibodies are needed. Polyclonal antibodies are particularly valuable for immunoprecipitation (*UNIT 10.16*) and immunoblotting (*UNIT 10.8*), whereas monoclonal antibodies can have exquisite specificity and can be derived for almost any purpose. Choice of the species of animal to be used for immunization is based in part on whether antibodies of great specificity are required—in which case genetically defined strains can be very helpful—or antibodies of wide cross-reactivity are needed.

The amount of antibody needed must also be evaluated. Clones of hybridomas (somatic cell hybrids of B cells from an immunized animal's spleen and myeloma tumors permissive for the production of monoclonal immunoglobulins) provide an essentially limitless supply of a constant reagent. Nevertheless, the initial investment in producing a monoclonal antibody is quite large, whereas relatively large amounts of a polyclonal antiserum can be obtained from a single rabbit or from several genetically identical rats or mice.

In this unit, the Basic and Alternate Protocols describe the production of polyclonal antisera specific for protein antigens in rabbits, rats, mice, and hamsters. The Support Protocol presents a method for preparing serum from blood. Polyclonal anti-peptide antisera can be produced by substituting carrier-conjugated peptides (*UNIT 11.16*) for the purified protein antigens.

STRATEGIC PLANNING

Production of good antisera depends in large part upon the quality, purity, and amount of available antigen as well as on the specificity and sensitivity of the assay. For protein antigens, if possible, the material should be biochemically homogeneous and, depending on the intended use, should be in either a native or denatured conformation. Be aware that minor contaminants are often (unfortunately) more antigenic than the immunogen of interest, and antisera resulting from immunization may have more activity against the contaminants than against the protein of interest. Antisera to be used for screening bacterial expression cDNA libraries or for immunoblots are best made against denatured protein, whereas those to be used for screening cDNAs expressed in eukaryotic transfection systems or for immunoprecipitation of native-cell-synthesized structures might best be made against native protein.

Although the advances offered by the development of monoclonal antibody techniques have revolutionized the specificity, uniformity, and quantity of antibodies, there remain many circumstances in which polyclonal antibodies are more desirable than monoclonal antibodies. Production of polyclonal antisera takes less time and effort than production of monoclonal antibodies, requires relatively simple and readily available equipment, and

produces reagents that can be used for immunoprecipitation, immunoblotting, and enzyme-linked immunosorbent assays (ELISAs).

Choice of animal for the production of antibodies depends upon the amount of antiserum desired, the evolutionary distance between the species from which the protein of interest has been derived and the species of the animal to be immunized, and prior experience with the immunogens. Rabbits are the usual animal of choice because they are genetically divergent from the human and mouse sources of the proteins most often studied. Rabbits provide as much as 25 ml of serum from each bleed without significant harmful effects. For smaller-scale experiments, or for those that rely on precisely defined antibody specificities, inbred mouse strains may be the system of choice. Because mice are smaller, the volume of antigen suspension used for immunization is significantly less and the amount of serum that can be obtained from a single bleed does not exceed 0.5 ml. Rats and hamsters may be used when larger amounts of serum are needed, or when the greater evolutionary distance is advantageous. With repeated bleeding, as much as 5 ml of serum can be obtained from these species. Additional discussion of the choice of species for the production of monoclonal antibodies is given in *UNIT 11.10*.

The choice of adjuvant for in vivo animal use has become problematic in recent years. Freund's adjuvant has been reliably and widely used for over fifty years (Freund et al., 1937). However, there is a degree of distress and discomfort to the animal associated with its use which requires that the responsible investigator explore alternatives. In most studies that have compared available alternatives to Freund's adjuvant, the Basic Protocol given here, which uses a CFA/IFA immunization regimen, gives far superior antibody titers to the commonly used commercially available adjuvants (Johnston et al., 1991; Deeb et al., 1992; Smith et al., 1992). However, in some instances TiterMax (Bennett et al., 1992) and Ribi Adjuvant Systems (Mallon et al., 1991) have performed as well as Freund's adjuvant. The use of these adjuvant systems as alternatives to Freund's adjuvant is described in the Alternate Protocol.

**BASIC
PROTOCOL**

**IMMUNIZATION TO PRODUCE POLYCLONAL ANTIBODIES USING
FREUND'S ADJUVANT**

In the presence of adjuvant, the protein antigen is injected intramuscularly, intradermally, or subcutaneously into an animal of the chosen species. Booster immunizations are started 4 to 8 weeks after the priming immunization and continued at 2- to 3-week intervals. Prior to the priming immunization and following the primary and each booster immunization, the animal is bled and serum prepared from whole blood (see Support Protocol).

Instructions on the different strategies for immunization (intramuscular, intradermal, or subcutaneous) can be found in Donovan and Brown (1995a) and for bleeding (from marginal vein or artery of ear for rabbit; various other sites for mouse, rat, or hamster) in Donovan and Brown (1995b). Factors important in preparing specific high-titer antisera, procedures for modifying protein antigens to enhance their immunogenicity, and choice of host animal are discussed in the Commentary. Protocols for immunization prior to production of monoclonal antibodies (*UNIT 11.11*) should be reviewed for these purposes.

Materials

- Rabbit, rat, mouse, or hamster of appropriate strain
- Complete Freund's adjuvant (CFA; Sigma)
- 1 to 2 mg/ml purified protein antigen in PBS (*APPENDIX 2*)
- Incomplete Freund's adjuvant (IFA; Sigma)
- 50-ml disposable polypropylene centrifuge tubes
- 3-ml glass syringes with 19-, 21-, and 22-G needles

**Production of
Polyclonal
Antisera**

11.12.2

Double-ended locking hub connector (Luer-Lok, Becton Dickinson) or plastic 3-way stopcock

CAUTION: CFA is an extremely potent inflammatory agent, particularly if introduced intradermally or into the eyes and may cause profound sloughing of skin or loss of sight. Self-injection can cause a positive TB test and lead to a granulomatous reaction. Use gloves and protective eyewear when handling CFA.

1. Bleed the animal prior to immunization and collect blood sample in a 50-ml centrifuge tube. Prepare serum from blood, then assay and store (see Support Protocol).

This preimmune bleed is critical as a control to ensure that the antibody activity detected in later bleeds is due to the immunization.

2. Shake CFA to disperse insoluble heat-killed *Mycobacterium tuberculosis* bacilli. Add 2 ml CFA to 2 ml of 0.25 to 0.5 mg/ml purified protein antigen in PBS at 4°C.

These volumes produce immunogen sufficient to immunize 4 rabbits or up to 80 mice. Do not use Tris-based buffers for generating the emulsion.

An effective and simple method for preparing purified protein antigen is by preparative SDS-PAGE (UNIT 10.2). If a standard-size 1.5-mm slab gel is used with a large-toothed comb, as much as 2 mg of a homogeneous protein can be loaded across the entire gel. Following electrophoresis, an edge can be sliced off with a razor blade, fixed and stained, and used to identify the region containing the protein band (UNIT 10.6). The gel slice containing the protein may then be directly added to several milliliters of PBS (APPENDIX 2) and emulsified as described below with an equal volume of CFA. The acrylamide serves as an additional component for the protein depot provided by the adjuvant.

3. Draw up the CFA/antigen mixture into a 3-ml glass syringe with a 19-G needle. Remove needle, expel as much air as possible, and attach syringe to the double-ended locking hub connector or the plastic 3-way stopcock (see Fig. 11.12.1). Attach an empty 3-ml glass syringe at the other end and force the mixture back and forth from one syringe to the other repeatedly. When the mixture is homogeneous and white, disconnect the connector or stopcock, attach a 21-G needle, and test whether the

Figure 11.12.1 Double-syringe device for preparation of antigen-adjutant emulsions.

emulsion is stable by extruding a small drop onto the surface of 50 ml cold water in a 100-ml beaker. A good oil-in-water emulsion should hold together as a droplet on the surface of the water. If the drop disperses, mix the antigen using the hub-connected syringes until it forms an emulsion.

Heat will be generated by this procedure. Chill on a bed of ice from time to time to keep the mixture as close to 4°C as possible.

4. Transfer all of the adjuvant-antigen emulsion to one syringe and remove the connector or stopcock. Attach a 22-G needle to the syringe and remove air bubbles.
5. Restrain the animal and inject the adjuvant/antigen emulsion into multiple intramuscular (i.m.), intradermal (i.d.), or subcutaneous (s.c.) sites.

Discard the unused immunogen. For extremely valuable antigens, the emulsion may be stored at 4°C for several weeks and re-emulsified before use. However, denaturation of protein antigens may take place under these conditions. For immunization of small rodents (e.g., mice), it is often better to carry out injections intraperitoneally (i.p.).

6. Bleed the animal 10 to 14 days following the priming immunization and collect blood sample. Prepare serum from blood (see Support Protocol).
7. Prepare antigen for booster immunizations, following steps 2 to 4. When CFA is the primary adjuvant, use IFA as the adjuvant for all subsequent immunizations.
8. Administer the first booster immunization 4 to 8 weeks after the priming immunization, bleed the animal 7 to 14 days later, and collect blood sample. Prepare serum from blood (see Support Protocol).

Some investigators will administer the first booster immunization as early as 2 weeks after the primary immunization.

9. Administer further booster immunizations at 2- to 3-week intervals. Bleed animal 10 to 14 days after each boost and collect blood sample. Prepare serum from blood (see Support Protocol).

Repeated intradermal immunization should be avoided as it can cause skin ulceration. Following primary intradermal or subcutaneous immunization, it is preferable to boost with intramuscular injections for the rabbit. Some investigators prefer primary intramuscular injections with boosters at other sites.

ALTERNATE PROTOCOL

IMMUNIZATION TO PRODUCE POLYCLONAL ANTISERUM USING OTHER ADJUVANTS

For highly immunogenic antigens the use of Freund's adjuvant can certainly be avoided. For other immunogens it may be necessary to test a number of adjuvant systems. The use of two commercially available adjuvants is described in this protocol.

Additional Materials (also see Basic Protocol)

TiterMax #R-1 (CytRx; store <24 months at 4°C) *or* Ribi Adjuvant System (RAS; Ribi ImmunoChem; store at 2 to 8°C and do not freeze)
1-ml plastic syringes

- 1a. *Using TiterMax:* Emulsify aqueous antigen with TiterMax adjuvant (see Basic Protocol; follow steps 1 through 5, except use 0.5 ml antigen and 0.5-ml vial TiterMax in step 2 and plastic syringe in step 3).

TiterMax contains microparticulate silica coated with block copolymer CRL-8941, sorbitan mono-oleate, and squalene.

Although glass syringes are recommended for Freund's adjuvant emulsions, all-plastic syringes should be used with TiterMax.

Each reconstituted 0.5-ml vial will immunize 20 mice or 10 rabbits. Unused antigen/adjuvant emulsion can be stored at 4°C, -20°C, or -70°C for as long as the antigen is stable. It may be necessary to re-emulsify before using.

- 1b. *Using Ribi Adjuvant System:* Warm the vial of RAS for 5 to 10 min at 40° to 45°C. Add 2 ml antigen in PBS directly through the rubber stopper using a syringe with a 21-G needle. Vigorously vortex the vial 3 min at room temperature with the cap seal in place.

The final volume of adjuvant/antigen is 2 ml containing 2% squalene oil.

Each vial of RAS contains 0.5 mg each of monophosphoryl Lipid A (MPL), synthetic trehalose dicorynomycolate (TDM), and cell wall skeleton (CWS) in 44 µl squalene and Tween 80.

Each reconstituted vial will immunize 10 mice or 2 rabbits. Unused adjuvant/antigen emulsion can be stored several months at 4°C. However, if the entire vial will not be used initially, it is better to reconstitute to 1.0 ml with saline alone, store at 4°C, and mix aliquots 1:1 with antigen in saline as needed.

2. Transfer the antigen emulsion to a 1-ml syringe, attach a 22-G needle to the syringe, and remove air bubbles.
3. Restrain the animal and inject the adjuvant/antigen emulsion.

Rabbits should receive 40 µl TiterMax/antigen emulsion i.m. in each thigh. High antibody titers have been obtained with 30 to 50 µg of antigen per rabbit. Rabbits should be immunized with 1.0 ml RAS containing 50 to 250 µg of antigen in multiple sites: 0.05 ml i.d. at six sites, 0.3 ml i.m. in each thigh and 0.1 ml s.c. in the neck.

4. Bleed the animal and prepare antigen for booster immunization (see Basic Protocol, steps 6 and 7).

Serum antibody responses have been reported to be slower for both RAS and TiterMax than for Freund's adjuvant (Smith et al., 1992).

5. Administer booster immunizations at 4, 8, and 12 weeks. Bleed the animal 10 to 14 days after each booster immunization. Prepare serum from blood (see Support Protocol) and cease immunization when high antigen-specific titers have been achieved.

Boosting with TiterMax may not be necessary for all antigens. If a second immunization is necessary, use soluble antigen in place of antigen/adjuvant at 4 weeks. If titers are still low after 10 to 14 days, a booster dose of antigen/TiterMax adjuvant can be given immediately. Increasing the amount of antigen may also help.

Ribi ImmunoChem strongly recommends that booster injections of RAS adjuvant/antigen be repeated no more frequently than every four weeks.

PREPARATION OF SERUM FROM BLOOD

Each blood sample is allowed to stand 4 hr at room temperature and overnight at 4°C until a clot forms. After removal of the clot and debris, the serum is assayed and stored at -20°C.

Additional Materials (also see Basic Protocol)

Blood samples (see Basic Protocol)
Sorvall H-1000B rotor or equivalent

Additional reagents and equipment for immunoblotting (UNIT 10.8),
immunoprecipitation (UNIT 10.16), and ELISA (UNIT 11.2)

1. Allow blood to stand in the 50-ml centrifuge tube 4 hr at room temperature to allow clot to form, then place overnight at 4°C to allow clot to retract.

SUPPORT PROTOCOL

Immunology

11.12.5

2. Gently loosen the clot from the sides of the tube with a wooden applicator stick (do not break up the clot), then remove the clot from tube with the applicator.

If a clot has not formed, initiate clotting by placing a wooden applicator stick into the tube containing the collected blood, then begin again at step 1.

3. Transfer serum to a 50-ml centrifuge tube. Pellet any remaining blood cells and debris by centrifuging 10 min at $2700 \times g$ (4000 rpm in H-1000B rotor), 4°C , and save supernatant.
4. Assay antibody titer by the appropriate method: immunoprecipitation, immunoblotting, ELISA, or double-immunodiffusion assay in agar.
5. Store serum in aliquots in screw-top tubes at -20°C .

Some sera lose activity on repeated freezing/thawing; others aren't stable at 4°C .

COMMENTARY

Background Information

The kinetics of development of a specific antibody response upon immunization of a rabbit with antigen are illustrated in Figure 11.12.2. After the primary immunization, naive B cells are stimulated to differentiate into antibody-secreting plasma cells. For most soluble protein antigens, specific antibody begins to appear in the serum 5 to 7 days after the animal is injected. The antibody concentration (titer) continues to rise and peaks around day 12, after which it decreases. Similar kinetics are observed with mice, rats, hamsters, and rabbits.

In addition to differentiating into antibody-forming cells, the antigen-stimulated B cells proliferate to form a large population of memory B cells, which quickly become activated after the booster injection is administered. Thus, the lag period before the appearance of the specific antibody is much shorter after a booster injection than that observed for the initial immunization. In addition, a significantly higher titer of specific antibody is

achieved and sustained for a longer period of time. The peak of antibody production occurs 7 to 14 days after boosting. As a consequence of the existence of the memory B cells, less antigen is required to stimulate a strong secondary response. Memory B cells are long-lived; therefore, a specific antibody response can be elicited as much as 6 months to a year after the last booster. Finally, the average affinity and degree of specificity of the antibody population for the antigen increase with repeated immunizations (Klinman and Press, 1975).

Adjuvants greatly enhance the specific antibody titer, as they allow the antigen to be released slowly, thus ensuring the continual presence of antigen to stimulate the immune system. Freund's adjuvant has been used extensively in the preparation of antigen because it induces a high, long-lasting antibody titer that is often still measurable 25 weeks or more after boosting. The presence of killed mycobacteria in complete Freund's adjuvant (CFA) activates the T cell population, providing necessary lymphokines for B cell stimulation and matu-

Figure 11.12.2 Kinetics of development of the specific antibody response. Arrows indicate when priming and boosting immunizations were administered. Actual amounts of specific antibody produced will vary considerably depending on immunogenicity of the protein.

ration. CFA may cause granuloma and subsequent necrotic abscesses, so it should be used only for primary immunization. Incomplete Freund's adjuvant (IFA) is adequate for booster injections. In the past decade, adjuvant research has concentrated on the production of effective adjuvants that minimize animal trauma. Wherever possible, to reduce animal discomfort, less noxious adjuvants should be used as described in the Alternate Protocol. In addition some countries are restricting the use of CFA in laboratory animals. Published comparisons of commercial adjuvants with the basic CFA/IFA protocol vary widely in their conclusions. In most cases, however, CFA/IFA produces higher titers of higher-affinity antibodies in a shorter time period (Johnston et al., 1991; Deeb et al., 1992; Smith et al., 1992). Conflicting results (Mallon et al., 1991; Bennett et al., 1992) may reflect differences in the immunogenicity of the antigens used.

Critical Parameters

New Zealand red or white rabbits are generally the best source of specific antisera because 30 to 50 ml of whole blood can be obtained at each bleed. The life span of a rabbit is 5 to 6 years, so a continual source of specific antiserum can be provided over a period of time by one rabbit after booster injections. In this regard, the recommended times between booster injections are not critical; the animal may be rested for several months between subsequent boosters, after the primary and secondary booster injections. Blood collection, however, must take place 7 to 14 days after each booster to ensure a high titer.

Preimmune serum from the same animal is the preferred negative control. If additional control serum is required, either immune serum from animals immunized with totally unrelated antigens or pooled serum from naive animals will be adequate. Occasionally, spurious antibody activities from nonimmunized animals may mimic the activity of the immune serum.

Antibody specificity may vary widely between individual animals with respect to the dominant antigenic epitopes recognized on a given protein antigen. Therefore, antiserum from a single animal should be used throughout a study. If more than one animal must be used for particular antisera, the antisera should be pooled. Large-scale production of antisera can be carried out in goats, sheep, and horses with appropriate veterinary guidance. If serum is taken from inbred animal strains, the variability

in antibody specificity, as observed in outbred rabbits, is less of a problem.

The most important factor in producing a highly specific polyclonal antiserum is the purity of the antigen preparation used for immunization. The immune system is very sensitive to the presence of foreign proteins. Any contaminating proteins in the antigen preparation can potentially induce a strong immune response when injected in the presence of adjuvant. When antisera are employed in sensitive techniques such as immunoblotting or the screening of cDNA or genomic libraries, significant antibody titers to protein contaminants can be a major problem. Thus, the antigen preparation should contain no significant contaminating proteins. Ideally, there should be no visible contaminating bands when 10 to 20 μg are analyzed on an SDS-polyacrylamide gel stained with Coomassie brilliant blue (*UNITS 10.2 & 10.6*).

If the antiserum is to be used in functional assays, extra care must be taken to ensure that the immunizing antigen is in its native form, because antibodies directed to denatured forms of the protein antigen will interact weakly, if at all, with the antigen in its native conformation. On the other hand, antibodies used in immunoblots, immunoprecipitation of primary in vitro translation products, and immunoscreening of $\lambda\text{gt}11$ expression libraries may be most effective if generated against a denatured protein with reduced and carboxymethylated disulfide bonds.

Troubleshooting

Inability to attain high-titer antiserum after several booster injections may be due to a variety of factors as described below.

Use of inappropriate adjuvant. Some experimentation may be necessary to optimize the antigen/adjuvant ratio for different antigens. If the alternate protocol still fails to produce a good antibody titer after three immunizations, switch to the basic protocol.

Inadequate antigen emulsification. If the emulsion fails the drop-on-water test described in the Basic Protocol (step 3), repeat the emulsification process. Be sure to use phosphate-buffered saline. Avoid plastic syringes and Tris-based buffers with CFA and IFA.

The antigen is a poor immunogen. In general, the immunogenicity of a protein is related to the degree to which it differs from "self" proteins (Benjamin et al., 1984). Large bacterial or viral proteins such as hemagglutinin or bacterial-coat proteins are highly immuno-

genic, whereas proteins from mammalian sources, such as polypeptide hormones or cell-surface receptors, may be poorly immunogenic due to tolerance. Protein antigens can be made more immunogenic in two ways. First, they can be chemically linked to a carrier protein that is known to be a good immunogen. Common carrier proteins include keyhole limpet hemocyanin (KLH), fowl immunoglobulin, and bovine serum albumin (BSA). Coupling peptides to carrier proteins is described in *UNIT 11.16*; the same protocols can be used to couple the protein antigen of interest to the desired carrier. Second, the immunogenicity of an antigen may be enhanced by its polymerization into large aggregates via a cross-linking agent such as glutaraldehyde. The protocol in *UNIT 11.16* for the coupling of peptide antigens to a carrier protein with glutaraldehyde can also be used to polymerize any protein antigen. With both the coupling and polymerization procedures, any insoluble antigen complexes formed should be removed prior to immunization by centrifuging 10 min at $15,000 \times g$, 4°C .

Host animal's immune system may be compromised by bacterial or viral infection. Refer to Donovan and Brown (1995c,d) for discussion of the consequences of poor animal husbandry. Utilize animals from reliable, pathogen-free sources and maintain them in appropriate infection-free facilities.

Only a few animals have been immunized. Because of the vagaries of immune-response genes in outbred animals such as rabbits, some antigens may not induce a good antibody response in a significant proportion of randomly selected animals. Thus, it is best to immunize several different animals and to screen the sera for the best responder. Obviously, this is less of a problem in homozygous inbred strains, but with a new antigen it is wise to test several strains for their antibody response.

An insufficient amount of antigen was used. Although recommended concentrations of antigen for rabbits are 0.25 to 0.5 mg/ml injected into multiple sites, for a total of 1 to 2 ml in the same animal, good results can be obtained with $1/10$ to $1/20$ of the concentration in the same volume. It is always tempting to use less of a precious antigen, but often too low a dose leads to too low a response.

Anticipated Results

For large or nonevolutionarily related proteins, a titer of 5 to 10 mg/ml of serum can be expected after repeated boosts (hyperimmunization). When immunizing with small or highly

conserved protein species, a titer of 1 to 2 mg/ml of specific antibodies is more likely. Antibody titers and affinity for the antigen will be low after primary immunization and the first booster immunization, but both titer and affinity will increase with subsequent immunizations.

Time Considerations

Preparation of the immunogen and immunization will take ~3 hr on each occasion. Collection of antisera will take 1 to 2 hr, depending on the number and species of animals.

Collection of antiserum after the primary immunization will be at 10 to 14 days. This will be a low-titer, low-affinity serum. The first booster normally is given 4 to 8 weeks after the primary immunization but can be given as early as 2 weeks after the primary if time is critical. Ideally, there should be at least 19 days between the primary and the secondary bleeds. A second booster is given at 6 weeks with a bleed on day 52 to 59. This will usually be the first high-titer bleed. If a titer of <1 mg/ml of specific antibody is obtained, subsequent boosting immunization will be necessary.

This unit describes the antigenic stimulation of in vitro antibody production by B cells and the subsequent measurement of secreted antibodies. Such in vitro systems have been extremely useful for studying the regulation of interacting cell types involved in antibody production—namely B cells, T cells, and macrophages—as well as their antigenic stimulants. In addition, these studies have revealed important information about cellular requirements for growth and differentiation factors during antibody production.

A generalized system for inducing in vitro antibody production, and which can accommodate various types of antigens under study, is first presented (see Basic Protocol 1). Secreted antibodies can then be measured with an enzyme-linked immunosorbent assay (ELISA; UNIT 11.2) or other soluble-antibody detection systems. Alternatively, the number of antibody-producing cells can be quantified by plaque-forming cell (PFC) assays: the Cunningham-Szenberg technique (see Basic Protocol 2) and the Jerne-Nordin technique (see Basic Protocol 3). Both methods employ specially prepared slide chambers (see Support Protocols 1 and 2) in which the antibody-producing B cells are mixed with complement and indicator sheep red blood cells (SRBC), or with trinitrophenol-modified SRBC (TNP-SRBC; see Support Protocol 3), with subsequent lysis and counting of plaques. Because IgM antibodies fix complement efficiently, whereas IgG and IgA antibodies do not, unmodified PFC assays measure only IgM antibodies. The assay can be modified, however, to measure all classes of antibodies or to enumerate total immunoglobulin-secreting B cells (see Alternate Protocol). Yet another method of measuring the number of antibody-producing B cells (in a class-specific fashion) is to use the ELISPOT technique (Lycke and Coico, 1996). The resting B cells used in these procedures are prepared as described in Support Protocol 5 for Percoll gradient centrifugation.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique must be used accordingly.

STRATEGIC PLANNING

Choice of Antigen

In setting up an in vitro system for antibody production and measurement, the antigen to be used is a critical factor that will determine the types of cells and lymphokines necessary for an adequate response.

A first consideration is whether the antigen to be used is one that contains immunogenic epitopes that the animal from which cells are to be obtained has “seen” in vivo. Generally speaking, if the antigen is new and a primary response is being elicited in vitro, the response will be small, perhaps below the limits of measurement, because the cells utilized do not contain the number of specific precursors necessary for a measurable in vitro response. Responses to most protein antigens fall into this category, so that in vitro induction with such antigens require the use of cells from in vivo primed animals. An apparent exception to this rule is the particulate antigen SRBC, which provides good responses even with unprimed cells. This, however, can be attributed to the fact that SRBC contain immunogenic epitopes that cross-react with those present in environmental antigens, so that the cell donor has, in fact, been exposed to this antigen in vivo. It should be noted in this regard that SRBC induce only IgM antibody responses in in vitro cells obtained from unprimed animals, probably reflecting the fact that cells from unprimed animals do not contain enough SRBC-specific precursors of isotype-switched B cells.

Thus, to obtain IgG responses with SRBC antigen, one must use cells from SRBC-primed animals.

A second consideration is whether the antigen is a T cell-dependent or -independent antigen. T cell-dependent antigens (most protein antigens) require the presence of antigen-primed T cells which provide the necessary factors (lymphokines) for B cell proliferation and differentiation. In addition, for these antigens there is increasing evidence that T cells are required for promoting cell-cell interactions necessary for antibody production. Perhaps the one exception to this rule is that certain T cell-dependent antigens such as SRBC can stimulate primed B cells in the absence of T cells, provided that T cell lymphokines are present.

T cell-independent antigens, as defined originally, can stimulate B cells in vitro in the absence of T cells. Type I antigens, such as trinitrophenylated lipopolysaccharide (LPS), have intrinsic polyclonal activating properties, whereas type II antigens, such as trinitrophenylated Ficoll and dextran, do not possess this characteristic. While both stimulate in vivo responses in nude mice and in vitro responses in T cell-depleted spleen cells, type I antigens can stimulate responses in immature neonatal B cells and in cells from *xid* immune-defective mice, but type II antigens stimulate responses only in immunologically mature B cells. The T cell-independent designation for these antigens is now outdated, as it has become clear that T cell-derived lymphokines are necessary for the response when very pure resting B cells are used (Mond et al., 1983; Thompson et al., 1984). Consequently, T cell-derived lymphokines are now usually added to systems that use T cell-independent antigens as a stimulant. It is therefore most correct to refer to this class of antigen as "T cell-regulated" or as "T cell-independent type I or type II."

Decisions concerning the type of antigen used (and the cell/lymphokine requirements) must be made in order that the response to be studied is precisely defined. In this regard, B cells responding to complex, multiepitopic antigens of any kind are a clonally diverse mixture of cells; the antibody response will therefore be heterogeneous and will comprise antibodies with specificity for the various immunodominant determinants on the antigen. However, if a modified antigen is utilized—i.e., an antigen conjugated to a chemically defined low-molecular-weight antigenic epitope—the response to this epitope can then be measured. In this case the known epitope is called the hapten and the molecule to which it is attached is called the carrier; since B cell responses are being quantified, the B cells in these systems recognize the hapten and T cells recognize other epitopes on the carrier (Mitchison, 1971). TNP is frequently employed as the hapten; this chemical group can be placed on various carriers, including soluble proteins (ovalbumin), to measure highly defined T cell-dependent B cell responses, as well as on other T cell-independent carriers such as *Brucella abortus* (BA) and LPS to measure type I responses, or on Ficoll and dextran to measure type II responses.

Table 11.13.1 summarizes lymphokine requirements of cellular responses to some antigens. This table is incomplete in that the type of lymphokine that is added may have considerable effect both on the quality of the responses (such as the isotype profile) and on the magnitude of the response. For example, in most systems IL-4 and IFN- γ are required lymphokines for stimulation of IgE and IgG2a responses, respectively.

A final consideration relating to choice of antigen concerns the need for macrophages, either as antigen-presenting cells (APC) or as sources of cytokines in the culture system. Whereas B cells can present those antigens for which they express specific surface Ig receptors, they are not generally sufficient in the usual in vitro culture systems because such antigen-specific cells are present in low numbers. Macrophages, on the other hand, take up and present antigen in an antigen-nonspecific manner and are thus the primary

choice of APC in in vitro systems. Thus, for responses to T cell–dependent antigens, where T cell activation is required for inducing a response, the need for macrophages is absolute. T cell–independent responses, however, are relatively independent of the requirement for macrophages. It is important to note that the presence of too many macrophages may be suppressive for some in vitro responses, because of the release of inhibitory substances (e.g., prostaglandins and certain cytokines).

Preparation of Cells

Prior to setting up cultures to measure in vitro antibody production, considerable thought has to be given to the methods for preparing the cell populations to be studied. Unprimed, unseparated cell populations may be obtained from a variety of lymphoid organs. More frequently, however, purified T and B cell populations are used (Hathcock, 1991a,b; Mage, 1993), or purified populations of resting B cells alone can be used. Priming of T cells is described in Kruisbeek and Shevach (1991); priming of B cells is accomplished by immunizing mice with hapten-carrier conjugate emulsified in complete Freund's adjuvant 3 to 5 weeks prior to cell harvest (using a different carrier than that used for T cell priming). It is best to size-separate B cells on Percoll gradients (see Support Protocol 5) after enrichment as in Hathcock (1991b) when studying T cell–independent responses, since responses of resting and partially activated B cells vary (Thompson et al., 1984). This cannot be done when studying T cell–dependent responses, as antigen-primed (activated) B cells are required.

INDUCTION OF ANTIGEN-SPECIFIC AND POLYCLONAL ANTIBODY PRODUCTION

Antibody production is induced by culturing B cells, desired antigens (either sheep red blood cells or trinitrophenylated carriers), appropriate lymphokines, and T cells for 4 to 5 days (see Strategic Planning, above). Secreted antibodies can be measured in the supernatant with ELISA assays (UNIT 11.2). Alternatively, the number of antibody-producing cells can be measured as in Basic Protocol 2 or Basic Protocol 3.

Materials

- Antigens (see recipe): SRBC, TNP-BA, TNP-Ficoll, TNP-dextran, TNP-ovalbumin (TNP-OVA), or TNP-LPS
- Recombinant lymphokines (for use with purified B cells): rIL-2 (Cetus or Schering) and/or rIL-1 (Hoffman La Roche)
- Complete RPMI-10 medium (see recipe) or complete DMEM-10 medium (see recipe)

Table 11.13.1 Cells and Lymphokines Required for Stimulation of In Vitro Antibody Production^a

Antigen	T Cells	B Cells	Lymphokines	PFC/culture
TNP-Ficoll	–	+	IL-1, IL-2, or IL-5	400 (IgM)
TNP-BA	–	+	IL-1, IL-2, or IL-5	2000 (IgM)
SRBC (T-independent)	–	+	IL-1, IL-2, or IL-5	1000 (IgM)
SRBC (T-dependent)	T'	+	–	3000 (IgM)
				4000 (IgG)
TNP-OVA	T'	+	–	500 (IgM)
				300 (IgG)

^aAbbreviations: BA, *Brucella abortus*; OVA, ovalbumin; PFC, plaque-forming cells; SRBC, sheep red blood cells; T', antigen-primed T cells; TNP, trinitrophenylated.

B lymphocytes purified from mice (Support Protocol 5) either nonimmunized or immunized 3 to 5 weeks previously with specific hapten-carrier conjugate (UNIT 11.12 and Table 11.13.1)

T cells primed to antigen or carrier (Kruisbeek and Shevach, 1991; Table 11.13.1)

96-well flat-bottom microtiter plates (Costar)

Refrigerated low-speed centrifuge (e.g., IEC 7R with 216 rotor)

Sterile gauze

1. Add antigens and recombinant lymphokines diluted to the appropriate concentrations in supplemented complete medium in a total volume of 0.15 ml to the wells of a 96-well microtiter plate. Set up in triplicate to permit calculation of standard error.

The amount of antigen to be used must be determined separately in each system. A wide range of concentrations should be tested in pilot experiments and one or two concentrations in later (more definitive) studies.

Approximate final concentrations in the wells for representative antigens:

2 × 10⁶ cells/well SRBC

10 µg/ml TNP-OVA

1:100 dilution of stock TNP-BA

10 ng/ml TNP-Ficoll

5 to 50 µg/ml TNP-LPS or unconjugated LPS

Lymphokines are added when responses to T cell-independent antigens are studied. If TNP-Ficoll or SRBC are used as the stimulating antigen, rIL-1 and rIL-2 (or alternatively, rIL-5) are recommended. When TNP-BA is used as antigen, only IL-2 or IL-5 is necessary. rIL-1 is used at 10 U/ml and rIL-2 at 100 U/ml. When T cells are added, lymphokines are not required.

2. Add 10⁵ to 10⁶ B cells in 50 µl to each well with multichannel pipettor to give a final volume of 0.2 ml.

Appropriate cell number must be determined empirically. Use lower cell concentrations for responses elicited by polyclonal stimuli, and higher cell concentrations for responses driven by specific antigens, but never use more than 10⁶ cells per well.

3. Incubate plates for 4 to 5 days at 37°C, 5% CO₂. If an assay of secreted antibody is desired, go to step 4. If a plaque assay is to be performed, go to step 7.

During the culture period, preparation can be made for analysis of culture supernatants by an enzyme-linked immunosorbent assay (UNIT 11.2).

4. Centrifuge plates 10 min at 1000 rpm (170 × g), 4°C. In a tissue culture hood, discard supernatant by inverting and flicking plate, then blot dry with sterile gauze.

5. Add 0.2 ml fresh supplemented complete medium to each well; repeat step 4 twice.

6. Add 0.2 ml fresh supplemented complete medium to each well and incubate plates 24 to 48 hr in a humidified 37°C, 5% CO₂ incubator. Remove and save 150 µl supernatant from each well with a multichannel pipettor if secreted antibody is to be measured using ELISA or other suitable technique.

7. Centrifuge plates 10 min at 170 × g, 4°C. Invert plates in one quick motion and flick off supernatant. Without reinverting plates, remove excess fluid by blotting plates on absorbent paper.

8. Add 0.2 ml supplemented complete medium to each well and repeat step 7.

9. Add 0.2 ml supplemented complete medium to each well. Tap plates gently or place on vibrating platform to ensure complete resuspension of cells.

Repeated washing of the wells is required to remove free antibody before the subsequent assay of antibody production. Antibody-producing B cells are now ready to be measured as described for plaque-forming cell assays (see Basic Protocols 2 and 3).

PLAQUE-FORMING CELL ASSAYS

B cells prepared in Basic Protocol 1 can be assayed for antibody production using a plaque-forming cell (PFC) assay. In this approach, the B cells are plated in (or on) a layer of hapten- or antigen-conjugated SRBC under conditions in which the secreted antibody will cause local SRBC lysis, resulting in pin-point areas of clearing in the lawn of SRBC (plaques) that can be counted. The two widely used PFC assays presented below are alike in principle but different in detail. Antibody-producing B cells are mixed with a source of complement and indicator RBC if SRBC are used as stimulating antigen, or TNP-RBC if TNP-conjugated antigens are used as the stimulating antigen. The B cell/SRBC mixture is then processed in Cunningham-Szenberg chambers or with Jerne-Nordin slides. This technique measures only cells secreting IgM since only antibody of the latter isotype fixes complement under the conditions of the assay. It can, however, be modified to measure cells secreting antibody of any class by the addition of isotype-specific rabbit anti-Ig antibody that binds to secreted immunoglobulin and forms complexes that fix complement. The PFC assays can also be modified to enumerate total immunoglobulin-secreting B cells stimulated by a polyclonal B cell activator, e.g., LPS (see Alternate Protocol).

There are advantages and disadvantages of both methods. The principle advantage of the Cunningham-Szenberg assay is that six to eight plates can be processed in one day. Its disadvantage is that extra time and effort are required for preparing the slide chambers, which cannot be reused, and for preabsorbing the complement. The Jerne-Nordin assay, on the other hand, accommodates only three 96-well plates in an 8-hr period. However, while this technique requires construction of a tray for holding the slides, the tray can be reused indefinitely; in addition, complement needn't be preabsorbed. Thus, for IgG or protein A plaquing, Jerne-Nordin is the assay of choice.

Cunningham-Szenberg Assay (Cunningham and Szenberg, 1968)

Materials

Supplemented complete RPMI-10 (see recipe) *or* DMEM-10 medium (see recipe)
7.5% (v/v) SRBC or 15% (v/v) TNP-SRBC (see Support Protocol 3) in
supplemented complete medium

Source of complement: 50% (v/v) guinea pig serum (Life Technologies; also see
recipe) in supplemented complete medium

Wax (tissue preparation grade; Fisher)

96-well round-bottom microtiter plate (Linbro # 36-311-05)

Cunningham-Szenberg chambers (see Fig. 11.13.1 and Support Protocol 1)

120-cm² glass petri dish

Dissecting microscope

NOTE: All reagents should be room temperature before addition to chambers, because cold reagents result in bubble formation during incubation.

**BASIC
PROTOCOL 2**

Immunology

11.13.5

Figure 11.13.1 The Cunningham-Szenberg chamber. **(A)** The chambers as they are made in strips. **(B)** The whole chamber. **(C)** The chambers being dipped into a petri dish and sealed with hot wax.

1. Prepare molten wax by heating in a 120-cm² glass petri dish on a hot plate; maintain at low heat.
2. To each well of an empty 96-well microtiter plate, add the following:
 - 50 μ l supplemented complete medium
 - 50 μ l 7.5% SRBC or 15% TNP-SRBC
 - 50 μ l suspended B cells (from step 9 of Basic Protocol 1)
 - 50 μ l diluted guinea pig serum

Mix the contents of each well with pipettor and fill Cunningham-Szenberg chambers by slowly expelling the contents of the pipet with the tip placed at an angle at the overlap edges (see Fig 11.13.1B).

Add guinea pig serum to only 24 wells at a time to prevent inactivation of the complement during the period the slides are kept at room temperature. The time needed to fill and seal 24 slides is at the upper limit necessary to prevent the chambers from drying out.

3. After filling 24 slide chambers, seal each side with molten wax (see Fig. 11.13.1). Incubate chambers 45 to 60 min at 37°C.

Metal trays from standard 37°C incubators are excellent for carrying slides; each tray holds ~72 slides.

Seal with wax within 20 min to prevent the chamber from drying out.

4. Remove chambers from incubator and count plaques under a dissecting microscope at 10 \times magnification.

Care must be taken to differentiate between air bubbles and real plaques. Air bubbles have clearly defined borders and are highly reflective. Plaques have hazy borders and are nonreflective (see Fig. 11.13.2).

Figure 11.13.2 Typical plaques from PFC assay. The plaques show pinpoint clearing in a lawn of RBC. This is due to lysis by complement and antibody being secreted by the B cell (center of plaque).

Jerne-Nordin Assay (Jerne and Nordin, 1963)

Materials

- 1% agarose (SeaPlaque; FMC Bioproducts)
- 2× basal Eagle medium (Life Technologies)
- 10% (v/v) SRBC or 20% (v/v) TNP-SRBC (see Support Protocol 3) in supplemented complete medium
- Phosphate-buffered saline (PBS; APPENDIX 2), 4°C
- Source of lyophilized guinea pig serum (Life Technologies)
- 5-ml pipets and 5-ml glass test tubes, prewarmed
- 42°C water bath
- Precoated agarose slides (see Support Protocol 2)
- Tray for holding slides (Fig. 11.13.3; not commercially available)

1. Mix equal amounts of 1% agarose with 2× basal Eagle medium in a 50-ml centrifuge tube. Using a prewarmed pipet, add 0.4 ml of this plaquing medium to glass test tubes (maintained in a rack in a 42°C water bath).

Maintain this mixture at 42°C until the B cells are added and placed onto the slides. This is critical, because at lower temperatures agarose slowly and imperceptibly gels and gives rise to false plaques. The cooled agarose can no longer be used.

2. To each test tube, first add 1 drop of 10% SRBC or 20% TNP-SRBC, then add (6 tubes at a time) 0.1 ml B cell suspension (from step 9 of Basic Protocol 1) after carefully resuspending cells.
3. Vortex tubes and immediately pour and spread suspensions onto precoated agarose slides. Allow slides to harden and turn upside down on a tray (see Fig. 11.13.3).

Trays are designed such that eight slides (or less) can be placed upside-down.

4. Cover tray with a damp cloth and place 60 to 90 min in an incubator at 37°C.

Even if a humidified incubator is used, do not omit the damp cloth.

5. Prepare complement by adding 5 ml of cold PBS to 5 ml lyophilized guinea pig serum. When serum is dissolved, add it to 95 ml of cold PBS.

**BASIC
PROTOCOL 3**

Immunology

11.13.7

Figure 11.13.3 Jerne-Nordin slide assembly. **(A)** Top view of tray sufficient for eight slides. In the corners, nails can be worked through to facilitate stacking of multiple trays. **(B)** Amplified cross-section of the tray with detailed dimensions (in cm). **(C)** Cross-section of tray with agarose-coated slide in place for incubation.

6. Add 2 ml of freshly diluted guinea pig serum per slide to the shallow well in the tray holding the slides (i.e., 16 ml/tray; see Fig. 11.13.3). Place slides in 37°C incubator for 90 min.

There is no further need for a damp cloth, as the complement maintains the moisture.

7. Remove slides from incubator and count plaques using a dissecting microscope at 10× magnification (Fig. 11.13.2).

ALTERNATE PROTOCOL

MEASUREMENT OF ISOTYPE-SPECIFIC ANTIBODY AND POLYCLONAL ANTIBODY RESPONSES

Isotype-Specific Antibody Response

The Jerne-Nordin PFC assay (see Basic Protocol 3) can be modified for measurement of IgG- and IgA-producing B cells as follows. At the end of step 1, add 50 μ l goat anti-IgM antibody to each tube containing plaquing medium to inhibit IgM (direct) plaques. Then, after the incubation in step 4 (before preparing complement in step 5), add developing anti-IgG (or anti-IgA) to the slides to develop IgG (or IgA)-producing B cells. This is done by filling the shallow well in the tray holding the slides with 2 ml of antibody. Incubate 1 hr at 37°C, then draw off the developing antibody with a Pasteur pipet connected to a vacuum suction flask. Proceed with the preparation and addition of complement as in steps 5 and 6.

Appropriate dilution of rabbit anti-IgM, -IgG, and -IgA antibodies (Jackson Labs) in supplemented complete medium must be predetermined for each batch of antibody, but is usually in the range of 1:100. Addition of developing antibodies is critical, since IgG and IgA antibodies fix complement poorly in their absence.

Polyclonal Antibody Response

The Jerne-Nordin PFC assay (see Basic Protocol 3) can also be modified to measure total Ig-secreting B cells stimulated by a polyclonal B cell activator—e.g., LPS. In this case, Ig of unknown antigenic specificity is measured; thus, an indicator cell must be used which binds Ig of all isotypes. The indicator cells are SRBC conjugated to protein A (see Support Protocol 4), a substance that binds both mouse and rabbit IgG with high avidity. Protein A–SRBC thus binds a developing rabbit anti-mouse Ig antibody that has been added to the B cell preparation and subsequently binds secreted mouse Ig. The resulting complex is then able to activate complement and effect SRBC lysis.

To assay polyclonal antibody response, prepare protein A–SRBC indicator cells according to Support Protocol 3. Proceed with step 1 of the Jerne-Nordin protocol (see Basic Protocol 3), then add 1 drop of 15% protein A–SRBC (see Support Protocol 4) suspended in supplemented complete medium (instead of unmodified SRBC or TNP-SRBC) in step 2. Proceed with steps 3 and 4, then add developing antibody (rabbit anti-IgM and anti-IgG) to the shallow well in the tray holding the slides. Incubate slides 1 hr at 37°C, then draw off the developing antibodies with a Pasteur pipet connected to a vacuum suction flask. Proceed with the preparation and addition of complement as in steps 5 and 6.

It is best (but not essential) to use affinity-purified antibodies (Jackson Immunoresearch) that have been pretitrated to determine optimum dilution in supplemented complete medium.

PREPARATION OF CUNNINGHAM-SZENBERG CHAMBERS

Materials

70% ethanol
Microscope slides
¼-in. double-sided tape (3M)

1. Place 15 to 30 microscope slides side-by-side on a bench in a row.
2. Stick double-sided ¼-in. tape on top and bottom edges. Place a third strip of tape between the other two, dividing slide into two sections (see Fig. 11.13.1).
3. Wipe slides with a paper towel soaked with 70% ethanol and allow to air dry.
4. Remove backing of double-sided tape and wipe a second slide with 70% ethanol, air dry, and place on first slide in the row. Overlap the slides on the side edges as in Figure 11.13.1 to facilitate filling the chamber. Repeat this process so the entire row of slides on the bench are covered with a second slide.
5. Apply slight pressure with a roller to ensure that the slides are stuck firmly together.

Each slide chamber can hold just under 0.1 ml of fluid on either side of the tape for a total of 0.2 ml per slide.

SUPPORT PROTOCOL 1

**PREPARATION OF GLASS SLIDES FOR THE
JERNE-NORDIN ASSAY**

Materials

1% agarose (SeaPlaque; FMC Bioproducts)
Microscope slides
2 × 2-in. sterile gauze pad (Johnson & Johnson)

1. Prepare microscope slides as for Cunningham-Szenberg chambers (see Support Protocol 1), but omit the double-sided tape (i.e., follow steps 1 and 3).
2. Boil 1% agarose and dilute 1:10 in water (0.1% final).
3. Apply a thin film of 0.1% agarose to prepared slides (frosted end up) with a sterile gauze pad.
4. Allow slides to dry.

Precoated slides can be stored for 2 months at room temperature in a dust-free environment.

PREPARATION OF MODIFIED INDICATOR SRBC FOR PFC ASSAYS

TNP-Modified SRBC (Rittenberg and Pratt, 1969)

Additional Materials

Modified barbital buffer (MBB; see recipe)
2,4,6-trinitrobenzenesulfonic acid, sodium salt (TNBS; Eastman Kodak)
Cacodylate buffer (see recipe)
120 mg glycylglycine (gly-gly; Sigma #10022) in 15 ml MBB (see recipe for MBB)
15-ml graduated conical tube (Costar)

1. Remove SRBC from stock bottle and centrifuge 15 min in IEC 216 rotor at 3000 rpm (1525 × g). Aspirate supernatant and transfer 3 ml of packed SRBC to a tube containing 50 ml MBB.
2. Wash SRBC with 50 ml MBB by centrifuging 10 min at 1525 × g. Repeat the washing procedure two more times. Resuspend SRBC in 50 ml MBB.
3. Add 60 mg TNBS to 21 ml cacodylate buffer in a 50-ml foil-covered tube (TNBS is light sensitive). Mix and allow the tube to stand 10 min at room temperature.
4. *Slowly* add 5 ml SRBC/MBB suspension to TNBS/cacodylate solution, while shaking. Cap tube and invert occasionally over the next 10 min.
5. Fill tube with MBB. Centrifuge 10 min in IEC 216 rotor at 2000 rpm (675 × g), 4°C, and discard supernatant.
6. Add glycylglycine solution to tube and resuspend SRBC. Place tube on ice 10 min.

Formation of glycylglycine solution is such that 20 mg of glycylglycine is used for every 10 mg of TNBS.

7. Centrifuge 10 min at 675 × g and discard supernatant.

The supernatant should be yellow. If it is not, the conjugation step was not successful.

8. Wash SRBC twice in 50 ml MBB and at least once in supplemented complete medium, using the conditions in step 2. Continue washing until there is no evidence of SRBC lysis (clear supernatant).

9. Spin cells at $675 \times g$ in a graduated 15-ml conical tube to determine final packed cell volume. Discard supernatant and resuspend SRBC in supplemented complete medium at a final concentration of 15% or 20% (v/v) for Cunningham-Szenberg or Jerne-Nordin assays respectively.

TNP-SRBC can be stored ~1 week but should be washed prior to use and should not be used until lysis is absent. (i.e., until supernatant stays clear after washing). Fresh SRBC make better targets and are more likely to survive the conjugation procedure.

Protein A–Modified SRBC (Gronowicz et al., 1976)

Materials

Saline (0.15 M NaCl; Life Technologies)
0.5 mg/ml protein A (Pharmacia Biotech) in saline (store frozen in saline at 1 mg/ml)
1× chromic chloride solution (see recipe)
15-ml conical test tube (Costar)

1. Wash SRBC in 50 ml saline by centrifuging 10 min in IEC-216 rotor at 2000 rpm ($675 \times g$), 4°C. Repeat the washing procedure two more times.
2. Pipet 0.5 ml packed cells into a 15-ml conical test tube.
3. Add 0.5 ml freshly prepared 0.5 mg/ml protein A and 5 ml of 1× chromic chloride solution to SRBC. Incubate 1 hr at room temperature. Invert tube gently every 10 min.
4. Wash twice in 50 ml saline and once in 50 ml supplemented complete medium as described in step 1.
5. Resuspend SRBC at a final concentration of 15% (v/v) in supplemented complete medium.

Protein A–SRBC are best used on the same day, but will keep for 3 days at 4°C.

ISOLATION OF B CELLS BY PERCOLL GRADIENT CENTRIFUGATION

Resting B cells are isolated from a suspension of spleen cells by elimination of T cells with an anti-Thy-1 MAb (Hathcock, 1991b), followed by enrichment using flotation on Percoll gradients (also see Kruisbeek and Shevach, 1991). However, instead of using the two layers of 55% and 70% Percoll described in Kruisbeek and Shevach (1991) (for enrichment of accessory cells), B cell enrichment requires four layers of 55%, 60%, 65%, and 70% Percoll. All other conditions are identical to those described in Kruisbeek and Shevach (1991). Resting B cells are collected from the 65% to 70% interface after centrifugation.

Additional Materials

Hank's balanced salt solution (HBSS; APPENDIX 2), ice cold
Percoll (store at 4°C; Pharmacia Biotech #17-0891-01)
Percoll mix solution (see recipe)

15- and 50-ml polypropylene centrifuge tubes
Sorvall H-1000B rotor (or equivalent)

Additional reagents and equipment for preparation of depleted B cell suspensions (Hathcock, 1991b; Mage, 1993), making cell suspensions (Kruisbeek, 1993), and counting cells (APPENDIX 3F)

**SUPPORT
PROTOCOL 4**

**SUPPORT
PROTOCOL 5**

Immunology

11.13.11

1. Prepare T cell–depleted B cell suspension from spleen. Resuspend cells in HBSS using 1 ml of HBSS for each spleen.

Be sure to include anti-Thy-1, anti-CD4, and anti-CD8 antibodies to deplete all T cells. If desired, deplete RBC present in spleen cell suspension using ACK lysing buffer, pH 7.4 (see recipe); however, small RBC contamination usually does not interfere with proliferation studies.

2. Prepare 70% Percoll by mixing 290 ml Percoll with 170 ml Percoll mix solution. Keep on ice at all times.
3. Prepare 50%, 60% and 66% Percoll as follows:

	<u>50%</u>	<u>60%</u>	<u>65%</u>
70% Percoll, ice-cold (ml)	21.42	25.71	27.86
HBSS, ice-cold (ml)	8.58	4.29	2.14

4. Prepare 50%/60%/65%/70% Percoll gradients in 15-ml conical centrifuge tubes:

- a. Add 2.5 ml 70% Percoll to 15-ml tube.
- b. Gently pipet 2.5 ml of 65% Percoll over 70% Percoll layer.
- c. Gently pipet 2.5 ml of 60% Percoll over 65% Percoll layer.
- d. Gently pipet 2.5 ml of 50% Percoll over 60% Percoll layer.

Careful layering of Percoll is essential to create the sharp gradient interfaces necessary for good cell separation.

Use polypropylene tubes to withstand high-speed centrifugation. Make ≥ 4 gradients for a suspension of cells from 10 spleens and ≥ 6 gradients for a suspension of cells from 20 spleens.

5. Allow prepared gradients to sit on ice for ≥ 15 min before adding cells and centrifuging.

Good cell separations depend on use of cold gradients.

6. Gently layer 2.5 ml of cell suspension (from step 1) onto the surface of each gradient. Add cell suspension slowly and down side of tube so as not to break gradient surface.
7. Centrifuge gradients 13 min in Sorvall H-1000B rotor at 3000 rpm ($\sim 1900 \times g$), 4°C. The brake must be off.
8. Aspirate HBSS and 50% Percoll layer; then, with a pipet, separately collect cells at each interface between remaining layers and place into 50-ml centrifuge tubes.

Cells at the 65%/70% interface are the small, resting B cells, whereas those at the 50%/60% interface are the large, activated B cells. Cells at the intermediate 60%/65% interface are mainly small, resting B cells; these cells can be used as resting cells if absolutely necessary.

9. Wash cells 3 times with HBSS, centrifuging at 1200 to 1500 rpm ($300 \times g$) each time.
10. Count cells after final wash.

REAGENTS AND SOLUTIONS

ACK lysing buffer

8.29 g NH₄Cl (0.15 M)
1 g KHCO₃ (10.0 mM)
37.2 mg Na₂EDTA (0.1 mM)
Add 800 ml H₂O
Adjust pH to 7.2 to 7.4 with 1 N HCl
Add H₂O to 1 liter
Filter sterilize through a 0.2- μ m filter
Store at room temperature

Antigens

The following antigens can be used for in vitro antibody production (Basic Protocol 1). Note that when used in conjunction with nonimmunized, purified B cells, these antigens must be used with lymphokines.

Sheep red blood cells (SRBC): T cell–dependent, particulate antigen which serves as a relatively potent in vitro immunogen; does not require the use of cells from in vivo primed animals (for IgM response). Several batches may need to be screened to obtain cells that stimulate reproducible responses; once found, use that source exclusively. This antigen results in nonspecific B cell response to various epitopes. SRBC can be purchased from Becton Dickinson (#11943).

Ovalbumin (OVA): Soluble protein that is a relatively weak immunogen and requires the use of cells from in vivo primed animals. Elicits nonspecific B cell response; however, trinitrophenylation of the protein (TNP-OVA) results in production of antibodies to the specific epitope. However, in this case, T cells must be primed to the carrier molecule (OVA), and B cells must be primed to the hapten molecule (TNP). TNP-OVA can be prepared by the method of Eisen et al. (1953).

Trinitrophenylated Ficoll and dextran (TNP-Ficoll and TNP-dextran): “Type 2,” high-molecular-weight multiepitope antigens that have no intrinsic polyclonal activating properties and stimulate responses only in immunologically mature B cells (CBA/N mice do not respond, but nude mice do). Use of these antigens requires the addition of T cell-derived lymphokines (IL-1 and IL-2; alternatively, IL-5) or the use of B cells partially activated in vivo (see commentary discussion of T cell-regulated antigens). TNP-Ficoll can be purchased from Biosearch or prepared by the method of Inman (1975).

Trinitrophenylated Brucella abortus and lipopolysaccharide (TNP-BA and LPS): “Type 1” antigens that have intrinsic polyclonal activating properties and can stimulate responses in cell from all mouse strains (immature neonatal B cells as well as B cells from *xid* immune-defective mice). Use of these T cell–regulated antigens requires addition of lymphokines (IL-2 only) or use of B cells partially activated in vivo (see commentary). Killed *B. abortus* is available from the U.S. Department of Agriculture (National Veterinary Services Labs, P.O. Box 844, Ames, IA 50010) and is trinitrophenylated as described by Mond et al. (1978). LPS is available from Difco as *E. coli* 0111:B4.

Barbital buffer, modified (MBB), 5 \times stock solution

2.875 g barbituric acid
1.875 g sodium barbital
0.1103 g CaCl₂·2H₂O
0.238 g MgCl₂·6H₂O
42.5 g NaCl
H₂O to 1 liter
Dilute 1:5 for working solution

Cacodylate buffer (0.28 M)

Dissolve 24 g cacodylic acid in deionized water (~300 ml). Adjust to pH 6.9 with concentrated HCl. Dilute to 400 ml. Store at room temperature ≤6 months.

Chromic chloride solution (2.5×10^{-4} M)

For 200× stock, dissolve 134 mg chromic chloride in 10 ml saline (not buffered). Mix well. Dilute to 1× with saline just before use.

DMEM-10 medium, supplemented, complete

Prepare in *modified* Dulbeccos minimal essential medium (DMEM):

10% fetal bovine serum (FBS; APPENDIX 3F)

1 mM sodium pyruvate

2 mM L-glutamine

50 µg/ml gentamycin

0.1 mM nonessential amino acids

0.3% sodium bicarbonate

25 mM HEPES

50 µM 2-mercaptoethanol (2-ME)

Modified DMEM contains L-glutamine, 1000 mg glucose/liter, and phenol red but does not contain sodium bicarbonate. L-glutamine is labile and is therefore added fresh. The medium can be stored up to 1 month at 4°C.

Fetal bovine serum (FBS) is a critical element in obtaining good in vitro responses for any protocols in this unit. It is not unusual to have to screen 10 to 20 different batches of FBS to obtain a batch that supports high specific responses but low background responses. Reliable sources of FBS are Hyclone and Armour.

Guinea pig serum

To use as a source of complement, preabsorb with TNP-SRBC (see Support Protocol 3) 30 min on ice using 1 ml packed cells and 5 ml serum. Complement may be refrozen and stored at -70°C. Commercial sources such as Life Technologies have worked well in the PFC assays.

Complement absorbed with TNP-SRBC can also be used for unmodified SRBC. Complement does not have to be absorbed for the Jerne-Nordin assay (Basic Protocol 3), as the agarose absorbs cytotoxic activity during the assay.

Percoll mix solution

45 ml 10× phosphate-buffered saline (PBS; APPENDIX 2)

3 ml 0.6 N HCl (1:20 dilution of 12 N HCl; J.T. Baker)

132 ml H₂O

Check that pH is 7.0 to 7.2

Filter sterilize using 0.22-µm filter; store at 4°C

RPMI-10 medium, supplemented, complete

Prepare in complete RPMI/10% FBS (APPENDIX 3F):

25 mM HEPES

1 mM sodium pyruvate

50 µg/ml gentamycin

0.25 µg/ml Fungizone (this supplementation includes 100 penicillin and 100 µg/ml streptomycin; Whittaker #17-745A)

See note regarding testing of FBS in recipe above for supplemented DMEM-10.

COMMENTARY

Background Information

In vitro antibody production by B cells following stimulation with T cell–dependent antigens (i.e., antigens that activate B cells only if antigen-specific T cells are present to provide essential help) involves a number of discrete cellular events. Initially, antigen is taken up by the B cell as a result of binding to and cross-linkage of specific Ig receptors on the cell surface; this is followed by expression of the processed antigen on the cell surface in the context of MHC class II antigens. Next, there is B cell presentation of the processed antigen to the T cell, which leads to interactions between the T cell receptor and the antigen–MHC class II complex as well as between adhesion antigens on the T cell and B cell. These cell-surface events lead to stimulation of both interacting cells—the T cells producing growth and differentiation factors (lymphokines) and the B cells differentiating into antibody-producing plasma cells. Macrophages also play a role in this process as antigen-presenting cells that interact with T cells early in the process to bring about T cell activation and lymphokine production; such interaction may be critical since B cells require T cell–derived cytokines for optimum activation and differentiation. It should be noted that a given clone of B cells recognizes one determinant (usually called the haptenic determinant) on the antigen via the Ig receptor, whereas the T cell usually recognizes another determinant (usually called the carrier determinant) expressed on the processed antigen.

B cells may also be activated and induced to secrete immunoglobulin in the absence of antigen-specific T cells by cross-linkage of the Ig receptor by antigens containing multiple copies of the same determinant (multivalent antigens). These so-called T cell–independent antigens (such as TNP-Ficoll or TNP-dextran) were originally felt to be capable of activating B cells in the complete absence of T cells; however, it is now known that even these antigens require the help of T cell-derived lymphokines to induce antibody production by resting B cells. It is therefore more appropriate to refer to this group of antigens as T cell–regulated antigens. These antigens can, however, induce B cells that have been partially activated in vivo to respond even in the absence of cytokine-mediated help.

The culture system for measuring in vitro antibody production described in this unit is essentially a miniaturized version of the system

originally developed by Mishell and Dutton (1966, 1967). Much early information about T cell and B cell function was derived using this system in conjunction with mouse spleen cells as a source of T and B cells and heterologous red blood cells as a source of antigen. One advantage of using SRBC to study in vitro T and B cell responses is that this antigen induces responses in cells obtained from unprimed animals, probably because animals are naturally primed in vivo with antigens that cross-react with those associated with SRBC. However, under the usual in vitro conditions, the response of unprimed cells consists mainly of IgM antibody production; thus, either priming of the T cell/B cell source or addition of lymphokines to the culture system is necessary if IgG responses are desired. One disadvantage of using SRBC (and other complex antigens) is that a large number of B cell clones with poorly defined anti-RBC specificities are activated during the response. To study more restricted responses (of individual cell clones), it is necessary to use purified peptide antigens as the immunogen; however, in this case the response is poor with regard to levels of antibody produced unless T cells from primed animals are used or lymphokines are added to the cultures.

Critical Parameters

Stimulation of antibody production in vitro can lead to inconsistent and, at times, unreliable results. It is recommended that a laboratory starting this technology obtain reagents and cells from an experienced laboratory group. The novice should also consult the original literature cited in this unit to gain a fuller sense of the many parameters affecting in vitro response, as well as review the strategic planning section at the beginning of this unit.

Responder cells. B cells from pathogen-free mice should be used. B cells obtained from mice that are chronically infected with endemic viruses show poor in vitro responses. Healthy, uninfected mice are available from Jackson Laboratory (*APPENDIX 4*) and the National Cancer Institute (see Silverman and La Via, 1976). A purer and more homogeneous population of B lymphocytes permits a more reliable interpretation of the results. However, as mentioned in strategic planning, many culture systems require the presence of macrophages. Finally, defined T cell populations should be utilized. In this regard, the use of T cell populations defined by various surface antigens, organs or

origin—as well as other parameters or clonal/hybridoma T cell populations—should be considered.

Media components. Fetal calf serum of different sources and batches vary in their ability to support *in vitro* B cell responses (Mishell and Dutton, 1967; Shiigi and Mishell, 1975). It is best to test as many different types of FCS as possible to find one that gives a low background response and high specific response. When different sources of FCS are to be tested, be sure that the supplier has available >20 to 30 liters of a particular lot, as it is not worth the time and effort to test a batch containing only a few liters. 2-mercaptoethanol is essential for most *in vitro* murine B cell responses. The 2-ME stock should be replaced every 2 months.

RBC stimulator cells. For use as an antigen in *in vitro* B cell systems and in PFC assays, the SRBC should be as fresh as possible. For direct anti-SRBC responses, they should be <2 months old, and different batches should be tested for efficacy of response (McCarthy and Dutton, 1975a,b). If anti-TNP or α -protein A responses are being examined, the cells should be <1 week old before conjugation, because SRBC become increasingly fragile with age. When older SRBC are conjugated, they lyse very easily, making it difficult to enumerate plaques.

Incubator. The quality of the incubator is very important. It must be capable of maintaining temperature, humidity, and percent CO₂ extremely accurately.

Cunningham-Szenberg assay. The guinea pig serum must be absorbed properly as described in reagents and solutions. In addition, the complement should be used within 20 min of thawing (during the assay). All reagents should be at room temperature before they are added to the chambers, because if they are cold, air bubbles form in the chambers during incubation, making plaques difficult to count. Chambers should be sealed with wax within 20 min of filling to prevent the chamber from drying out.

Jerne-Nordin assay. It is essential that the agarose does not cool below 42°C before it is poured onto the slides. After the slides are poured, the agarose must be solidified by allowing to cool to room temperature before the slides are inverted and put on the racks.

Antigen removal. When assaying supernatants for specific antibody responses, it is important to wash the cells to remove the antigen prior to collecting supernatants for the ELISA. The timing of antigen removal and

collection of supernatants will depend on the system being employed. In general, antigen can be removed 3 to 6 days after the onset of culture, and supernatant can be collected after 4 to 7 days. In studying polyclonal immunoglobulin secretion induced by lipopolysaccharide or lymphokine, there is no need to remove these stimuli, as they do not interfere with the ELISA.

Manipulations of cells. Most importantly, when working with cells *in vitro* one should always be aware that any manipulation, however minor, may influence the responsiveness of the cell and may lead to variability in the results. To minimize these occurrences, attention should be paid to treating cells with care—e.g., not centrifuging at speeds greater than 1000 rpm, not vortexing for prolonged periods of time, and maintaining cells on ice in medium that is appropriately buffered and supplemented with FBS.

Anticipated Results

For antibody secretion, the number of PFC generated will depend on the nature of the stimulus and/or the presence of added lymphokines. However, typical responses for 10⁶ purified B cells cultured with stimulatory lymphokines are presented in Table 11.13.1.

Time Considerations

Preparing purified resting B cells by Percoll gradient centrifugation (Support Protocol 5) takes ~4 hr, while preparing antigen and distributing the cells into the plates normally takes ~2 hr. The exact length of time will depend on the size and complexity of the experiment and the skill of the investigator.

Supernatants for ELISA—washing the plates to remove excess antigen takes 0.5 hr; harvesting supernatants for assay takes 0.5 hr (the ELISA takes ~7 hr).

Preparation of modified SRBC—TNP-SRBC and Protein A-SRBC both take ~3 hr.

Jerne-Nordin assay—precoating the slides takes ~15 min; the maximum size of an experiment is three 96-well plates, which would take an experienced worker 8 hr.

Cunningham-Szenberg assay—preparation of slides takes ~1 hr per 120 slides; absorption of complement takes ~2 hr; an experienced worker can assay six 96-well plates in 8 hr.

Purification of Immunoglobulin G Fraction from Antiserum, Ascites Fluid, or Hybridoma Supernatant

UNIT 11.14

This unit describes the isolation of the immunoglobulin G (IgG) fraction (containing antibodies of all specificities) from a complex protein mixture such as antiserum, ascites fluid, or hybridoma supernatant. The Basic Protocol utilizes saturated ammonium sulfate solution to precipitate the IgG fraction, while the Alternate Protocol describes fractionation of IgG by chromatography on DEAE–Affi-Gel Blue resin. The purification of IgG by affinity chromatography utilizing staphylococcal protein A or antigen-Sepharose is described in *UNIT 11.11*.

PRECIPITATION OF IgG WITH SATURATED AMMONIUM SULFATE

**BASIC
PROTOCOL**

Antiserum or ascites fluid is adjusted to 33% with respect to the concentration of saturated ammonium sulfate, resulting in the precipitation of the IgG. At this concentration of saturated ammonium sulfate, a large percentage—but not all—of the contaminating protein species present in the antiserum or ascites remains in solution.

Materials

- Saturated ammonium sulfate (SAS) solution (see recipe)
- 33% SAS solution (see recipe)
- Immunoglobulin-containing antiserum, ascites, or tissue culture supernatant
- Additional reagents and equipment for dialysis (*APPENDIX 3C*)

1. Add 1 vol SAS solution dropwise with a Pasteur pipet to 2 vol antiserum, ascites, or tissue culture supernatant with constant mixing at 4°C.
2. Allow precipitate to form over a period of 2 to 4 hr at 4°C with constant mixing. Pellet precipitate by centrifugation for 20 min at 12,000 × *g*, 4°C.
3. Wash pellet by resuspending (vortexing) it in a volume of cold 33% SAS solution equivalent to the original volume of antiserum, ascites, or tissue culture supernatant. Repeat wash step once.
4. Dissolve pellet in appropriate cold buffer by gentle vortexing.

A convenient volume for solubilizing the IgG fraction is 5% to 10% of the original antiserum, ascites, or hybridoma supernatant volume.

5. Dialyze IgG solution over 48 hr at 4°C against three changes of the desired buffer (4 liters per change) to fully remove the ammonium sulfate.

See APPENDIX 3C for preparing dialysis membrane (molecular weight cutoff 12,000 to 14,000; Spectrapor 2 or equivalent) and for large-volume dialysis.

Immunology

11.14.1

FRACTIONATION OF IgG BY CHROMATOGRAPHY ON DEAE-AFFI-GEL BLUE

This alternate procedure can be used to isolate the IgG fraction from either ascites or antiserum or to further purify the IgG fraction obtained after SAS precipitation. Under low salt concentrations, many protein species present in ascites or antiserum, including IgG, are bound to DEAE-Affi-Gel Blue resin with varying affinities. When increasing the salt concentration in small increments, the IgG fraction is selectively eluted, leaving the majority of the contaminating protein species still bound to the resin. This protocol describes the fractionation of murine IgG.

Additional Materials (also see Basic Protocol)

Loading buffer (see recipe)
Elution buffer (see recipe)
NaN₃, crystalline form
DEAE-Affi-Gel Blue (Bio-Rad)

Additional reagents and equipment for gel-filtration chromatography (UNIT 10.9)
and SDS-polyacrylamide gel electrophoresis (UNIT 10.2)

1. Prepare a column of DEAE-Affi-Gel Blue according to manufacturer's instructions (see Fig. 10.9.1) and equilibrate with five bed volumes of loading buffer.

It is recommended that a total bed volume of 7 ml/ml antiserum or ascites be used.

This and subsequent steps should be carried out at 4°C.

2. Dialyze IgG-containing sample against two changes of loading buffer (4 liters per change) for ~40 hr at 4°C.
3. Apply sample to the column at a flow rate of 10 ml/hr. Elute unbound protein with three bed volumes of loading buffer at the same flow rate.

Alternatively, elution of the unbound material may be carried out overnight; however, at least three bed volumes of loading buffer must be run down the column before the specific elution of the IgG fraction.

4. Elute bound IgG fraction with elution buffer at a flow rate of 10 ml/hr. Collect 10-ml fractions and store at 4°C until they are pooled.

Transferrin (M_r76,000) usually coelutes with the IgG fraction.

5. Identify fractions containing IgG by analyzing 30 to 50 µl of each fraction on a 10% SDS-polyacrylamide gel (UNIT 10.2), under reducing conditions (see UNIT 10.2).

Under reducing conditions, the IgG heavy and light chains will run separately with molecular weights of 50,000 and 25,000, respectively.

The amount of transferrin contaminating the IgG will be determined at this step. The amount present will vary depending on the source of the antibody. It can be removed by gel-filtration chromatography (UNIT 10.9).

6. Pool fractions containing IgG and dialyze over 40 hr at 4°C against two changes of the desired buffer (4 liters per change).
7. Re-equilibrate DEAE-Affi-Gel Blue column with five bed volumes of loading buffer, add a few crystals of NaN₃ to retard bacterial growth, and store at 4°C.

REAGENTS AND SOLUTIONS

Elution buffer (20 mM Tris·Cl/50 mM NaCl, pH 8.0)

2.4 g Tris base
2.92 g NaCl
900 ml H₂O
Adjust to pH 8.0 with concentrated HCl
H₂O to 1 liter

Loading buffer (20 mM Tris·Cl/30 mM NaCl, pH 8.0)

2.4 g Tris base
1.75 g NaCl
900 ml H₂O
Adjust to pH 8.0 with concentrated HCl
H₂O to 1 liter

Saturated and 33% saturated ammonium sulfate (SAS) solution

450 g ammonium sulfate
H₂O to 500 ml

Heat solution on a heated stirring plate until ammonium sulfate dissolves completely. Filter solution while it is still warm and then allow it to cool. Upon cooling, crystals will form and should not be removed. Check pH of cooled solution; adjust to pH 7.5 with ammonium hydroxide. For 33% SAS solution, mix 33 ml SAS solution with 67 ml phosphate-buffered saline (PBS; APPENDIX 2).

A quantity of 760 g of ammonium sulfate is required per 1000 ml for a 100% saturated solution. A total of 450 g/500 ml is used to ensure sufficient crystal formation to maintain saturation. A slightly different recipe for saturated ammonium sulfate solution in Tris buffer is contained in UNIT 11.1 and may be substituted in this protocol.

COMMENTARY

Background Information

Affinity chromatography, in which the relevant protein antigen or peptide antigen is coupled to an affinity resin (see UNIT 11.11), is the method of choice for the purification of specific antibody. However, under certain circumstances, such purification procedures are either unnecessary or not applicable (e.g., when the antigen is not available in adequate quantities). In this unit two procedures are described for the isolation of the IgG fraction from ascites or antiserum. In both cases, however, the total IgG component is isolated.

The precipitation of protein using ammonium sulfate is achieved by dehydration in the microenvironment of the protein molecule. In solution, a large number of water molecules are bound to the sulfate ion (SO₄⁼), significantly reducing the amount of water available to interact with the protein molecules. At a particular concentration of ammonium sulfate an insufficient quantity of unbound water will remain to keep a given protein species in solution, resulting in the precipitation of that protein. The exact concentration of ammonium sulfate re-

quired to precipitate a protein will be determined by the characteristics of the amino acid side chains exposed to the solvent. Precipitation of the IgG fraction of antiserum or ascites fluid at an ammonium sulfate concentration of 33% efficiently isolates the IgG fraction from major contaminating proteins such as albumin and hemoglobin, yielding an IgG preparation that is relatively pure. However, a significant number of other proteins will coprecipitate. Therefore, this fractionation protocol serves as an excellent initial step in the purification of IgG. The SAS-precipitated IgG fraction can then be further purified by immunoaffinity chromatography or on a DEAE–Affi-Gel Blue column (see Alternate Protocol). In addition, the IgG fraction can be stored for a long period of time (1 to 2 years) as a suspension of precipitate in SAS solution without loss of antibody-binding activity. Fresh antiserum or ascites can be brought to the desired ammonium sulfate concentration and safely stored until further purification of the IgG fraction is required.

Affinity chromatography using DEAE–Affi-Gel Blue is a combination of dye-interac-

tion and ion-exchange (IEX) chromatography. The DEAE–Affi-Gel Blue is a bifunctional resin bearing both diethylaminoethyl groups and Cibacron F3GA molecules. The dye-interaction chromatographic function is based on the ability of the dye, Cibacron blue F3GA, to bind a large variety of enzymes and other proteins with a range of affinities. A comprehensive discussion on the nature and use of this dye, when attached to an affinity chromatography matrix, is given in the technical literature found on the Bio-Rad website (<http://www.bio-rad.com>). Blue Sepharose 6 Fast Flow is the equivalent matrix produced by Amersham Pharmacia Biotech (<http://www.apbiotech.com>). In addition, the IEX moieties on the resin interact with the remaining acidic proteins in the antiserum or ascites. Overall, a large percentage (70% to 80%) of contaminating proteins are separated from the IgG fraction under the elution conditions described. The chromatographic conditions given in the Basic Protocol for the selective elution of the immunoglobulin fraction from the DEAE–Affi-Gel Blue column have been optimized for murine IgG. The manufacturers recommend that 0.02 M K_2HPO_4 (adjusted to pH 8.0 with KOH) buffer be used when fractionating the IgG component from human antiserum. For isolating the IgG fraction from rabbit antiserum, it is recommended that 0.02 M Tris-Cl, pH 8.0/0.03 M NaCl (i.e., the loading buffer used in the Alternate Protocol) be used. It is stated that the human and rabbit IgG fractions do not bind to the column when using these respective buffers.

Pure preparations of immunoglobulins of the G and M isotypes can be achieved by a variety of other chromatographic procedures, including gel filtration and IEX. These protocols are described in this manual (*UNITS 10.9 & 10.10*). The application of electrophoresis to the isolation of pure immunoglobulin species is also described in the former volume.

Critical Parameters

The addition of SAS solution to the antiserum or ascites must be carried out slowly. High local concentrations of ammonium sulfate will result in the coprecipitation of other contaminating protein species that usually precipitate at SAS concentrations >33%. The precipitation should be carried out between 4° and 25°C. Outside this temperature range, the degree of saturation of ammonium sulfate deviates by >3%. Also, to maintain total saturation of the SAS solution, ensure that a significant quantity

of ammonium sulfate crystals are always present at the bottom of the saturated solution.

The optimal elution conditions isolating murine IgG using DEAE–Affi-Gel Blue have been described. As stated in background information, the optimal conditions for fractionating IgG from other species will vary. It is also possible that individual monoclonal antibodies may elute under slightly different salt concentrations than those given in the Basic Protocol. Therefore, the buffer system should be tested by running a small volume of the antibody containing sample down a mini-column of DEAE–Affi-Gel Blue resin before committing a larger quantity of sample to the column.

Troubleshooting

In general, immunoglobulins are a very homogeneous family of proteins and will therefore precipitate when the SAS solution is at a concentration of 33%. In some instances, however, precipitation may be only partial or may not occur at all under these conditions. This problem is more commonly observed when attempting to precipitate an individual monoclonal antibody from ascites fluid. Under such circumstances, it is necessary to increase the ammonium sulfate saturation to 40% or 50%. It must be noted that the number of contaminating protein species will increase with increasing ammonium sulfate concentration. If the IgG fraction is not selectively eluted from the DEAE–Affi-Gel Blue column under the conditions described in the basic protocol and in background information, it may be necessary to adjust the NaCl concentration in the elution buffer. However, do not increase the NaCl concentration above 75 mM, as contaminating protein species begin to elute above this level of salt concentration.

Anticipated Results

An efficient precipitation or ion-exchange purification of the IgG fraction will be achieved using these procedures. However, in many cases, transferrin will coprecipitate or copurify and may be removed by gel-filtration chromatography (*UNIT 10.9*; IgG: MW 150,000; transferrin: MW 76,000). The preferred procedure for purifying antibodies from serum or ascites fluid is by immunoaffinity chromatography on a ligand-bearing affinity matrix or with protein A–Sepharose (*UNIT 11.11*).

Time Considerations

Precipitation of the IgG fraction using SAS can be completed within 4 to 6 hr. After allow-

ing 24 hr for dialysis, affinity chromatography on DEAE–Affi-Gel Blue can be completed over a 24-hr period. It is usually convenient to wash the unbound material through the column overnight, using the loading buffer.

PREPARATION OF ANTIPEPTIDE ANTIBODIES

Introduction to Peptide Synthesis

DEVELOPMENT OF SOLID-PHASE PEPTIDE-SYNTHESIS METHODOLOGY

A number of synthetic peptides are significant commercial or pharmaceutical products, ranging from the dipeptide sugar substitute aspartame to clinically used hormones such as oxytocin, adrenocorticotrophic hormone, and calcitonin. Rapid, efficient, and reliable methodology for the chemical synthesis of these molecules is of utmost interest. The stepwise assembly of peptides from amino acid precursors has been described for nearly a century. The concept is a straightforward one, whereby peptide elongation proceeds via a coupling reaction between amino acids, followed by removal of a reversible protecting group. The first peptide synthesis, as well as the creation of the term “peptide,” was reported by Fischer and Fourneau (1901). Bergmann and Zervas (1932) created the first reversible N^α -protecting group for peptide synthesis, the carbobenzoxy (Cbz) group. DuVigneaud successfully applied early “classical” strategies to construct a peptide with oxytocin-like activity (duVigneaud et al., 1953). Classical, or solution-phase methods for peptide synthesis have an elegant history and have been well chronicled. Solution synthesis continues to be especially valuable for large-scale manufacturing and for specialized laboratory applications.

Peptide synthesis became a more practical part of present-day scientific research following the advent of solid-phase techniques. The concept of solid-phase peptide synthesis (SPPS) is to retain chemistry that has been proven in solution but to add a covalent attachment step that links the nascent peptide chain to an insoluble polymeric support (resin). Subsequently, the anchored peptide is extended by a series of addition cycles (Fig. 11.15.1). It is the essence of the solid-phase approach that reactions are driven to completion by the use of excess soluble reagents, which can be removed by simple filtration and washing without manipulative losses. Once chain elongation has been completed, the crude peptide is released from the support.

In the early 1960s, Merrifield proposed the use of a polystyrene-based solid support for peptide synthesis. Peptides could be assembled stepwise from the C to N terminus using N^α -protected amino acids. SPPS of a tetrapeptide was achieved by using Cbz as an α -amino-protecting group, coupling with N,N' -dicyclohexylcarbodiimide (DCC), and liberating the peptide from the support by saponification or by use of HBr (Merrifield, 1963). SPPS was later modified to use the *t*-butyloxycarbonyl (Boc) group for N^α protection (Merrifield, 1967) and hydrogen fluoride (HF) as the reagent for removal of the peptide from the resin (Sakakibara et al., 1967). SPPS was thus based on “relative acidolysis,” where the N^α -protecting group (Boc) was labile in the presence of moderate acid (trifluoroacetic acid; TFA), while side-chain-protecting benzyl (Bzl)-based groups and the peptide/resin linkage were stable in the presence of moderate acid and labile in the presence of strong acid (HF). The first instrument for automated synthesis of peptides, based on Boc SPPS, was built by Merrifield, Stewart, and Jernberg (Merrifield et al., 1966). From the 1960s through the 1980s, Boc-based SPPS was fine-tuned (Merrifield, 1986). This strategy has been utilized for synthesis of proteins such as interleukin-3 and active enzymes including ribonuclease A and all-L and all-D forms of HIV-1 aspartyl protease.

In 1972, Carpino introduced the 9-fluorenylmethoxycarbonyl (Fmoc) group for N^α protection (Carpino and Han, 1972). The Fmoc group requires moderate base for removal, and thus offered a chemically mild alternative to the acid-labile Boc group. In the late 1970s, the Fmoc group was adopted for solid-phase applications. Fmoc-based strategies utilized *t*-butyl (*t*Bu)-based side-chain protection and hydroxymethylphenoxy-based linkers for peptide attachment to the resin. This was thus an “orthogonal” scheme requiring base for removal of the N^α -protecting group and acid for removal of the side-chain protecting groups and liberation of the peptide from the resin. The milder conditions of Fmoc chemistry as compared to Boc chemistry—which include elimination of repetitive moderate acidolysis steps and the

final strong acidolysis step—were envisioned as being more compatible with the synthesis of peptides that are susceptible to acid-catalyzed side reactions. In particular, the modification of the indole ring of Trp was viewed as a particular problem during Boc-based peptide synthesis (Barany and Merrifield, 1979), which could be alleviated using Fmoc chemistry. One example of the potential advantage of Fmoc chemistry for the synthesis of multiple-Trp-containing peptides was in the synthesis of gramicidin A. Gramicidin A, a pentadecapeptide containing four Trp residues, had been synthesized previously in low yields (5% to 24%) using Boc chemistry. The mild conditions of Fmoc chem-

istry dramatically improved the yields of gramicidin A, in some cases up to 87% (Fields et al., 1989, 1990). A second multiple-Trp-containing peptide, indolicidin, was successfully assembled in high yield by Fmoc chemistry (King et al., 1990). Thus, the mild conditions of Fmoc chemistry appeared to be advantageous for certain peptides, as compared with Boc chemistry.

One of the subsequent challenges for practitioners of Fmoc chemistry was to refine the technique to allow for construction of proteins, in similar fashion to that which had been achieved with Boc chemistry. Fmoc chemistry had its own set of unique problems, including suboptimum solvation of the peptide/resin,

Figure 11.15.1 Generalized approach to solid-phase peptide synthesis. Symbols: A, N^α -protecting group; circle, side-chain protecting groups; R, X, Y, and Z, side-chain functionalities.

slow coupling kinetics, and base-catalyzed side reactions. Improvements in these areas of Fmoc chemistry (Atherton and Sheppard, 1987; Fields and Noble, 1990; Fields et al., 2001) allowed for the synthesis of proteins such as bovine pancreatic trypsin inhibitor analogs, ubiquitin, yeast actin-binding protein 539-588, human β -chorionic gonadotropin 1-74, mini-collagens, HIV-1 Tat protein, HIV-1 nucleocapsid protein Ncp7, and active HIV-1 protease.

The milder conditions of Fmoc chemistry, along with improvements in the basic chemistry, have led to a shift in the chemistry employed by peptide laboratories. This trend is best exemplified by a series of studies (Angeletti et al., 1997) carried out by the Peptide Synthesis Research Committee (PSRC) of the Association of Biomolecular Resource Facilities (ABRF). The PSRC was formed to evaluate the quality of the synthetic methods utilized in its member laboratories for peptide synthesis. The PSRC designed a series of studies from 1991 to 1996 to examine synthetic methods and analytical techniques. A strong shift in the chemistry utilized in core facilities was observed during this time period—i.e., the more senior Boc methodology was replaced by Fmoc chemistry. For example, in 1991 50% of the participating laboratories used Fmoc chemistry, while 50% used Boc-based methods. By 1994, 98% of participating laboratories were using Fmoc chemistry. This percentage remained constant in 1995 and 1996. In addition, the overall quality of the peptides synthesized improved greatly from 1991 to 1994. Possible reasons for the improved results were any combination of the following (Angeletti et al., 1997):

1. The greater percentage of peptides synthesized by Fmoc chemistry, where cleavage conditions are less harsh.
2. The use of different side-chain protecting group strategies that help reduce side reactions during cleavage.
3. The use of cleavage protocols designed to minimize side reactions.
4. More rigor and care in laboratory techniques.

The present level of refinement of solid-phase methodology has led to numerous, commercially available instruments for peptide synthesis (Table 11.15.1).

The next step in the development of solid-phase techniques includes applications for peptides containing non-native amino acids, post-translationally modified amino acids, and pseudoamino acids, as well as for organic molecules in general. Several areas of solid-phase

synthesis need to be refined to allow for the successful construction of this next generation of biomolecules. The solid support must be versatile so that a great variety of solvents can be used, particularly for organic-molecule applications. Coupling reagents must be sufficiently rapid so that sterically hindered amino acids can be incorporated. Construction of peptides that contain amino acids bearing post-translational modifications should take advantage of the solid-phase approach. Finally, appropriate analytical techniques are needed to assure the proper composition of products.

THE SOLID SUPPORT

Effective solvation of the peptide/resin is perhaps the most crucial condition for efficient chain assembly during solid-phase synthesis. Swollen resin beads may be reacted and washed batch-wise with agitation, then filtered either with suction or under positive nitrogen pressure. Alternatively, they may be packed in columns and utilized in a continuous-flow mode by pumping reagents and solvents through the resin. ^1H , ^2H , ^{13}C , and ^{19}F nuclear magnetic resonance (NMR) experiments have shown that, under proper solvation conditions, the linear polystyrene chains of copoly(styrene-1%-divinylbenzene) resin (PS) are nearly as accessible to reagents as if free in solution. ^{13}C and ^{19}F NMR studies of Pepsyn (copolymerized dimethylacrylamide, *N,N'*-bisacryloylethylenediamine, and acryloylsarcosine methyl ester) have shown similar mobilities at resin-reactive sites as PS. Additional supports created by grafting polyethylene glycol (polyoxyethylene) onto PS—either by controlled anionic polymerization of ethylene oxide on tetraethylene glycol-PS (POE-PS) or by coupling N^{Boc} - or Fmoc-polyethylene glycol acid or -polyethylene glycol diacid to amino-functionalized PS (PEG-PS)—combine the advantages of liquid-phase synthesis (i.e., a homogeneous reaction environment) and solid-phase synthesis (an insoluble support). ^{13}C NMR measurements of POE-PS showed the polyoxyethylene chains to be more mobile than the PS matrix, with the highest T_1 spin-lattice relaxation times observed with POE of molecular weight 2000 to 3000. Other supports that have been developed that show improved solvation properties and/or are applicable to organic synthesis include polyethylene glycol polyacrylamide (PEGA), cross-linked acrylate ethoxylate resin (CLEAR), and augmented surface polyethylene prepared by chemical transformation (ASPECT). As the solid-phase

method has expanded to include organic-molecule and library syntheses, the diversity of supports will enhance the efficiency of these new applications.

Successful syntheses of problematic sequences can be achieved by manipulation of the solid support. In general, the longer the synthesis, the more polar the peptide/resin will become (Sarin et al., 1980). One can alter the solvent environment and enhance coupling efficiencies by adding polar solvents and/or chaotropic agents (Fields and Fields, 1994). Also, using a lower substitution level of resin to avoid interchain crowding can improve the synthesis (Tam and Lu, 1995). During difficult syntheses, deprotection of the Fmoc group can proceed slowly. By spectrophotometrically monitoring deprotection as the synthesis proceeds, one can detect problems and extend base-deprotection times and/or alter solvation conditions as necessary.

COUPLING REAGENTS

The classical examples of in situ coupling reagents are *N,N'*-dicyclohexylcarbodiimide (DCC) and the related *N,N'*-diisopropylcarbodiimide (Rich and Singh, 1979). The generality of carbodiimide-mediated couplings is extended significantly by the use of either 1-hydroxybenzotriazole (HOBT) or 1-hydroxy-7-azabenzotriazole (HOAt) as an additive, either of which accelerates carbodiimide-mediated couplings, suppresses racemization, and inhibits dehydration of the carboxamide side chains of Asn and Gln to the corresponding nitriles. Protocols involving benzotriazol-1-yl-oxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP), benzotriazol-1-yl-oxy-tris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP), 7-azabenzotriazol-1-yl-oxytris(pyrrolidino)phosphonium hexafluorophosphate (PyAOP), *O*-benzotriazol-1-yl-*N,N,N',N'*-tetramethyluronium hexafluorophosphate (HBTU), *O*-(7-azaben-

zotriazol-1-yl)-*N,N,N',N'*-tetramethyluronium hexafluorophosphate (HATU), and *O*-benzotriazol-1-yl-*N,N,N',N'*-tetramethyluronium tetrafluoroborate (TBTU) result in coupling kinetics even more rapid than that obtained with carbodiimides. Amino acid halides have also been applied to solid-phase peptide synthesis (SPPS). *N*^α-protected amino acid chlorides have a long history of use in solution synthesis. Fmoc-amino acid chlorides and fluorides react rapidly under SPPS conditions in the presence of HOBt/*N,N*-diisopropylethylamine (DIEA) and DIEA, respectively, with very low levels of racemization. For convenience, tetramethylfluoroformamidinium hexafluorophosphate (TFFH) can be used for automated preparation of Fmoc-amino acid fluorides. Amino acid fluorides have been found to be especially useful for the preparation of peptides containing sterically hindered amino acids, such as peptaibols. All of the coupling reagents and additives discussed here are commercially available (see Table 11.15.2).

SYNTHESIS OF MODIFIED RESIDUES AND STRUCTURES

Peptides of biological interest often include structural elements beyond the 20 genetically encoded amino acids. Particular emphasis has been placed on peptides containing phosphorylated or glycosylated residues or disulfide bridges. Incorporation of side-chain-phosphorylated Ser and Thr by solid-phase peptide synthesis (SPPS) is especially challenging, as the phosphate group is decomposed by strong acid and lost with base in a β-elimination process. Boc-Ser(PO₃phenyl₂) and Boc-Thr(PO₃phenyl₂) have been found to be useful derivatives, where hydrogen fluoride (HF) or hydrogenolysis cleaves the peptide/resin and hydrogenolysis removes the phenyl groups. Fmoc-Ser(PO₃Bzl,H) and Fmoc-Thr(PO₃Bzl,H) can be used in conjunction with Fmoc chemistry with some care. Alternatively, peptide/resins that were built up by Fmoc chemistry to include unprotected Ser or Thr side chains may be subject to “global” or post-assembly phosphorylation. Side-chain-phosphorylated Tyr is less susceptible to strong-acid decom-

position and is not at all base-labile. Thus, SPPS has been used to incorporate directly Fmoc-Tyr(PO₃methyl₂), Fmoc-Tyr(PO₃*t*Bu₂), Fmoc-Tyr(PO₃H₂), and Boc-Tyr(PO₃H₂). Phosphorylation may also be accomplished on-line, directly after incorporation of the Tyr, Ser, or Thr residue but prior to assembly of the whole peptide.

Methodology for site-specific incorporation of carbohydrates during chemical synthesis of peptides has developed rapidly. The mild conditions of Fmoc chemistry are more suited for glycopeptide syntheses than Boc chemistry, as repetitive acid treatments can be detrimental to sugar linkages. Fmoc-Ser, -Thr, -5-hydroxylysine (-Hyl), -4-hydroxyproline (-Hyp), and -Asn have all been incorporated successfully with glycosylated side chains. The side-chain glycosyl is usually hydroxyl-protected by either benzoyl or acetyl groups, although some SPPSs have been successful with no protection of glycosyl hydroxyl groups. Deacetylation and debenzoylation are performed with hydrazine/methanol prior to glycopeptide/resin cleavage or in solution with catalytic methoxide in methanol.

Disulfide-bond formation has been achieved on the solid-phase by air, K₃Fe(CN)₆, dithiobis(2-nitrobenzoic acid), or diiodoethane oxidation of free sulfhydryls, by direct deprotection/oxidation of Cys(acetamidomethyl) residues using thallium trifluoroacetate or I₂, by direct conversion of Cys(9-fluorenylmethyl) residues using piperidine, and by nucleophilic attack by a free sulfhydryl on either Cys(3-nitro-2-pyridinesulfonyl) or Cys(*S*-carboxymethylsulfonyl). The most generally applicable and efficient of these methods is direct conversion of Cys(acetamidomethyl) residues by thallium trifluoroacetate.

Intra-chain lactams are formed between the side-chains of Lys or Orn and Asp or Glu to conformationally restrain synthetic peptides, with the goal of increasing biological potency and/or specificity. Lactams can also be formed via side-chain-to-head, side-chain-to-tail, or head-to-tail cyclization (Kates et al., 1994). The residues used to form intra-chain lactams must be selectively side-chain deprotected, while all side-chain protecting groups of other residues remain intact. Selective deprotection is best achieved by using orthogonal side-chain protection, such as allyloxycarbonyl or 1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl protection for Lys and allyl or *N*-[1-(4,4-dimethyl-2,6-dioxocyclohexylidene)-3-methylbutyl]aminobenzyl protection for Asp/Glu in combination with an Fmoc/*t*Bu strategy. Cycli-

zation is carried out most efficiently with BOP in the presence of DIEA while the peptide is still attached to the resin.

The three-dimensional orthogonal protection scheme of Fmoc/*t*Bu/allyl protecting groups is the strategy of choice for head-to-tail cyclizations. An amide linker is used for side-chain attachment of a C-terminal Asp/Glu (which are converted to Asn/Gln) and the α -carboxyl group is protected as an allyl ester. For side-chain-to-head cyclizations, the N-terminal amino acid (head) can simply be introduced as an N ^{α} -Fmoc derivative while the peptide-resin linkage and the other side-chain protecting groups are stable to dilute acid or carry a third dimension of orthogonality.

PROTEIN SYNTHESIS

There are three general chemical approaches for constructing proteins. First is stepwise synthesis, in which the entire protein is synthesized one amino acid at a time. Second is "fragment assembly," in which individual peptide strands are initially constructed stepwise, purified, and finally covalently linked to create the desired protein. Fragment assembly can be divided into two distinct approaches: (1) convergent synthesis of fully protected fragments, and (2) chemoselective ligation of unprotected fragments. Third is "directed assembly," in which individual peptide strands are constructed stepwise, purified, and then noncovalently driven to associate into protein-like structures. Combinations of the three general chemical approaches may also be employed for protein construction.

Convergent synthesis utilizes protected peptide fragments for protein construction (Albericio et al., 1997). The advantage of convergent protein synthesis is that fragments of the desired protein are first synthesized, purified, and characterized, ensuring that each fragment is of high integrity; these fragments are then assembled into the complete protein. Thus, cumulative effects of stepwise synthetic errors are minimized. Convergent synthesis requires ready access to pure, partially protected peptide segments, which are needed as building blocks. The application of solid-phase synthesis to prepare the requisite intermediates depends on several levels of selectively cleavable protecting groups and linkers. Methods for subsequent solubilization and purification of the protected segments are nontrivial. Individual rates for coupling segments are substantially lower than for activated amino acid species by stepwise synthesis, and there is always a risk of racemization at the C-terminus of each segment. Care-

ful attention to synthetic design and execution may minimize these problems.

As an alternative to the segment condensation approach, methods have been developed by which unprotected peptide fragments may be linked. "Native chemical ligation" results in an amide bond being generated between peptide fragments (Muir et al., 1997). A peptide bearing a C-terminal thioacid is converted to a 5-thio-2-nitrobenzoic acid ester and then reacted with a peptide bearing an N-terminal Cys residue (Dawson et al., 1994). The initial thioester ligation product undergoes spontaneous rearrangement, leading to an amide bond and regeneration of the free sulfhydryl on Cys. The method was later refined so that a relatively unreactive thioester can be used in the ligation reaction (Dawson et al., 1997; Ayers et al., 1999). Safety-catch linkers are used in conjunction with Fmoc chemistry to produce the necessary peptide thioester (Shin et al., 1999).

SIDE-REACTIONS

The free N^α-amino group of an anchored dipeptide is poised for a base-catalyzed intramolecular attack of the C-terminal carbonyl. Base deprotection of the Fmoc group can thus release a cyclic diketopiperazine while a hydroxymethyl-handle leaving group remains on the resin. With residues that can form *cis* peptide bonds, e.g., Gly, Pro, *N*-methylamino acids, or D-amino acids, in either the first or second position of the (*C* → *N*) synthesis, diketopiperazine formation can be substantial. The steric hindrance of the 2-chlorotrityl linker may minimize diketopiperazine formation of susceptible sequences during Fmoc chemistry.

The conversion of side-chain protected Asp residues to aspartimide residues can occur by repetitive base treatments. The cyclic aspartimide can then react with piperidine to form the α- or β-piperidide or α- or β-peptide. Aspartimide formation can be rapid, and is dependent upon the Asp side-chain protecting group. Sequence dependence studies of Asp(O*t*Bu)-X peptides revealed that piperidine could induce aspartimide formation when X = Arg(2,2,5,7,8-pentamethylchroman-6-sulfonyl; Pmc), Asn(triphenylmethyl; Trt), Asp(O*t*Bu), Cys(Acm), Gly, Ser, Thr, and Thr(*t*Bu) (Lauer et al., 1995). Aspartimide formation can also be conformation-dependent. This side-reaction can be minimized by including 0.1 M HOBt in the piperidine solution (Lauer et al., 1995), or by using an amide backbone protecting group (i.e., 2-hydroxy-4-methoxybenzyl) for the resi-

due in the X position of an Asp-X sequence (Quibell et al., 1994).

Cys residues are racemized by repeated piperidine deprotection treatments during Fmoc SPPS. Racemization of esterified (C-terminal) Cys can be reduced by using 1% 1,8-diazabicyclo[5.4.0]undec-7-ene in *N,N*-dimethylformamide (DMF). Additionally, the steric hindrance of the 2-chlorotrityl linker minimizes racemization of C-terminal Cys residues. When applying protocols for Cys internal (not C-terminal) incorporation which include phosphonium and aminium salts as coupling agents, as well as preactivation in the presence of suitable additives and tertiary amine bases, significant racemization is observed. Racemization is generally reduced by avoiding preactivation, using a weaker base (such as collidine), and switching to the solvent mixture DMF-dichloromethane (DCM) (1:1). Alternatively, the pentafluorophenyl ester of a suitable Fmoc-Cys derivative can be used.

The combination of side-chain protecting groups and anchoring linkages commonly used in Fmoc chemistry are simultaneously deprotected and cleaved by TFA. Cleavage of these groups and linkers results in liberation of reactive species that can modify susceptible residues, such as Trp, Tyr, and Met. Modifications can be minimized during TFA cleavage by utilizing effective scavengers. Three efficient cleavage "cocktails" quenching reactive species and preserving amino acid integrity, are TFA-phenol-thioanisole-1,2-ethanedithiol-H₂O (82.5:5:5:2.5:5) (reagent K) (King et al., 1990), TFA-thioanisole-1,2-ethanedithiol-anisole (90:5:3:2) (reagent R) (Albericio et al., 1990), and TFA-phenol-H₂O-triisopropylsilane (88:5:5:2) (reagent B) (Solé and Barany, 1992). The use of Boc side-chain protection of Trp also significantly reduces alkylation by Pmc or 2,2,4,6,7-pentamethyldihydro-benzofuran-5-sulfonyl (Pbf) groups.

PURIFICATION AND ANALYSIS OF SYNTHETIC PEPTIDES

Each synthetic procedure has limitations, and even in the hands of highly experienced workers, certain sequences defy facile preparation. The maturation of high-performance liquid chromatography (HPLC) has been a major boon to modern peptide synthesis, because the resolving power of this technique facilitates removal of many of the systematic low-level by-products that accrue during chain assembly and upon cleavage. Peptide purification is most commonly achieved by reversed-phase HPLC

(RP-HPLC; UNIT 10.14). Either alternatively to or in tandem with RP-HPLC, ion-exchange HPLC (UNIT 10.10) and gel-filtration HPLC (UNIT 10.9) can be used for isolation of desired peptide products. The progress of peptide purification can be monitored rapidly by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) or ion-trap electrospray MS (UNITS 10.21 & 10.22).

The homogeneity of synthetic materials should be checked by at least two chromatographic or electrophoretic techniques—e.g., RP-HPLC (UNIT 10.14), ion-exchange HPLC (UNIT 10.10), and capillary zone electrophoresis (UNIT 10.20). Also, determination of a molecular ion by MS (UNIT 10.21) using a mild ionization method is important for proof of structure. Synthetic peptides must be checked routinely for the proper amino acid composition, and in some cases sequencing data are helpful. The PSRC studies (see discussion of Development of Solid-Phase Peptide Synthesis Methodology) have allowed for a side-by-side comparison of a variety of analytical techniques. Efficient characterization of synthetic peptides best been obtained by a combination of RP-HPLC and MS, with sequencing by either Edman degradation sequence analysis or tandem MS (UNIT 10.21) being used to identify the positions of modifications and deletions. Proper peptide characterization by multiple techniques is essential.

Synthetic Peptides for Production of Antibodies that Recognize Intact Proteins

Antibodies that recognize intact proteins can be produced through the use of synthetic peptides based on short stretches of the protein sequence, without first having to isolate the protein. The procedure for selecting stretches of protein sequence likely to be antigenic is relatively straightforward. However, no procedure will identify a single sequence guaranteed to be effective, nor will it usually identify the best single sequence to use. Rather, several sequences will be identified that have a higher-than-average probability of producing an effective antigen.

The steps to produce an effective antibody include: (1) designing the peptide sequence based on the sequence of the protein; (2) synthesizing the peptide; (3) preparing the immunogen either by coupling the synthetic peptide to a carrier protein or through the use of a multiple antigenic peptide (MAP); (4) immunizing the host animal; (5) assaying antibody titer in the host animal's serum; and (6) obtaining the antiserum and/or isolating the antibody. This unit covers steps 1 and 3; step 2 requires a laboratory with expertise in peptide synthesis. Peptide synthesis services are widely available both academically and commercially.

The best method to select potentially effective sequences is via a computer-assisted strategy (see Basic Protocol 1). An alternative manual method is also described (see Alternate Protocol 1) but is not recommended to replace the use of algorithms if there is a choice. A small synthetic peptide is usually insufficiently immunogenic on its own, and two methods have been developed to solve this problem. The first (see Basic Protocol 2) involves chemically coupling the synthetic peptide to a carrier protein to boost the immune response. The second method (see Alternate Protocol 2) entails direct synthesis of a MAP covalent multimer of the simple peptide sequence. Both methods have proven effective and it is a matter of personal preference which to use. Coupling to a carrier protein requires additional chemical manipulations after synthesis of the peptide, while the MAP is complete and ready for immunization at the conclusion of the synthetic protocol. Disadvantages of MAPs are that they are more difficult to produce homogeneously and to analyze postsynthetically. They also may be more prone to insolubility problems.

A carrier protein is a relatively large molecule capable of stimulating an immune response independently. A synthetic peptide coupled to a carrier protein acts as a hapten and produces antibodies specific for the hapten (antibodies against the carrier protein are also produced). The most commonly used carrier proteins are keyhole limpet hemocyanin (KLH) and bovine or rabbit serum albumin (BSA or RSA). KLH is usually preferred, because it tends to elicit a stronger immune response and is evolutionarily more remote from mammalian proteins. A common problem with KLH, however, has been its solubility. Pierce Chemical Company sells a preparation of KLH purported to have better solubility properties (see below).

Alternatively, peptides can be coupled to carrier proteins through either their amino (see Alternate Protocol 3) or carboxyl groups (see Alternate Protocol 4). These two alternate protocols are not recommended as a first choice for coupling, but are included because they have been used successfully and may be advantageous for certain special applications discussed in the Commentary. Also presented are methods for assaying free sulfhydryl content and for reducing disulfide bonds in synthetic peptides (see Support Protocols 1 and 2).

Once the coupling procedure has been performed, it is possible to determine the approximate degree of coupling by amino acid analysis (see Support Protocol 3). However, in most instances this is unnecessary and the product can be used directly.

COMPUTER-ASSISTED SELECTION OF APPROPRIATE ANTIGENIC PEPTIDE SEQUENCES

An antibody produced in response to a simple linear peptide will most likely recognize a linear epitope in a protein. Furthermore, that epitope must be solvent-exposed to be accessible to the antibody. The general features of protein structure that correspond to these criteria are turns or loop structures, which are generally found on the protein surface connecting other elements of secondary structure, and areas of high hydrophilicity, especially those containing charged residues. As a consequence, computer algorithms that predict protein hydrophilicity and tendency to form turns are very useful. Several analytic programs or algorithms that attempt to do this have been developed. Although the choice of method may rely on availability or personal preference, there tends to be a high level of agreement among them. As stated earlier, none of the methods will identify the one single sequence guaranteed to produce an effective antibody against any given protein. Rather, the methods will offer several good candidates, one or several of which can be used.

Many of these algorithms may already be available on a local computer system. They are included in many commercial software packages such as GCG (Genetics Computer Group; see *APPENDIX 4*). The ExPASy Web site of the University of Geneva offers free access to a variety of different programs over the Internet at <http://expasy.org/tools>.

The following protocol utilizes the hydropathy index developed by Kyte and Doolittle (1982) and the secondary structure prediction method for β turns developed by Chou and Fasman (1974) found in the tool "ProtScale" at the ExPASy Internet address.

1. Using the selected algorithms, compute the hydropathy index and the tendency for β -turns of the protein sequence. Use a window size of 7 or 9 and give equal weight to each amino acid. Record the results in either graphical or numerical form, or both.

As an example, the graphical representation of these results for the protein sequence shown in Figure 11.16.1 is presented in Figure 11.16.2.

A window size determines the number of amino acids to be used in computing a value for the amino acid at the center of the window. For example, a window size of 9 includes 4

10	20	30	40	50	60

amino acids on each side of the central amino acid. The value computed for the central amino acid is the simple average of the values for each amino acid in the window.

2. Compare the results of the two analyses and look for areas of sequence that are high in turn tendency and high in hydrophilicity (low in hydrophobicity).

In Figure 11.16.2, these areas correspond to positive peaks in the Chou-Fasman analysis and negative peaks in the Kyte-Doolittle analysis. The three best areas in terms of amplitude and correlation are shaded. These correspond to the sequences underlined in Figure 11.16.1. (Note the alignment of these peak optima as compared to the peaks around residue 300.)

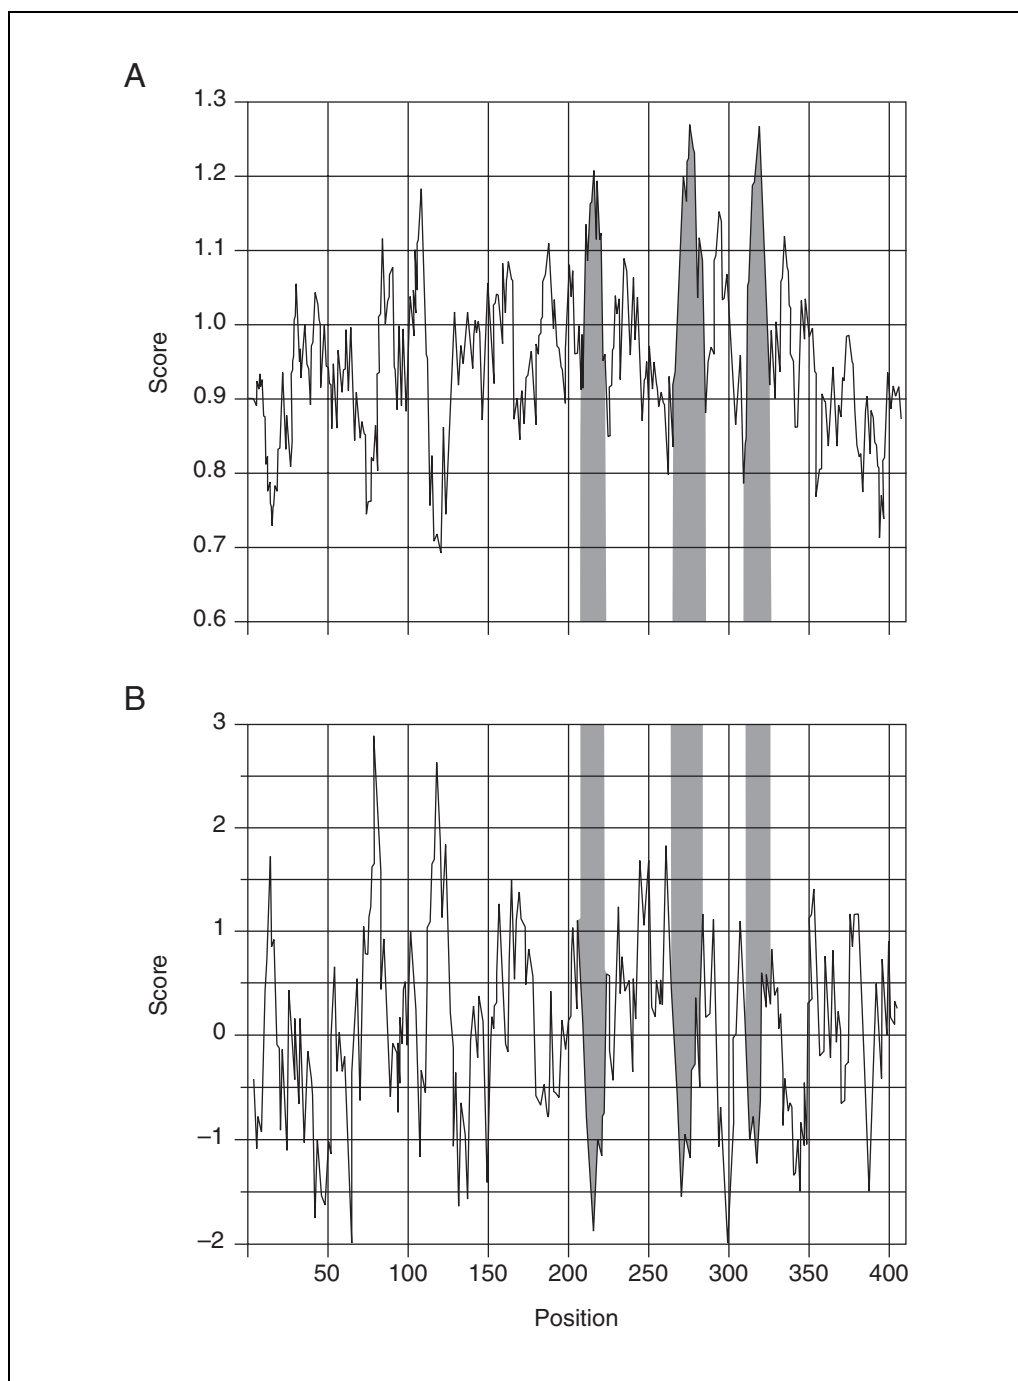

Figure 11.16.2 Graphical representation of the results generated by a computer algorithm for the sequence in Figure 11.16.1, analyzed by the method presented in Basic Protocol 1. The shaded areas represent three regions in the sequence meeting criteria for selection as potential immunogens. **(A)** Analysis for β turns (Chou and Fasman, 1974). **(B)** Analysis for hydrophobicity (Kyte and Doolittle, 1982).

3. Examine the sequences for glycosylation site motifs and discard any sequences that contain them unless it is known that the protein is not glycosylated.

Amino acids in glycosylated regions may be shielded from presentation to an antibody by masking carbohydrates.

Amino-linked carbohydrate chains can occur at Asn-X-Ser or Asn-X-Thr sequences. Hydroxyl-linked carbohydrate chains do not appear to have a set motif. A program to assist in the prediction of mucin-type GalNAc O-glycosylation sites in mammalian lipoproteins is found in the tool "NetOGlc" at the ExPASy site (<http://expasy.org/tools>). However, before using read the documentation carefully and keep in mind that such prediction methods cannot always be successful.

4. Select the best sequences resulting from this analysis to use as antigenic peptides. These are sequences where the largest positive values (peaks with positive deflection) for turn propensity correspond in position to the largest negative values (peaks with negative deflection) for hydrophobicity. The values obtained in these analyses are relative and dependent on the individual protein's composition, so it is not possible to set an arbitrary minimum value as a cutoff for rejecting a particular peak. Rather, always select the peaks of greatest magnitude in any given sequence. In addition, the immediate amino-terminal and carboxyl-terminal regions of proteins are often exposed to solvent. If these areas appear to be hydrophilic in nature, they are also acceptable candidates. Thus each analysis may provide several potential sequences. How many peptides to make (see Anticipated Results) is a matter of individual choice.

ALTERNATE PROTOCOL 1

MANUAL INSPECTION TO SELECT APPROPRIATE PEPTIDE SEQUENCES

If computer algorithms are not available, it is possible to select potential sequences by manual inspection. Although there is no evidence that a manual method is any less effective than the use of computer algorithms, there is a greater probability of overlooking potentially important areas of sequence. It is therefore recommended that computer analysis be used whenever it is available. Although it can be done, it would be very time consuming and labor intensive to manually calculate values for every overlapping peptide offset by a single amino acid in the same way that the algorithms do. For this reason, areas rich in polar residues are selected for manual calculation of hydrophilicity and turn propensity.

1. Visually inspect the protein sequence and select areas that contain at least two to three charged residues (Lys, Arg, His, Asp, Glu) within a 10- to 15-residue span.

If this criterion cannot be met, select sequences with the greatest number of charged residues.

2. From the sequences identified in step 1, select a subset of sequences that are the highest in Ser, Thr, Asn, Gln, Pro, and Tyr content.
3. Calculate average hydrophilicity and turn propensity for each amino acid in the selected sequences using the values given in Table 11.16.1 and a window of 9 residues (see Basic Protocol 1, step 1).

Be sure to include the residues flanking the selected sequence for calculation of values for the residues at the ends of the selected sequence. In other words, do not use different size windows.

4. Plot the values for each amino acid of a chosen sequence.

Sequences whose optimal values for hydrophilicity and turn propensity correspond (as in Fig. 11.16.2) are considered good candidates.

5. Inspect sequences for glycosylation motifs and discard these candidates (see Basic Protocol 1, step 3).

Table 11.16.1 Hydrophobic and β -Turn Indices of Amino Acids

Amino acid	Symbols	Hydrophobicity value ^a	β -turn propensity ^b
Arginine	Arg (R)	-4.5	0.95
Lysine	Lys (K)	-3.9	1.01
Aspartic acid	Asp (D)	-3.5	1.46
Glutamic acid	Glu (E)	-3.5	0.74
Asparagine	Asn (N)	-3.5	1.56
Glutamine	Gln (Q)	-3.5	0.98
Histidine	His (H)	-3.2	0.95
Proline	Pro (P)	-1.6	1.52
Tyrosine	Tyr (Y)	-1.3	1.14
Tryptophan	Trp (W)	-0.9	0.96
Serine	Ser (S)	-0.8	1.43
Threonine	Thr (T)	-0.7	0.96
Glycine	Gly (G)	-0.4	1.56
Alanine	Ala (A)	1.8	0.66
Methionine	Met (M)	1.9	0.60
Cysteine	Cys (C)	2.5	1.19
Phenylalanine	Phe (F)	2.8	0.60
Leucine	Leu (L)	3.8	0.59
Valine	Val (V)	4.2	0.50
Isoleucine	Ile (I)	4.5	0.47

^aKyte and Doolittle (1982).^bChou and Fasman (1974).

Amino acids of glycosylated regions may be masked in native proteins, so an antibody raised against them would be ineffective.

6. Select the best sequences (see Basic Protocol 1, step 4 for criteria), choosing a high turn-propensity-to-hydrophobicity ratio.

DESIGNING A SYNTHETIC PEPTIDE FOR COUPLING TO A CARRIER PROTEIN

Although there is no direct evidence to show that the state of the termini of the peptide affects its ability to produce antibodies that will react with the protein, most procedures suggest that the termini of the peptide should mimic their native state. Thus, sequences whose terminal residues normally are in peptide linkage in the protein can have their amino-terminal and carboxyl-terminal groups modified by acetylation and amidation, respectively, during synthesis.

Modification of the amino or carboxyl termini will decrease the polarity of the peptide in solution and could have a significant effect on the peptide's solubility. If the peptide lacks sufficient protonatable side chains, modification of the termini can be omitted. A general rule to predict solubility is that the total number of charges at a given pH should be at least 20% of the number of residues in the peptide.

1. Choose a sequence of 10 to 15 amino acid residues for the synthetic peptide.

Longer peptides are more difficult and expensive to make, and they are usually unnecessary.

BASIC PROTOCOL 2

Immunology

11.16.5

Try to choose a stretch of sequence that contains some charged residues such as Arg, Lys, His, Glu, and Asp. In addition to the high likelihood of these amino acids being located on the surface of the protein, they aid handling of the synthetic product by promoting solubility.

- 2a. *If the selected sequence does not contain an internal cysteine:* Place a cysteine on either the amino or carboxyl terminus for use in coupling to a carrier protein with a heterobifunctional cross-linking reagent such as MBS, *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (see Basic Protocol 3).

*Cross-linking with heterobifunctional reagents is the recommended procedure for most peptides (see Basic Protocol 3). As an alternative to using a chemical cross-linking reagent, any peptide, regardless of amino acid content, can also be photochemically linked to a carrier protein if *p*-benzoyl benzoic acid is added to the peptide during synthesis (see Alternate Protocol 5). Although photochemical cross-linking is effective, it is not widely used.*

If the sequence includes the immediate amino or carboxyl terminal sequence of the protein, the cysteine should be placed on the end that would normally be engaged in the internal peptide bond. For sequences internal to the protein, the cysteine may be placed at either end according to the preference of the synthetic chemist. However, if amino-terminal capping (acetylation) is used after the coupling of each amino acid during synthesis, it is preferable to place the cysteine on the amino-terminal end of the peptide since then only the full-length peptide will contain the cysteine residue. In this way, if synthetic difficulties are encountered, only the full-length peptide will couple to the carrier. If placed on the carboxyl terminal end, the cysteine residue tends to racemize during synthesis unless a chlorotriyl resin is used. However, this should not have an effect on the rest of the peptide or the generation of antibodies.

- 2b. *If the sequence contains an internal cysteine residue:* Do not add a terminal cysteine for MBS cross-linking. Rather, use an alternative coupling procedure (see Alternate Protocols 3, 4, or 5) or synthesize a multiple antigenic peptide (MAP; see Alternate Protocol 2).

Internal cysteine sulfhydryl groups will also cross-link to the carrier protein, and multiple cysteines will result in a peptide attached at multiple points. If the sulfhydryl will eventually be important for antibody recognition of the protein, the immunization may not produce effective antibodies. Furthermore, the additional constraint produced by the existence of multiple points of coupling may affect the ultimate ability of the antibody to recognize the protein.

- 3a. *For sequences whose terminal residues are in peptide linkage within the protein:* If the peptide is coupled using a heterobifunctional reagent such as MBS (see Basic Protocol 3), modify the amino and carboxyl ends by acetylation and amidation, respectively, during the synthetic procedure. If coupling is performed with a homobifunctional reagent that reacts with amino groups such as glutaraldehyde (see Alternate Protocol 3) or by the photochemical method (see Alternate Protocol 5), only amidate the carboxyl terminus. If coupling is performed with EDC (see Alternate Protocol 4), only acetylate the amino terminus.

- 3b. *For sequences that are amino or carboxyl terminal to the protein:*

- i. *If the sequence is the immediate amino or carboxyl terminal sequence of the protein and the peptide will be coupled with a heterobifunctional reagent such as MBS (see Basic Protocol 3), leave the end that is not in peptide linkage (and the end that does not contain the additional cysteine residue for MBS coupling) as the free amino or carboxyl group unless it is known that they are normally blocked.*
- ii. *If the sequence is the immediate amino terminal sequence of the protein and the peptide will be coupled with a homobifunctional reagent that reacts with amino*

Figure 11.16.3 Representation of a four-branched multiple antigenic peptide (MAP). The MAP core is usually synthesized with a β -alanine residue attached to the solid phase support followed by a scaffold of lysine residues. The first lysine residue, attached through its α -carboxyl group to β -alanine, provides two primary amino groups (α and ϵ) for chain elongation. The next level of the lysine scaffold consists of two lysine residues which in turn provide four primary amino groups for chain elongation. MAPs with eight branches are formed by providing one additional layer of lysine to that depicted here.

groups such as glutaraldehyde (see Alternate Protocol 3) or photochemically (see Alternate Protocol 5), amidate the C-terminus.

- iii. If the sequence is the immediate carboxyl terminal sequence of the protein and the peptide will be coupled with glutaraldehyde (see Alternate Protocol 3) or photochemically (see Alternate Protocol 5), leave both termini free.
4. If the peptide will be coupled with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC; see Alternate Protocol 4), block the amino terminus by acetylation.

This should be done even if the sequence is at the immediate amino terminus of the protein, since treatment with EDC can result in the production of covalent multimers of the peptide through reaction with the N-terminal amino group. Some procedures recommend using citraconylation to temporarily protect the amino group. However, this also adds a free carboxyl group that could result in multiple site attachment of the peptide to the carrier.

DESIGNING A SYNTHETIC MULTIPLE ANTIGENIC PEPTIDE

A multiple antigenic peptide (MAP; Posnett et al., 1988; Tam, 1988) is an effective alternative to coupling a simple linear peptide to a carrier protein. MAPs are covalent constructs consisting of a simple peptide sequence synthesized on a branched core (Fig. 11.16.3) with one copy of the peptide sequence on each of four or eight branches. One advantage of a MAP is that it is suitable for use as an immunogen at the conclusion of the synthetic process. On occasion, MAPs have produced effective protein antibodies when the conventional peptide coupled to carrier protein has not. Thus, MAPs represent an effective alternative approach for antiserum production.

1. Select a sequence between 10 and 15 residues in length.

Longer sequences are unnecessary and increase the probability of synthetic problems. The presence of internal cysteine residues are not a concern with MAPs, but if present, take precautions to keep them reduced.

2. Synthesize the MAPs utilizing a four-branch core.

Synthesize the MAP core de novo, or purchase resins for solid-phase peptide synthesis with four- or eight-branched cores (available commercially from Advanced ChemTech, Novabiochem, Applied Biosystems, AnaSpec, and Bachem Bioscience). Eight-branched cores are suitable if the peptide is no more than 12 to 14 residues and has a high degree of hydrophilicity. There are more synthetic problems with eight-branched MAPs, presumably due to the higher density of structure during synthesis: they are more difficult to characterize and probably raise a diverse antibody population against some synthetic artifacts (see Mints et al., 1997).

3. *Optional.* If the selected sequence was not the amino terminus of the protein, acetylate the new amino terminus.

In the case of a MAP, the carboxyl terminus will remain in covalent linkage to the branched core.

4. Use the MAP directly as an immunogen.

Coupling to a carrier protein as described in Basic Protocol 3 is usually not necessary.

COUPLING SYNTHETIC PEPTIDES TO A CARRIER PROTEIN USING A HETEROBIFUNCTIONAL REAGENT

If the synthetic peptide was designed with a cysteine residue at one terminus (see Basic Protocol 2, step 2a), the following procedure should be followed for coupling to keyhole limpet hemocyanin (KLH) or other carrier proteins. Care must be taken to assure that the cysteine sulfhydryl group has remained reduced. Under normal synthetic conditions, if the peptide was lyophilized and stored dry immediately after synthesis, the sulfhydryl usually remains in the reduced state. The presence of free sulfhydryl groups in the peptide can be determined with Ellman's reagent (see Support Protocol 1) just prior to use; alternatively, high-resolution mass spectrometry can be used. If reduction is needed, follow the cysteine reduction procedure (see Support Protocol 2) before starting the coupling process.

The reagent most commonly used for this purpose is *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS). However, several related reagents (all available from Pierce) offer some additional features. Sulfo-MBS (Pierce) is a water-soluble alternative to MBS. Succinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (SMCC) and its sulfonated analog sulfo-SMCC provide the same chemistry with a more pH-stable maleimide (see step 1). The MBS and SMCC reagents can be used interchangeably in this protocol (the sulfo reagents can be dissolved in aqueous solution, while the others must be dissolved in an organic solvent; the concentrations listed are appropriate for all four).

Materials

- Keyhole limpet hemocyanin (KLH; Pierce, Sigma, Calbiochem, or Boehringer Mannheim)
- 0.01 M sodium phosphate buffer, pH 7.5 (*APPENDIX 2*)
- 10 mg/ml MBS in fresh *N,N*-dimethylformamide (DMF)
- 0.05 M and 0.1 M sodium phosphate buffer, pH 7.0 (*APPENDIX 2*)
- Synthetic peptide with a reduced cysteine residue at either the N- or C-terminus
- 6 M guanidine-HCl (see recipe)
- Small glass vial with flat bottom
- ~0.9 × 15-cm gel filtration column with Sephadex G-25 or G-50 (Pharmacia Biotech) or Bio-Gel P2 or P4 (Bio-Rad) resin; *or* prepacked PD-10 column (Pharmacia Biotech)
- Additional reagents and equipment for gel filtration chromatography (*UNIT 10.9*)

NOTE: Do not use Tris or other buffers with primary amino groups in this procedure.

CAUTION: MBS is a moisture-sensitive irritant. Read the Material Safety Data Sheet before use.

1. Dissolve 5 mg KLH in ~0.5 ml of 0.01 M sodium phosphate buffer, pH 7.5, in a small, flat-bottomed vial.
A pH range of 7.0 to 7.5 offsets competing reactions. Although the unprotonated form of the amine reacts with the N-hydroxysuccinimide ester and would be optimal at pH >8.0, hydrolysis of the ester bond and reaction of the maleimide group with amines is enhanced at higher pH.
2. Add 100 µl of 10 mg/ml MBS/DMF solution and stir gently with a micro stir-bar 30 min at room temperature.
A small amount of precipitate may form during this procedure and is acceptable. However, if the precipitate is large, perform the procedure again with fresh components.
As an alternative to performing this coupling procedure from scratch, it is possible to purchase MBS-activated KLH (Pierce; Boehringer Mannheim) or kits containing MBS-activated KLH and an alternate MBS-activated protein for use in ELISA assays (Pierce).
3. Separate MBS-activated KLH from free MBS on a ~0.9 × 15-cm gel filtration column, equilibrating and eluting the column with 0.05 M sodium phosphate buffer, pH 7.0. Collect 0.5-ml fractions and read their absorbance at 280 nm (*UNIT 10.9*).
The first peak to elute is the KLH-MBS conjugate. These fractions may appear cloudy. The second peak is uncoupled MBS.
4. Pool the KLH-MBS conjugate fractions in a separate tube.
5. Dissolve 5 mg of the synthetic peptide in 0.01 M sodium phosphate buffer, pH 7.0, immediately prior to use. If the peptide is poorly soluble, use 6 M guanidine-HCl.
Maleimide groups react specifically with sulfhydryls at slightly acid to neutral pH.
6. Add the peptide solution to the KLH-MBS conjugate. Stir gently with a micro stir-bar 3 hr at room temperature.
The coupling may be continued overnight.
7. Dialyze against 4 liters distilled water overnight at 4°C. Use for immunizations within 24 hr.

ASSAY OF FREE SULFHYDRYLS WITH ELLMAN'S REAGENT

Free sulfhydryl content of a peptide can be quantitatively determined with Ellman's reagent, 5,5'-dithio-bis(2-nitrobenzoic acid). The molar extinction coefficient at 412 nm of thionitrobenzoate, the colored species generated when the reagent reacts with a free thiol, is 14,150 in 0.1 M sodium phosphate buffer (see Fig. 11.16.4). The sensitivity of the reaction is in the low nmol/ml range for sulfhydryl groups, making it well suited for synthetic peptides. By dry weight most synthetic peptides are only ~60% to 75% peptide, the remainder consisting of counterions and water of hydration. Amino acid analysis (see UNIT 11.9) is needed to establish the actual peptide content unambiguously, but such precise measurement is not usually necessary for qualitative evaluation of the free sulfhydryl content of a peptide sample.

Materials

Cysteine standard stock solution (see recipe)
0.1 M sodium phosphate, pH 8.0 (APPENDIX 2)
Peptide to be assayed
Ellman's reagent solution (see recipe)
13 × 100-mm glass test tubes

1. Prepare a cysteine standard curve by adding 25 μ l, 50 μ l, 100 μ l, 150 μ l, 200 μ l, and 250 μ l of cysteine standard stock solution to separate 13 × 100-mm tubes. Add \leq 250 μ l of each peptide to be tested to separate tubes. Bring the volume in each tube to 250 μ l with 0.1 M sodium phosphate, pH 8.0. Add 250 μ l of 0.1 M sodium phosphate, pH 8.0, to a blank tube.

The cysteine content of the peptide to be assayed should fall within the range of the standard curve (37.5 to 375 nmol).

2. Add 50 μ l Ellman's reagent solution and 2.5 ml of 0.1 M sodium phosphate, pH 8.0, to each tube. Mix and incubate 15 min at room temperature.
3. Measure absorbance at 412 nm (A_{412}).
4. Plot the A_{412} values of the standards after subtracting the value for the blank to produce a standard curve. Use this curve to determine the free sulfhydryl content of the peptides.

REDUCING CYSTEINE GROUPS IN PEPTIDES

When a peptide is synthesized with a terminal cysteine residue to be used for coupling with MBS (see Basic Protocol 3), the cysteine must be in the reduced state (present as free -SH rather than as a disulfide) in order to participate in the reaction with the coupling reagent. If peptides are lyophilized immediately after extraction from the resin cleavage cocktail or reversed-phase HPLC and used immediately after reconstitution, oxidation of cysteine side chains is usually not a problem. However, if oxidation to disulfides has occurred, the peptide can be reduced prior to use with the protocol presented here.

Dithiothreitol (DTT) is preferred to 2-mercaptoethanol (2-ME) as a reducing agent because its lower redox potential allows it to be effective at lower concentrations, and the reaction goes to completion because formation of the six-membered ring containing an internal disulfide is energetically favorable (see Fig. 11.16.4).

To determine if reduction is necessary, quantitate the level of free sulfhydryl groups with Ellman's reagent (see Support Protocol 1).

Additional methods for reducing disulfides include using sodium borohydride (Gailit, 1993) and Tris(2-carboxyethyl)phosphine (TCEP; Getz et al., 1999).

Materials

Synthetic peptide
0.1 M sodium phosphate, pH 8.0 (*APPENDIX 2*)
1 M aqueous dithiothreitol (DTT)
1 N HCl

100- or 250- μ l polypropylene tubes
Nitrogen gas source

Additional reagents and equipment for reversed-phase HPLC of peptides (see *UNIT 10.14*)

1. Dissolve 5 to 10 mg of peptide in 0.1 M sodium phosphate, pH 8.0.
2. Add 100 μ l of 1 M DTT.
3. Flush nitrogen over the surface of the liquid, seal the tube, and incubate 1 hr at 37°C.
4. Acidify with 1 N HCl and desalt by reversed-phase HPLC (*UNIT 10.14*).
5. Pool peptide fractions and lyophilize. Store lyophilized at 4°C until ready to use (up to several days).

The oxidation state of the peptide can usually be followed by analytical monitoring of its elution position on reversed-phase HPLC. Disulfide-linked dimers of peptides generally elute later than the monomeric peptide.

ALTERNATE PROTOCOL 3

COUPLING SYNTHETIC PEPTIDES TO A CARRIER PROTEIN USING A HOMOBIFUNCTIONAL REAGENT

The available homobifunctional reagents couple compounds through primary amino groups. Therefore, peptides with internal lysine residues should not be used in this procedure. The reagent most commonly used for this procedure is glutaraldehyde, but it should not be used with peptides containing internal Cys, Tyr, or His residues. Other homobifunctional cross-linking reagents that can be used in the same way as glutaraldehyde, but do not cross react with Cys, Tyr, or His residues, are also available: disuccinimidyl suberate (DSS), disuccinimidyl glutarate (DSG), and bis(sulfosuccinimidyl) suberate (BS3; all available from Pierce). However, these reagents are not widely employed for coupling peptides to proteins and are not considered the method of choice, and methods for their use have not been formalized. This is probably because coupling of the synthetic peptide to itself and aggregation of the carrier protein can occur with homobifunctional reagents such as these. Glutaraldehyde, on the other hand, although also subject to this limitation, has generally been used successfully.

Additional Materials (*also see Basic Protocol 3*)

50 mM sodium borate buffer, pH 8.0: adjust pH with HCl
Glutaraldehyde solution (see recipe)
1 M glycine in 50 mM sodium borate buffer, pH 8.0

NOTE: Do not use Tris or other buffers with primary amino groups in this procedure.

1. Dissolve 5 mg KLH in ~1.0 ml of 50 mM sodium borate buffer, pH 8.0.
2. Add 5 mg synthetic peptide.
3. Slowly add 1 ml fresh glutaraldehyde solution with gentle mixing at room temperature. Allow to react for an additional 2 hr with gentle mixing.

Formation of a yellowish color or milkiness is normal and does not affect the sample.

4. Add 0.25 ml of 1 M glycine to bind unreacted glutaraldehyde.

A darker yellow to brown color may develop.

5. Dialyze the reaction mixture overnight at 4°C against 4 liters of 50 mM sodium borate buffer, pH 8.0, and then overnight against water. Use immediately.

COUPLING SYNTHETIC PEPTIDES TO A CARRIER PROTEIN USING A CARBODIIMIDE

**ALTERNATE
PROTOCOL 4**

This procedure couples amino groups to carboxyl groups by way of activation of the carboxyl group with a water-soluble carbodiimide. Since the procedure is most easily performed in one step, peptides containing internal Asp, Glu, Lys, Tyr, or Cys residues should not be used. Also, in order to avoid making polymers of the peptide, the amino terminus should be blocked by acetylation during synthesis (see Basic Protocol 2). While this method has been used successfully, it is not considered to be the method of choice except in special situations.

Additional Materials (also see *Basic Protocol 3*)

- 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC; Pierce), used fresh or stored desiccated and frozen
- 0.1 N HCl

NOTE: Buffers containing amino or carboxyl groups should not be used in this procedure. According to some reports, buffers containing phosphate groups should also be avoided. Water is the safest choice as a solvent.

1. Dissolve 5 mg synthetic peptide in 1 ml water.
2. Add 25 mg EDC and carefully adjust pH to 4.0 to 5.0 by adding small amounts of 0.1 N HCl. Allow to react for 5 to 10 min at room temperature with gentle mixing.
pH paper suffices to monitor this adjustment.
3. Dissolve 5 mg KLH in 0.5 ml water and add to solution from step 2. React 2 hr at room temperature with gentle mixing.
4. Dialyze against 4 liters of water overnight at 4°C. Use immediately.

COUPLING SYNTHETIC PEPTIDES TO A CARRIER PROTEIN PHOTOCHEMICALLY

**ALTERNATE
PROTOCOL 5**

Most synthetic peptides today are made with 9-fluorenylmethyloxycarbonyl (Fmoc) chemistry (see Fig. 18.1.1), and therefore the following protocol links the photoactive group to the free amino terminus of the peptide. An alternative approach if *t*-butyloxycarbonyl (Boc) chemistry is used is to link it to an ϵ -amino group of a terminal lysine (Gorka et al., 1989).

Additional Materials (see also *Basic Protocol 3*)

- 4-benzoyl benzoic acid (Sigma or Aldrich)
- Quartz spectrophotometry cuvettes

1. Have the synthetic chemist who is making the peptide attach a benzoyl benzoic acid group to the amino terminus simply by treating the reagent as the terminal residue during normal synthesis.

This blocks the amino terminus.

Immunology

11.16.13

**SUPPORT
PROTOCOL 3**

2. Dissolve 5 mg KLH in ~0.5 ml of 0.01 M sodium phosphate buffer, pH 7.5.
3. Add 2 mg of synthetic peptide containing the benzoyl benzoate adduct.
4. Place in a 1-cm quartz cuvette and irradiate with 366-nm light for 3 hr at a distance of 0.5 cm. Use immediately.

The peptide can be used directly for immunization.

CALCULATION OF THE MOLAR RATIO OF PEPTIDE TO CARRIER PROTEIN

The molar ratio of peptide to carrier protein coupling efficiency can be calculated to determine the level of substitution achieved by the coupling procedure. This information can be obtained using the results of amino acid compositional analysis. By performing the calculations presented in this protocol, the molecules of peptide in the conjugate per molecule of carrier protein in the conjugate can be determined.

1. Obtain the amino acid composition of the carrier protein, the peptide, and the peptide/carrier conjugate. Amino acid compositional analysis (of these hydrolysates) is usually available at sources that provide automated peptide synthesis (see *UNIT 11.15*). Be sure that the conjugate is free of unconjugated peptide (i.e., it should be well dialyzed).
2. Determine a scaling factor (SF) that relates the moles of protein in the unconjugated carrier protein to the moles of protein in the peptide/carrier conjugate. This is done by comparing the molar ratio of ≥ 3 amino acids present in the carrier protein and peptide/carrier conjugate but not present in the peptide. For example, if the peptide TGLRDSC (Table 11.16.2) is coupled to a carrier protein, choose A, K, and I. The calculation is done as:

Table 11.16.2 Sample Calculation of the Extent of Coupling of the Peptide TGLRDSC to Carrier Protein^a

Amino acid	Composition of carrier protein	Composition of peptide/carrier conjugate	Amount of carrier protein amino acids in conjugate	Amount of peptide amino acids in conjugate
D	80	185	160	25
E	110	222	220	—
G	95	215	190	25
S	65	150	130	20
T	70	163	140	23
H	10	19	20	—
P	25	51	50	—
A	103	206	206	—
M	5	11	10	—
V	60	118	120	—
F	22	45	44	—
L	55	133	110	23
I	65	135	130	—
C	7	22	14	8
Y	13	25	26	—
K	65	125	130	—
R	<u>75</u>	<u>177</u>	<u>150</u>	<u>27</u>
Total pmol amino acid	925	2002	1850	151

$$SF = [(pmol\ A\ in\ conjugate/pmol\ A\ in\ carrier) + (pmol\ K\ in\ conjugate/pmol\ K\ in\ carrier) + (pmol\ I\ in\ conjugate/pmol\ I\ in\ carrier)]/3.$$

For these amino acids, the carrier protein yields are as follows: A = 103 pmol, K = 65 pmol, and I = 65 pmol. For these same amino acids, the peptide/carrier conjugate yields: A = 206 pmol, K = 125 pmol, and I = 135 pmol.

From these values, the relative amount of carrier protein in the conjugate versus the unconjugated carrier protein (SF) can be calculated as follows: $(206/103 + 125/65 + 135/65)/3 = 2.0$, indicating that there is twice as much carrier protein in the peptide/carrier conjugate hydrolysate as in the carrier-protein hydrolysate.

3. Calculate the moles of peptide present in the conjugate by subtracting the moles of amino acid present in the carrier from the moles of amino acid present in the conjugate. Choose ≥ 3 amino acids present in the peptide. The relative amount (SF) of protein present in the carrier protein versus the amount in the conjugate as calculated in step 2, must also be considered as follows:

$$pmol\ peptide\ in\ conjugate = \{[pmol\ G\ in\ conjugate - (SF \times pmol\ G\ in\ carrier)] + [pmol\ L\ in\ conjugate - (SF \times pmol\ L\ in\ carrier)] + [pmol\ R\ in\ conjugate - (SF \times pmol\ R\ in\ carrier)]\}/3$$

Therefore, the amount of peptide in the conjugate hydrolysate for the example shown in Table 9.4.1, calculated using the amino acids G, L, and R, is $\{[215 - (2 \times 95)] + [133 - (2 \times 55)] + [177 - (2 \times 75)]\}/3 = 25$ pmol.

4. Calculate the number of moles of protein in the conjugate hydrolysate as follows:

$$pmol\ carrier\ protein\ in\ conjugate = \frac{\text{total pmol carrier protein amino acids}}{\text{molecular weight of carrier protein}} \times 110$$

where total pmol carrier protein amino acids = SF \times (total amino acid composition of carrier in pmol) and 110 is the average molecular weight of an amino acid.

In this example, there are 1850 pmol of carrier protein amino acids in the conjugate; therefore, $1850\ pmol \times (110/100,000) = 2.04$ pmol carrier protein in conjugate.

5. Determine the ratio of peptide to carrier protein as follows:

$$\frac{\text{molecules peptide in conjugate}}{\text{pmol peptide in conjugate}} / \frac{\text{molecules carrier protein in conjugate}}{\text{pmol carrier protein in conjugate}} =$$

Using the values calculated in steps 3 and 4, the result is: $25\ pmol\ peptide\ in\ conjugate / 2.04\ pmol\ carrier\ protein\ in\ conjugate = 12.2$ molecules peptide in conjugate per molecule carrier protein in conjugate.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cysteine standard stock solution

Dissolve 26.3 mg cysteine hydrochloride monohydrate in 100 ml of 0.1 M sodium phosphate, pH 8.0 (APPENDIX 2). Prepare immediately before use.

Ellman's reagent solution

Dissolve 4 mg Ellman's reagent, 5,5'-dithio-bis-(2-nitrobenzoic acid) (Pierce), in 1 ml of 0.1 M sodium phosphate, pH 8.0 (APPENDIX 2). Prepare immediately before use.

Glutaraldehyde solution, 0.15%

Add 30 μ l of 25% aqueous glutaraldehyde solution to 5 ml of 50 mM sodium borate buffer, pH 8.0 (pH adjusted with HCl). Prepare fresh and use immediately. If the glutaraldehyde precipitates, check the pH. It should not be above 8.0; a slightly lower pH can be used (pH 7 to 8).

CAUTION: *Glutaraldehyde is a sensitizing agent that should be handled in a hood and only according to the recommendations in the Material Safety Data Sheet. When mixing solutions or performing reactions, keep the container covered to prevent vapors from escaping into the atmosphere.*

Guanidine-HCl, 6 M

Dissolve 1 g guanidine-HCl in 1 ml of 0.05 M sodium phosphate, pH 7.0 (APPENDIX 2). Store up to several weeks at room temperature.

The resulting 1.8-ml solution should be ~0.025 M phosphate/6 M guanidine-HCl at pH 7.0.

COMMENTARY

Background Information

Synthetic peptides are linear arrays of amino acids that in most instances possess a random structure in solution. While it is not difficult to produce antipeptide antibodies, it does not necessarily follow that the antibodies will recognize a protein containing the same stretch of sequence found in the peptide. In order for this to occur, the amino acids in the protein must be oriented to the antibody in a way similar to that of the synthetic peptide. This generally requires three basic features of the protein: (1) that the stretch of sequence be exposed to solvent; (2) that the sequence be a continuous stretch of amino acids; and (3) that it not possess a higher-order structure that renders it unrecognizable by the antibody population.

The large number of model protein structures now available indicate that almost all of the ionized groups in water-soluble proteins are on the protein surface. Asp, Glu, Lys, and Arg residues, on the average, comprise 27% of the protein surface and only ~4% of the protein interior. The fraction of residues that are at least 95% buried range from 0.36 to 0.60 for nonpolar residues and 0.01 to 0.23 for polar residues. Only 1% of Arg and 3% of Lys residues fall

into the 95% buried range (Creighton, 1993). Therefore, it is reasonable to expect solvent-exposed areas of proteins to display relatively high levels of polar and charged residues, particularly Arg and Lys.

Proteins display three kinds of secondary structure: α -helices, β -sheets, and turns or loops. Turns or loops generally connect elements of α -helices and β -sheets, and can either fit one of several rather strict motifs with recognizable hydrogen bonding patterns or be of a more extended, random nature. These turn or loop structures appear to be most useful for antibody production because they tend to be found on the surface of proteins connecting larger arrays of helices and sheets, and they consist of continuous stretches of amino acids. Although many amino acid residues in helices and sheets are also exposed at the surface, the regular geometry of amino acids contained within them makes them less suitable for this purpose. For instance, in β -sheet structures the side chain of each successive amino acid in the β -sheet strand points in the opposite direction to the ones immediately preceding and following it. Thus, even if the amino acid side chains are not predominantly buried in the interior of

the protein, only every other side chain is exposed on the same surface of the sheet. This can hinder recognition by an antibody produced with a linear peptide capable of assuming a more random structure. A similar situation exists for α -helices. Although the change in direction of the side chains of successive amino acids is perhaps not as abrupt as in β -sheets, only approximately every third or fourth side chain is found on the same surface of the helix. Epitopes in proteins have been identified in amphipathic helices, but unless the synthetic peptide assumes a similar helical structure in solution, recognition by the antibody may be problematic.

These considerations have led to more useful methods for predicting sequences that will produce antibodies recognizing intact proteins. A variety of different indices that predict hydrophilicity or hydrophobicity and secondary structure are available. In addition, predictive methods based on segmental mobility, side chain accessibility, and sequence variability (see Van Regenmortel et al., 1988) have also been proposed. All of these methods generally tend to yield similar results, but it must be noted that these procedures were developed for (and work best with) water-soluble proteins composed of a single globular structure. Additional complications can arise with multisubunit proteins, where normally exposed structures may be shielded by subunit interactions, or membrane proteins with large sections shielded from the solvent.

The method presented in this unit utilizes the correlation between the hydrophilic character of a peptide sequence (Kyte and Doolittle, 1982) and its propensity to form β -turn structures (Chou and Fasman, 1974). Free access to these and many other algorithms is provided at the ExpASY Web site of the University of Geneva at <http://expasy.org.tools>.

After selection of the peptide sequence, an effective immunogen is generally produced by coupling the peptide to a carrier protein or by synthesizing a multiple antigenic peptide (MAP), with four or eight identical peptides assembled simultaneously on the α and ϵ amines of the terminal lysines of a branched core (see Fig. 11.16.3).

Critical Parameters

Analyzing protein sequences with algorithms or tables of assigned values for amino acids is a well-established procedure, but evaluating these results and selecting the candidate

sequences requires some consideration. To take full advantage of the results, choose areas of sequence that give the maximum values for the properties being evaluated and that also show the highest degree of residue-by-residue correlation. In other words, choose areas of maximum amplitude where the centers of the peaks correspond to the same sequence with a divergence of no more than two to three residues. Examples of this are given in Figure 11.16.2, which shows results from the method presented in Basic Protocol 1 for the sequence shown in Figure 11.16.1. The top panel in Figure 11.16.2 predicts β -turns as calculated by the method of Chou and Fasman (1974). The bottom panel is a prediction of hydrophobicity using the parameters of Kyte and Doolittle (1982). The data are analyzed by looking for areas of high turn propensity (maximum positive deflection in the top panel) and high hydrophilicity (maximum negative deflection in the bottom panel). The shaded areas in Figure 11.16.2 designate three segments that meet these criteria. Note that the maximum and minimum values of these three stretches of protein sequence correlate very well. Additional areas of high hydrophilicity (bottom panel) are found near residues 64, 132, 137, 149, and 345, although the β -turn values of these secondary candidates are not as high as those of the three shaded areas. Two equally hydrophilic areas at residues 49 and 299 correspond to downward deflections in the β -turn profile and are thus not good candidates based on this analysis.

Many different chemistries are available for coupling synthetic peptides to carrier proteins to produce effective immunogens (Van Regenmortel et al., 1988). In many cases, however, side reactions or incompatibilities in chemistry between the coupling agent and the residues present in the peptide can be problematic. In order to simplify the process and present the greatest probability of success in most cases, only a few coupling methods are presented in this unit. In this regard, the recommended coupling procedure is cross-linking of the peptide via cysteine residues to keyhole limpet hemocyanin (KLH) with the heterobifunctional reagent *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS; see Basic Protocol 3). This effective method has enjoyed great success and can be used for virtually any peptide. The one caveat is that it is not recommended for peptides with internal cysteine residues, since they will also link to the carrier. It is also critical, when coupling with MBS through an added terminal

cysteine residue, that the sulfhydryl group of the peptide be present in the free or reduced form (see Support Protocols 1 and 2).

In addition to MBS coupling, other procedures commonly used (see Alternate Protocols 3 and 4) are included as alternatives for use in special situations, but these are not recommended as a general alternative to MBS because they are more restrictive and have the potential for undesirable side reactions. Glutaraldehyde coupling (see Alternate Protocol 3) should not be used with peptides containing internal Lys, Cys, Tyr, or His residues and, since it is a homobifunctional reagent, cross-linking of the peptide to itself and the carrier to itself can occur. The latter lowers antigenicity and can result in extensive aggregation and precipitation of the carrier. 1-ethyl-3(3-dimethylaminopropyl) carbodiimide (EDC; see Alternate Protocol 4) is a water-soluble carbodiimide and should not be used with peptides containing internal Lys, Glu, Asp, Tyr, or Cys residues. Alternate Protocol 5 describes a simple photochemical coupling strategy (Gorka et al., 1989).

Another good alternative for most peptides is the production of a multiple antigenic peptide (MAP; see Alternate Protocol 2). With this method the composition of the peptide is not a concern beyond its potential solubility properties. In most cases, since hydrophilic sequences are selected, this also is not a major problem. Both four- and eight-branched MAPs have been found to be effective. However, four-branched MAPs are recommended because they are less prone to synthesis problems and are easier to characterize.

As with any synthetic peptide, the product must be well characterized before use. If the peptide is not what it was intended to be, this decreases the probability of generating antibodies that will recognize the protein. At the very least, check synthetic peptides for homogeneity by analytical HPLC and correct mass by mass spectrometry (see *UNITS 10.21 & 10.22*). Characterization of MAP can be more problematic due to their multibranching nature (Mints et al., 1997): HPLC and mass spectrometric analysis can be compromised by the presence of four to eight peptide chains per molecule, each of which may have only a small percentage of modification at any particular residue but which in the aggregate contribute to broad spectra. However, this feature of MAPs usually does not tend to compromise their ability to form antigens of the proper peptide since the correct sequence is usually present in high enough concentration that a significant amount of specific antibody is pro-

duced among the polyclonal population. Amino acid analysis (*UNIT 10.1B*), which is less sensitive to multiple small differences, tends to give a reasonable assessment of the MAP integrity.

Anticipated Results

The methods outlined in this unit produce an effective polyclonal antiserum against an intact protein from a single peptide sequence ~50% to 70% of the time. Therefore, it is advisable to prepare two or three different peptides from a given protein to increase the probability of at least one of them being effective.

Time Considerations

Computer-assisted analysis of a protein sequence and inspection of the data to select several candidate sequences takes from 5 to 30 min. Manual analysis of a protein sequence can take several hours but can certainly be accomplished in <1 day. Selection of peptide design and manner of synthesis as well as selection of a coupling method will take <1 hr. Actual preparation of the peptide can be accomplished in 3 to 4 days, but this may vary depending on the turnaround time of the synthetic laboratory. Coupling a synthetic peptide to a carrier protein takes from 1 to 2 days. Although not covered in this unit, production of the antisera will vary with the animal and protocol used, but generally requires 2 to 3 months. It is therefore advisable to inject several animals with different peptides at one time.

DETERMINATION OF SPECIFIC ANTIBODY TITER AND ISOTYPE

Determination of the Specific Antibody Titer

The amount of specific antibody present in polyclonal antiserum, ascites fluid, or hybridoma supernatant can be quantitated by either solid-phase radioimmunoassay (RIA) or by direct enzyme-linked immunosorbent assay (ELISA; UNIT 11.2). In the solid-phase assay described here (see Basic Protocol), serially diluted antiserum is incubated in microtiter wells previously coated with the relevant antigen. Bound antibody is detected by employing ^{125}I -labeled anti-immunoglobulin antibodies. The amount of specific antibody in the antiserum is then determined from a standard curve generated with a specific antibody of known concentration. The unknown antiserum and the standard antibody are assayed in parallel. The support protocols describe the chloramine T (see Support Protocol 1) and IODO-GEN (see Support Protocol 2) procedures for radioiodination of the anti-immunoglobulin reagent. The use of the solid-phase RIA procedure to determine the light-chain (κ and λ) and heavy-chain (γ , μ , α) isotypes present in polyclonal antisera and fluids containing monoclonal antibodies is also described as Support Protocol 3.

SOLID-PHASE RADIOIMMUNOASSAY (RIA) FOR DETERMINATION OF ANTIBODY TITER

In this assay, a specific antigen is used to coat the wells of the microtiter plate.

Materials

- Antigen
- Coating buffer (see recipe)
- Control antigen (non-cross-reactive protein)
- Phosphate-buffered saline (PBS; APPENDIX 2)
- ^{125}I anti-immunoglobulin reagent (see recipe; Ab must be specific for the species in which the test antibody was raised—e.g., ^{125}I goat anti-mouse for mouse hybridoma or ^{125}I goat anti-rabbit for rabbit sera)
- Wash buffer (UNIT 11.2)
- 1% bovine serum albumin in phosphate-buffered saline (BSA/PBS)
- Standardized antibody solution (5 mg/ml in diluting buffer)
- Diluting buffer (see recipe)
- 96-well microtiter plates compatible with γ counter such as Wallac ScintiStrips
- Repeater pipet (e.g., Eppendorf with disposable Combi-tips)
- Multichannel pipet
- Automated γ counter that counts 96-well plates such as a Wallac MicroBeta TriLux

1. Prepare antigen and control antigen solutions (0.005 to 0.01 mg/ml) in coating buffer.

The optimal antigen concentration will depend on the nature of the antigen employed. To determine the optimal coating concentration, incubate a relatively concentrated dilution of antiserum (1:100 dilution) in microtiter wells previously coated with serial dilutions of antigen. Bound antibody is then detected as described below in this protocol. Counts per minute (cpm) are plotted against coating antigen concentration. The optimal coating concentration is that at which coating antigen is saturating (i.e., at an antigen concentration corresponding to a point on the plateau of the curve).

The antigen need not be pure, although for accurate and reproducible antibody titers, it is desirable to use a preparation containing a consistent antigen concentration. Bovine serum albumin (BSA) is a frequently used control antigen; however, the best control antigen is an immunologically non-cross-reactive protein of similar molecular weight to the antigen of interest.

If the antigen is stable, the antigen-coated plate can be prepared in advance and stored in PBS for up to 1 week at 4°C.

2. Pipet 50 μ l of appropriately diluted antigen into columns 1, 2, and 3, and columns 7, 8, and 9 of rows A to H of a 96-well microtiter plate, as shown in Figure 11.17.1. Add control antigen to wells 4, 5, and 6, and 10, 11, and 12 of rows A to H. Cover plate to avoid evaporation and incubate 2 hr at room temperature or overnight at 4°C.

It is desirable to assay each antiserum dilution in triplicate. In general, eight serial dilutions of antiserum are sufficient.

The volumes of antigen, antibody, and [¹²⁵I]anti-immunoglobulin reagent may be halved if antigen and/or antibody are precious.

3. Remove coating antigens by shaking into sink. Add 100 μ l wash buffer and incubate 5 min at room temperature. Remove wash buffer and repeat wash cycle twice.

If the antigen is difficult to obtain, the coating antigen solution may be removed with a repeater pipet, stored at -20°C, and reused. The length of time it may be stored and the number of times it may be reused depend on the antigen, but it should not be used >5 times

4. Pipet 100 μ l BSA/PBS into each coated well, cover plate, and incubate 1 hr at room temperature or overnight at 4°C. Shake out blocking buffer and wash three times with wash buffer as described above.

An alternative to BSA/PBS is 5% preimmune horse serum prepared in PBS.

5. Make serial dilutions of polyclonal antiserum (or ascites fluid or hybridoma supernatant) and standardized antibody solution (5 mg/ml) in diluting buffer. Dilutions can be made in small glass tubes or plastic 1-ml microcentrifuge tubes. Initially, a 1:5 dilution of antiserum is made, followed by seven five-fold dilutions as follows:

- a. Label tubes from 1 to 8.
- b. Pipet 400 μ l diluting buffer into all tubes.
- c. Pipet 100 μ l undiluted antiserum into tube 1 and mix well by pipetting up and down without producing foam.
- d. Transfer 100 μ l diluted antiserum from tube 1 to tube 2 and mix well. Continue to transfer 100 μ l diluted antiserum from tubes 2 to 8 as described. Finally, remove and discard 100 μ l from tube 8.

6. Follow step 5 for serial dilutions of the standard antibody solution using tubes 9 to 16.

The standardized antibody solution (5 mg/ml) is ideally a purified solution of antibody prepared by affinity chromatography (UNIT 11.11), with the same antigen specificity as the antiserum of interest and raised in the same host animal species. The concentration of the antibody is determined from the A_{280} and adjusted to 5 mg/ml. (A solution of 1 mg/ml immunoglobulin has an A_{280} of 1.4).

7. Pipet 50 μ l diluted antiserum from tubes 1 to 8 into the first six columns of rows A to H, respectively, as indicated in Figure 11.17.1. In a similar fashion, pipet 50 μ l of each dilution of standard antibody from tubes 9 to 16 into wells 7 to 12 of rows A to H, respectively. Cover plate and incubate 2 hr at room temperature.

Dilutions may be made while coating antigen is incubating on the plate and then stored at 4°C until required.

		Specific antigen			Control antigen			Specific antigen			Control antigen			
Antibody dilution factor	Tube	1	2	3	4	5	6	7	8	9	10	11	12

7.8×10^4	7	G												
3.9×10^5	8	H												
			Antiserum						Standard antibody					

Figure 11.17.1 The microtiter plate setup for the determination of specific antibody titer. Wells are initially coated with the specific antigen or the control antigen. Serial dilutions of specific antiserum, ascites fluid or hybridoma supernatant are then incubated in the coated wells. Bound antibody is detected using a [125 I]anti-immunoglobulin reagent.

8. Shake diluted antiserum and standard antibody from the plate and wash three times with wash buffer as described in step 3.
9. Pipet 50 μ l of appropriately diluted [125 I]anti-immunoglobulin reagent into each well. Cover plate and incubate ≥ 4 hr at room temperature, or overnight at 4°C.

Steps 9 to 12 should be carried out in a well-ventilated fume hood designated for radioactive work.

A repeater pipet is convenient for delivering the 50- μ l aliquots of [125 I]anti-immunoglobulin reagent.
10. Remove radioactive supernatant from wells using a multichannel pipet and discard waste into appropriate radioactive waste container. Add 100 μ l wash buffer to each well and gently pipet up and down three times with the multichannel pipet. Remove wash buffer and discard it into radioactive waste container. Repeat this procedure twice. Wash wells five more times with 100 μ l wash buffer per well.

The final five washes may be poured into the sink, as the radioactivity will be negligible; however, first check radiation safety regulations.
11. Allow plates to dry for 4 hr at room temperature or under a heat lamp for 30 min.
12. Count each plate in gamma counter for one minute.
13. Determine amount of specific antibody bound from antiserum of interest and from standardized antibody solution as follows:
 - a. Calculate average cpm (cpm_{av}) for triplicate values obtained for each antibody dilution.
 - b. For each dilution of antiserum, subtract cpm_{av} obtained when a given dilution is incubated in wells coated with control antigen (background) from cpm_{av} measured on wells coated with specific antigen ($\text{cpm}_{\text{bound}}$).
 - c. Plot $\text{cpm}_{\text{bound}}$ versus \log_{10} (antiserum dilution; see Fig. 11.17.2A).
 - d. Plot $\text{cpm}_{\text{bound}}$ versus \log_{10} (standard antibody in mg/ml; see Fig. 11.17.2B).
 - e. Select a value of $\text{cpm}_{\text{bound}}$ from linear section of binding curve (y in Fig. 11.17.2A) constructed for the antiserum of interest. Translate this value onto the standard

Figure 11.17.2 Theoretical binding curves for the determination of specific antibody titer. **(A)** The experimental curve. Serial dilutions of specific antiserum, ascites fluid, or hybridoma supernatant are incubated in antigen-coated wells. **(B)** The standard curve. Serial dilutions of the standard antibody are incubated in the antigen-coated wells. The specific antibody titer is calculated as shown: Specific antibody titer = $x \times z$, where x is the antibody dilution that yields y $\text{cpm}_{\text{bound}}$ and z is the standard antibody concentration that yields y $\text{cpm}_{\text{bound}}$.

curve and determine standard antibody concentration corresponding to this $\text{cpm}_{\text{bound}}$ (z in Fig. 11.17.2B). This concentration is equal to that of specific antibody present in polyclonal antiserum at the dilution giving the selected $\text{cpm}_{\text{bound}}$.

- f. Calculate initial specific antibody concentration (i.e., titer) in undiluted serum by multiplying standard antibody concentration (z) derived from selected $\text{cpm}_{\text{bound}}$ (y) by corresponding dilution factor of antiserum (x in Fig. 11.17.2A).

SUPPORT PROTOCOL 1

IODINATION OF ANTI-IMMUNOGLOBULIN REAGENT USING CHLORAMINE T

This protocol is a clean and efficient method for covalently linking ^{125}I to tyrosine residues in the protein of interest. Unbound ^{125}I is quenched with a saturated tyrosine solution and separated from the protein-bound fraction by passage down a small desalting column.

CAUTION: Under no circumstances should the iodination reaction be carried out on an open bench. Use a well-ventilated fume hood (confirmed by radiation safety department); do not use tissue culture hood. During the reaction, significant quantities of free $^{125}\text{I}_2$ are liberated which can concentrate in the thyroid gland. Therefore, as ^{125}I is a strong gamma emitter, it cannot be stressed strongly enough that extreme care must be taken to contain the radioactive reaction products within a well-ventilated fume hood so that they are isolated from the environment.

Ensure that lead bricks line the front of the fume hood to protect against gamma emission. Additionally, a lab coat and two layers of protective gloves should be worn throughout the iodination procedure.

It is recommended that the experimenter have his or her thyroid tested by the institutional radioactive safety department before and within 1 week after carrying out this reaction. If all safety precautions are followed correctly, contamination will not occur.

Determination of the Specific Antibody Titer

11.17.4

Materials

Sephadex G-25 (Amersham Pharmacia Biotech), washed and equilibrated in PBS
(see APPENDIX 2 for PBS)
DEAE-Sephadex (Amersham Pharmacia Biotech), washed and equilibrated in PBS
Mixed bed resin (Bio-Rad #AG 501-X8), washed and equilibrated in PBS
1% bovine serum albumin in phosphate-buffered saline (BSA/PBS)
Protein to be iodinated (1 mg/ml, preferably in iodinating buffer)
Iodinating buffer (see recipe)
Saturated tyrosine solution (see recipe)
Na[¹²⁵I] (1 mCi in 10 to 5 µl of 0.1 M NaOH, specific activity 17 Ci/mg; NEN
Life Sciences)
Chloramine T solution (see recipe)
Plastic tubing (3 mm i.d., 10 cm long) with clamps
Silanized glass wool (UNIT 5.6)
Small column stand
1-ml syringes equipped with 22-G needles
Plastic collection tubes with caps
Lead pig

1. Prepare desalting column by pushing plastic tubing securely onto tip of a Pasteur pipet and attaching a small clamp to tubing. Place a small wad of siliconized glass wool into neck of pipet. Clamp pipet to a small column stand.

The glass wool is the bed on which the chromatography resins are packed. Therefore, it is important that the wool is packed at the neck of the pipet tightly enough to stop the resin beads from passing through, yet loosely enough to allow the column to flow freely.

2. Layer 1.5 to 2.0 cm Sephadex G-25 onto glass wool. After the Sephadex G-25 has settled, gently layer 3 to 4 cm DEAE-Sephadex on top.

The DEAE-Sephadex removes aggregated protein.

3. Allow DEAE-Sephadex to settle and then layer 1.5 to 2.0 cm mixed bed resin on top.

The mixed bed resin adsorbs any free ¹²⁵I⁻ remaining in the solution.

4. Pour 50 ml BSA/PBS down the column.

The 1% BSA in the buffer saturates the resin bed and inhibits the nonspecific adsorption of iodinated protein during the desalting procedure.

5. Draw up 50 µl saturated tyrosine solution into a 22-G needle connected to a 1-ml syringe and 250 µl saturated tyrosine solution into a second 22-G needle connected to a 1-ml syringe.

Do not remove air bubble from inside syringe barrel. The air bubble should separate the base of the plunger from the solution so that the full contents of the syringe can be expelled when required.

6. Take all reagents and necessary equipment to a well-ventilated fume hood that has been designated previously for radioactive use (preferably one used specifically for iodination of proteins using ¹²⁵I; see cautionary statements preceding materials list). Place the following equipment in the hood ready for use:
 - a. The desalting column and collection tubes. Remove BSA/PBS from top of desalting column. Remove caps from collection tubes and place them close by the column.
 - b. A number of Pasteur pipets and pipet bulbs for column elution.

- c. The two syringes containing saturated tyrosine solution (from step 5).
 - d. One 22-G needle.
 - e. The lead pig containing a vial of Na[¹²⁵I].
 - f. A box of protective gloves beside the hood, within easy reach.
7. Into a third 1-ml syringe (connected to a 22-G needle), take up the following: 50 μl protein solution (do not remove air bubble between base of plunger and protein solution), 40 μl air space, and 30 μl chloramine T solution.

This step can be carried out outside the fume hood, but it must be done immediately prior to commencing the reaction. Because chloramine T is a strong oxidant, the protein must be in contact with it for as short a time as possible.

8. Remove vial of Na[¹²⁵I] from lead pig and remove cap from inner container, leaving the small glass vial containing the radioactivity inside the inner container.

The inner container will provide shielding from the radioactivity. Under no circumstances should the open vial be removed from the fume hood.

9. Insert 22-G needle into rubber lid of vial containing Na[¹²⁵I].

The 22-G needle acts as a vent when the protein/chloramine T solution is injected into the vial. Ensure that the needle tip lies just below the lid, well above the liquid in the vial.

10. Inject protein/chloramine T solution into vial and allow reaction to proceed one minute. Stop the reaction by injecting 50 μl saturated tyrosine solution into vial.
11. Remove contents of vial using the syringe that contained 50 μl saturated tyrosine solution and load contents carefully onto the desalting column.
12. Rinse vial by injecting 250 μl saturated tyrosine solution (from step 5). Remove this wash solution and load it onto the column.
13. Allow sample to penetrate into column bed and elute with BSA/PBS. Collect twenty 0.5-ml fractions.
14. Count 1-μl aliquots from each fraction on a gamma counter to determine where the iodinated protein peak has eluted. Pool fractions containing the radiolabeled protein and store them at -20°C in a lead pig.

The ¹²⁵I-labeled protein is usually eluted within the first 2 to 3 ml.

The sample may be stored in aliquots (e.g., 100 μl), depending on the volume required to make the appropriate dilutions for the RIA.

CAUTION: Dispose of all contaminated solutions and equipment, including the desalting column, in appropriate radioactive waste receptacles.

SUPPORT PROTOCOL 2

IODINATION OF ANTI-IMMUNOGLOBULIN REAGENT USING IODO-GEN

IODO-GEN (1,3,4,6-tetrachloro-3α,6α-diphenylglycouril) can be substituted for chloramine T as the iodination agent. This reagent is reported to be gentler than chloramine T. Because IODO-GEN has a longer reaction time (10 to 15 min) than chloramine T (1 min), the investigator can vary this parameter for labeling unstable proteins. The chloramine T support protocol (see Support Protocol 1) is modified according to the steps below when using IODO-GEN.

Materials

iodo-GEN (Pierce #28600T)
Methylene chloride
iodo-GEN-coated glass test tubes (Pierce #28601T or see recipe)
Drierite

Additional reagents and equipment for iodination of anti-immunoglobulin reagent using chloramine T (see Support Protocol 1)

1. Proceed with steps 1 to 6 of the chloramine T protocol (see Support Protocol 1).
2. Rinse iodo-GEN-coated glass tube with 200 μ l iodinating buffer to remove any loose microscopic flakes of iodo-GEN. If flakes are visible, reagent has not been properly plated and another tube should be tested. Add 100 μ l protein solution.
3. Proceed with step 8 of the chloramine T protocol (see Support Protocol 1). Insert third syringe into vial containing Na[¹²⁵I] and transfer contents into the iodo-GEN-coated vial containing protein to be labeled. Incubate mixture for 10 to 15 min at room temperature.
4. Proceed as described in steps 11 to 14 of the chloramine T protocol (see Support Protocol 1).

DETERMINATION OF ANTIBODY ISOTYPES

The optimal dilutions of the isotyping reagents (anti- μ , γ , α , λ , and κ) are determined using a set of standard monoclonal antibodies of the μ , γ , α , λ , or κ isotype, respectively. This protocol describes the determination of the optimal dilution of an anti- μ isotyping reagent, but the same protocol can be used for optimization of isotyping reagents of all specificities. Optimization assays for all isotyping reagents must be carried out in parallel.

After establishing the optimal dilutions of isotyping reagents, their use in determining the isotypes of mouse antiserum is described for the μ , γ_1 , γ_2 , and γ_3 heavy chains and κ and λ light chains. Initially, the specific antibody of interest is bound to the wells of a 96-well microtiter plate coated previously with the antigen. The appropriately diluted isotyping reagents are then incubated within the wells. The extent of specific binding is determined using a second [¹²⁵I]anti-immunoglobulin antibody specific for the animal species from which the isotyping reagents were derived.

Additional Materials (also see Basic Protocol)

Isotype standards (0.1 μ g/ml)
Isotyping reagents (see recipe)

Determine the optimal dilutions for isotyping reagents

1. Pipet 25 μ l of μ , γ , α , λ , and κ isotype standards (0.1 μ g/ml) and control antigen (0.1 μ g/ml) into all wells of columns 1 and 2, 3 and 4, 5 and 6, 7 and 8, 9 and 10, and 11 and 12, respectively, of a microtiter plate (see Fig. 11.17.3 for diagram). Cover plate to avoid evaporation and incubate 2 hr at room temperature or overnight at 4°C (see Fig. 11.17.4).
2. Remove isotype standards from plate by flicking contents into the sink. Add 100 μ l wash buffer to each well, cover plate, and incubate 5 min at room temperature. Remove wash buffer and repeat the wash step twice.

SUPPORT PROTOCOL 3

												Control antigen	
		μ	γ	α	λ						κ		
Isotyping reagent dilution	Tube	1	2	3	4	5	6	7	8	9	10	11	12
10^2	1	A											
5×10^2	2	B											
2.5×10^3	3	C											
1.3×10^4	4	D											
6.3×10^4	5	E											
3.1×10^5	6	F											
1.6×10^6	7	G											
7.8×10^6	8	H											

Figure 11.17.3 Microtiter plate setup for the determination of the optimal dilutions of the isotyping reagents. The wells are coated with the appropriate isotype standards. Serial dilutions of the isotyping reagent are incubated in the coated wells. Bound isotyping reagent is detected using a [125 I]anti-immunoglobulin reagent specific for the animal species from which the isotyping reagent is derived.

- Pipet 100 μ l blocking buffer onto each coated well, cover plate, and incubate 1 hr at room temperature or overnight at 4°C. Shake out blocking buffer and wash three times as in step 2.
 - Label a set of 1.5-ml microcentrifuge tubes 1 to 8.
 - Add 990 μ l diluting buffer to tube 1 and 800 μ l diluting buffer to tubes 2 to 8.
 - Pipet 10 μ l anti- μ isotyping reagent into tube 1 and mix well by pipetting up and down.
 - Remove 200 μ l of 1:100 dilution anti- μ isotyping reagent from tube 1, add it to tube 2, and mix well. Continue to transfer 200 μ l diluted anti- μ reagent from tube 2 to 8 as described. Finally, remove and discard 200 μ l from tube 8.
 - Pipet 50 μ l of each dilution of the anti- μ reagent from tubes 1 to 8 into wells of rows A to H, respectively, and incubate plate 2 hr at room temperature.
- Each dilution of the isotyping reagent is assayed in duplicate.*
- Remove isotyping reagent from plate and wash plate as described in step 2.
 - Carry out the remainder of the assay (see Basic Protocol, steps 9 to 12).
 - Average the cpm of the duplicate values (cpm_{av}) for each dilution of isotyping reagent bound to each isotype standard.
 - Subtract the cpm_{av} value obtained for a given dilution of anti- μ reagent incubated in wells coated with control antigen from the cpm_{av} value calculated for that dilution incubated in wells coated with each of the isotype standards, respectively ($\text{cpm}_{\text{bound}}$).
 - Choose the dilution of anti- μ isotyping reagent at which minimal, if any, cross-reactivity with the nonspecific isotype standards is observed.

The dilutions chosen for all isotyping reagents must yield equivalent cpm_{av} values to ensure comparable sensitivity of detection for each isotype within a given antibody population.

		Isotyping reagents											
		anti- μ		anti- γ_1		anti- γ_2		anti- γ_3		anti- κ		anti- λ	
		1	2	3	4	5	6	7	8	9	10	11	12
specific antigen	A	2580	2612	347	302	106	80	91	76	1386	1235	83	67
	B	80	123	2464	2398	44	98	105	125	1068	1039	55	69
control antigen	C	106	54	81	93	24	51	118	91	59	78	96	148
	D	103	51	108	102	81	68	62	80	75	37	97	66

Figure 11.17.4 Microtiter plate setup for the determination of the isotype/s of the specific antibody population. The specific antibody (10 $\mu\text{g/ml}$) is incubated in the antigen (specific or control) coated wells. The appropriately diluted isotyping reagent is then added to the wells. Bound isotyping reagent is detected using a [^{125}I]anti-immunoglobulin reagent specific for the animal species from which the isotyping reagent is derived. Typical (data as cpm [^{125}I]anti-immunoglobulin antibody bound) is shown for a mouse $\mu\kappa$ antibody in rows A and C and a mouse g1k antibody in rows B and D.

Determine the isotypes

- Pipet 50 μl coating antigen (i.e., specific antigen) into all wells of rows A and B of the microtiter plate and 50 μl control antigen into all wells of rows C and D. Cover plate to avoid evaporation and incubate 2 hr at room temperature, or overnight at 4°C.

Each isotyping reagent will be assayed in duplicate. The volumes of antigen, antibody, and [^{125}I]anti-immunoglobulin reagent may be reduced if antigens and/or antibody are in limited supply.

- Remove coating antigens and block wells (see Basic Protocol, steps 3 and 4).

In this assay only a single specific antibody concentration (10 $\mu\text{g/ml}$) is required.

- Add 50 μl antiserum (diluted to give a specific antibody concentration of 10 $\mu\text{g/ml}$) to each well. Incubate plate 2 hr at room temperature. After incubation, shake out antibody, add 100 μl wash buffer to each well, and incubate plate 5 min at room temperature. Remove wash buffer and repeat wash step twice.
- Pipet 50 μl of each of the appropriately diluted isotyping reagents (in duplicate) into the designated wells: anti- μ into rows 1 and 2, anti- γ_1 into rows 3 and 4, anti- γ_2 into rows 5 and 6, anti- γ_3 into rows 7 and 8, anti- κ into rows 9 and 10, and anti- λ into rows 11 and 12. Cover plate and incubate 2 hr at room temperature.

When using anti- γ isotyping reagents, nonspecific binding to the μ heavy chain can be significantly reduced by adding 5 μl of 0.1 M 2-mercaptoethanol to the 50 μl of antigen-specific antibody in each well prior to the 2-hr incubation period.

- Wash wells as described in step 16 above. Complete remainder of assay (see Basic Protocol, steps 9 to 12).
- Determine amount of each isotyping reagent specifically bound in the wells as follows:
 - Average the cpm for each set of duplicates (cpm_{av}).
 - For each isotype specificity, subtract the cpm_{av} observed in wells coated with control antigen from the cpm_{av} observed in wells coated with specific antigen ($\text{cpm}_{\text{bound}}$).

20. Compare cpm_{av} values obtained for each heavy- and light-chain isotyping reagent to determine the immunoglobulin isotypes present. See Figure 11.17.4 for typical results for a mouse $\gamma_1\kappa$ antibody and a mouse $\mu\kappa$ antibody.

REAGENTS AND SOLUTIONS

Chloramine T solution

Prepare an 0.56 mg/ml solution by adding 5.6 mg chloramine T to 10 ml iodinating buffer (recipe below). Use immediately.

Coating buffer (0.1 M carbonate buffer, pH 9.6)

Stock A, 0.2 M: 21.2 g Na_2CO_3 (anhydrous) per liter H_2O

Stock B, 0.2 M: 16.8 g NaHCO_3 per liter H_2O

For pH 9.6, add 80 ml A + 170 ml B + 250 ml H_2O

Diluting buffer

0.5 g Tween 20

2.5 g bovine serum albumin (BSA; 0.25%)

1.0 g sodium azide (0.1%)

Add phosphate-buffered saline (PBS; APPENDIX 2) to 1 liter

2.5 g BSA may be replaced with 10 ml preimmune horse serum (1% final concentration).

NOTE: Do not add sodium azide if the HRPO-antibody conjugate is being used.

[^{125}I]anti-immunoglobulin reagent

Choose anti-immunoglobulin reagent specific for the animal species from which the antibody population being assayed is derived and iodinate according to Support Protocol 1 or 2. Dilute the stock solution of [^{125}I]anti-immunoglobulin reagent in diluting buffer to give 20,000 cpm/50 μl .

5 ml of diluted [^{125}I]anti-immunoglobulin reagent are required per 96-well plate.

Exercise extreme caution at all times when using radioactive materials, no matter how dilute the sample. Follow all institutional radiation safety regulations with respect to pertinent biological hazards and radioactive containment procedures.

Iodinating buffer (0.5 M phosphate buffer, pH 7.5)

Stock A: 137.03 g $\text{Na}_2\text{HPO}_4 \cdot 7\text{H}_2\text{O}$ per liter H_2O

Stock B: 68.99 g NaH_2PO_4 (anhydrous) per liter H_2O

Add 400 ml stock A to 100 ml stock B and check pH

iodo-GEN-coated glass test tubes

Pipet 100 μl methylene chloride solution containing 10 μg IODO-GEN into a 12 \times 75 mm glass tube (suitable for 100 μl protein at 1 mg/ml) and leave overnight to evaporate in a well-ventilated fume hood under a gentle stream of nitrogen.

IODO-GEN is insoluble in aqueous media and will remain immobilized on the reaction vessel wall after the iodinated sample has been removed. It is stable and can be stored coated on the glass up to 2 months at -20°C over Drierite in a desiccator.

Isotyping reagents

Anti-rabbit isotyping reagents are available from ICN Immunobiologicals. Anti-mouse isotyping reagents are available from a number of immunochemical suppliers.

Saturated tyrosine solution

Mix 50 g tyrosine and 50 ml iodinating buffer in a test tube. Cap the tube and incubate 30 min in a boiling water bath. Allow to cool before use.

COMMENTARY

Background Information

The solid-phase RIA described here provides a very sensitive method for the determination of the specific antibody titer within a given antiserum. The protein antigen is immobilized on the walls of the microtiter wells, which results in the denaturation of a significant proportion of the antigen. Thus, the solid-phase RIA allows the detection of antibodies that recognize both the native and denatured forms of the antigen. The immobilization of the protein antigen greatly enhances the antigen-antibody interaction, making the assay relatively affinity independent. The specific antibody titer determined using this assay includes both conformationally dependent and independent antibody specificities, as well as antibodies whose affinity for the antigen is extremely low ($K_a = 10^1$ to 10^2 M^{-1}). In addition, the solid-phase RIA is extremely useful for studying antibody specificity when quantities of protein antigen are limited.

In the Basic Protocol, [^{125}I]anti-immunoglobulin reagent is in the RIA as an alternative to the ELISA (UNIT 11.4), which can also be used to detect bound antibody. A wide variety of species-specific anti-immunoglobulin reagents can now be easily obtained from many biotechnology companies and can be labeled with ^{125}I using either of the procedures described in the support protocols. In some cases, it may be more convenient to use ^{125}I -labeled protein A in place of the anti-immunoglobulin reagent. However, protein A does not bind all species of immunoglobulin. A list of immunoglobulin species to which protein A binds is shown in Table 11.17.1. A more extensive list is provided by Goding (1978).

Support Protocol 1 describes the covalent coupling of ^{125}I to protein molecules using chloramine T. Although this procedure yields high specific activities (12 to 16 $\mu Ci/\mu g$ of immunoglobulin), given a sufficient number of surface-exposed tyrosine residues, chloramine T is a strong oxidant and can cause significant

losses in antibody activity after limited exposure (i.e., >1 min). In addition, some proteins may be much more susceptible to denaturation through oxidation than immunoglobulins. In such cases, a less harsh method of radio-iodination should be used: the IODO-GEN procedure described in Support Protocol 2 or the lactoperoxidase procedure (see Hudson and Hay, 1980; Mishell and Shiigi, 1980). Both of these procedures also link ^{125}I to proteins through tyrosines residues but yield lower specific activities. Finally, the addition of a large atom, such as the iodine atom, to the protein surface can potentially lead to some degree of conformational change, regardless of the radio-iodination procedure employed. Therefore, it is important that no more than one atom of ^{125}I is incorporated per protein molecule. The above protocols yield a substitution level well below this level.

Monoclonal antibodies are used in a variety of techniques such as immunoprecipitation (UNIT 10.16), western blotting (UNIT 10.8), ELISAs (UNIT 11.2), radioimmunoassays, and immunohistochemistry. In such techniques a second antibody reagent, tagged with a readily detectable molecule (e.g., ^{125}I , alkaline phosphatase, or horseradish peroxidase) is often required to enhance the sensitivity and/or selectability of the technique. As a consequence, it is necessary to determine the isotype of the monoclonal antibody to be used. Since polyclonal antisera are also frequently employed in these techniques, it is desirable to know the distribution of isotypes within the specific antibody population. As a result of its monoclonality, the isotype of a given monoclonal antibody is singular; however, a polyclonal antiserum will usually contain specific antibodies bearing a variety of isotypes. The heavy-chain isotypes found in rabbits are μ , γ_1 , γ_2 , α_1 , α_2 , and ϵ . Similar isotypes are found in mice and humans, although these species have more subtypes in the μ , γ , α , and ϵ families. The light-chain isotypes in all mammals are either λ or κ but in

Table 11.17.1 Binding of Immunoglobulin Classes and Subclasses to Protein A

Species	Classes which bind well	Classes which bind weakly
Rabbit	IgG	IgM
Mouse	IgG _{2a} IgG _{2b} IgG ₃	IgG ₁ IgM
Human	IgG ₁ IgG ₂ IgG ₄ IgA ₂	IgM
Rat	IgG	IgM

varying ratios. Thus, although these assays are described for polyclonal rabbit antisera, they may also be used to isotype sera or monoclonal antibodies from other species. The RIA will give only a qualitative estimation of the spectrum of specific isotypes present in an antiserum. A more quantitative estimation of the specific isotypes present may be obtained by affinity chromatography, as described in *UNIT 11.11*, using anti-isotype reagents conjugated to affinity resins.

Critical Parameters

For the accurate determination of specific antibody titer using the solid-phase RIA, it is critical that the standardized antibody solution be of similar composition to that of the antiserum being titered. First, both standard and unknown antibody populations must be derived from the same animal species and be specific for the same antigen. Second, because the different immunoglobulin isotypes will vary in their affinity for antigen and in their interaction with the anti-immunoglobulin reagent, the isotype composition within the standard antibody population and antiserum of interest should be equivalent. Third, it is important that the standard antibody retains maximum binding activity. A significant population of denatured or otherwise inactive standard antibody will result in low binding activity per milligram of protein (standard antibody) and therefore an underestimation of specific antibody titer.

All anti-immunoglobulin reagents cross-react to a certain extent with different isotypes. Therefore, preliminary assays must be carried out on each isotyping reagent to determine the optimal dilution that will allow minimal nonspecific cross-reactivity while yielding a sensitivity equivalent to that attained for the other isotyping reagents.

To achieve unambiguous and reproducible results, the optimal working dilutions of the isotyping reagents must be determined accurately. It is important that a working dilution be chosen at which little, if any, cross-reactivity with other nonspecific isotypes occurs. At the same time, the dilution of each isotyping reagent should be chosen such that the maximum numbers of cpm specifically bound by each reagent, at the chosen dilution, are equivalent. This ensures that the RIA will be able to detect the individual immunoglobulin isotypes, via the specific recognition of the respective isotyping reagents, with equivalent sensitivity.

Troubleshooting

The solid-phase RIA is very reliable as long as all reagents are prepared carefully. However, two potential problems may arise. First, a high level of nonspecific binding may occur when assaying the antiserum of interest. For the higher dilutions of antiserum (i.e., 1:125 to 1:390,000), the nonspecific binding should be <5% of the maximum specific binding. If higher values are obtained, it is likely that other serum components are adhering to the walls of the plastic wells or to the antigen and subsequently interacting nonspecifically with the RIA reagents. Protein aggregates can be removed from the antiserum by ultracentrifugation for 1 hr at $145,000 \times g$. Initially diluting the antiserum 1:10 or 1:25, instead of 1:5, also may help to reduce the background. If these procedures do not alleviate the problem, it may be necessary to remove the nonspecifically bound serum proteins using DEAE-Affi-Gel Blue chromatography (see *UNIT 11.14*, Alternate Protocol).

A second potential problem is the denaturation of the anti-immunoglobulin reagent during the iodination procedure. As stated in Support Protocol 1, chloramine T is a strong oxidant which should not be in contact with protein for any longer than specified. If no radioactivity is detected when the wells are counted in the gamma-counter, the ^{125}I -labeled anti-immunoglobulin reagent has most likely lost its binding activity. Repeat the iodination procedure ensuring that the antiimmunoglobulin reagent is in contact with the chloramine T for as short a time as possible. Alternatively, the IODO-GEN procedure (see Support Protocol 2) can be used.

In addition, the following should be considered: although the working dilutions of the isotyping reagents are optimized so that cross-reactivity with nonspecific isotype standards are minimal, significant cross-reactivity among the heavy-chain isotypes often occurs when assaying polyclonal antisera.

Anticipated Results

The titer of specific antibody in a given antiserum is dependent on the immunogenicity of the antigen (see introduction to this chapter). A titer of 5 to 10 mg/ml of specific antibody can be expected for a plant or bacterial antigen. A mammalian protein antigen may produce a titer significantly less than this, 0.1 to 2 mg/ml depending on the evolutionary relationship between the protein antigen and the analogous protein in the host.

Time Considerations

The solid-phase RIA can be completed in 1 or 2 days, depending on the length of the coating and blocking incubations. Labeling the anti-immunoglobulin reagent with ^{125}I can be completed within 60 to 90 min. The actual reaction time is 1 to 5 min.

PREPARATION AND USE OF SPECIALIZED ANTIBODIES

SECTION VI

Identification of Polyol-Responsive Monoclonal Antibodies for Use in Immunoaffinity Chromatography

UNIT 11.18

The extreme specificity of an antigen-antibody reaction can be used as a powerful step in protein purification processes. For most applications, the antibody is covalently coupled to a supporting matrix (such as cross-linked agarose). A crude or partially purified preparation of material containing the protein antigen is passed over the antibody-matrix, resulting in the selective capture of the target protein. However, one of the limitations of this technique, known as immunoaffinity chromatography (UNIT 10.11A), has been that high-affinity antigen-antibody complexes are difficult to dissociate, often leading to inactivation of the protein product during elution from the immobilized antibody.

Some antigen-antibody complexes are dissociated in the presence of a combination of a low-molecular-weight polyhydroxylated compound (polyol) and a nonchaotropic salt. These conditions seem to be generally nondenaturing and, in some cases, even protein-stabilizing. This type of antibody is designated “polyol-responsive.” These antibodies can be easily identified and isolated as monoclonal antibodies (MAbs) from a typical fusion, using standard hybridoma procedures. They have proven to be very valuable reagents for the immunoaffinity purification of active, labile, multi-subunit protein complexes.

The basic protocol describes pertinent steps in hybridoma production (steps 1 to 6), screening of MAbs for polyol responsiveness (steps 7 to 17), optimization of eluting conditions (steps 18 to 23), preparation of the MAb and the MAb-conjugated resin (steps 24 to 40), use of the MAb-conjugated resin in immunoaffinity chromatography (steps 41 to 47), and, finally, regeneration and storage of the MAb-conjugated resin (steps 48 to 50).

**BASIC
PROTOCOL**

Screening of the MAbs for polyol responsiveness is essential to identifying the appropriate MAb early in the process and can be performed even at the master-well stage during standard hybridoma production, after the fusion but before cloning. Alternatively, an existing collection of MAbs can be screened by this method before a large amount of MAb is produced for preparation of the MAb-conjugated resin. The screening procedure is a modified enzyme-linked-immunosorbent assay (ELISA), termed “ELISA-elution assay.” The ELISA-elution assay can also be used to help optimize the elution conditions.

Materials

- Purified or partially purified immunogen
- Mice for immunization (UNIT 11.4)
- 1× phosphate buffered saline (PBS; see recipe for 10×)
- HAT medium (UNIT 11.6)
- 1% nonfat dry milk (see recipe)
- PBST (see recipe)
- 1× TE buffer, pH 7.9 (see recipe for 10×)
- 1× TE buffer, pH 7.9 (see recipe for 10×) containing salt-polyol at appropriate concentration
- Polyols (e.g., ethylene glycol, propylene glycol, 2, 3-butanediol, glycerol)

Salts (e.g., ammonium sulfate, sodium chloride, potassium glutamate)
 Anti-mouse IgG conjugated to horseradish peroxidase (HRPO)
 OPD substrate (see recipe; or use other suitable substrate for HRPO)
 1 M H₂SO₄
 Mouse sub-isotyping kit (e.g., American Qualex; also see *UNIT 11.3*)
 Protein A-agarose (Repligen) or DE-52 cellulose (Whatman)
 Cyanogen bromide-activated Sepharose 4B (Sigma, or see *UNIT 10.16*)
 1 mM HCl
 Bicarbonate coupling buffer (see recipe)
 1 M ethanolamine, pH 8.3 (see recipe)
 Acetate washing buffer (see recipe)
 2% (w/v) NaN₃
 Crude material containing protein of interest
 1× TE buffer, pH 7.9 (see recipe for 10×) containing 2 M potassium thiocyanate (KSCN)
 1× TE buffer, pH 7.9 (see recipe for 10×) containing 100 mM NaCl and 0.02% NaN₃

 96-well cell culture plates
 Microtiter plate reader capable of reading at 490 nm
 30-ml sintered glass filter and vacuum flask
 End-over-end rotator
 10-ml disposable polypropylene column (Bio-Rad)

 Additional reagents and equipment for production of monoclonal antibodies (*UNITS 11.4-11.11*), ELISA (*UNIT 11.2*), immunoblotting (*UNIT 10.8*), preparation of antibody-Sepharose (*UNIT 10.16*), dialysis (*APPENDIX 3C*), and protein assays (*UNIT 10.1*)

Prepare mouse hybridomas

1. Immunize mice with desired immunogen (*UNIT 11.4*) and monitor the response by an indirect ELISA (*UNIT 11.2*) and immunoblotting (*UNIT 10.8*). Identify mice that have a titer well over 1:1000.
Several injections, administered over 4 to 6 weeks, are usually necessary to achieve such a titer.
2. About 1 month after the last immunization dose, inject the mouse to be used for the fusion intraperitoneally or intravenously with soluble immunogen dissolved in 1× PBS. Use ~2 to 3 times the amount of immunogen that was used in the last immunization dose.
3. Three days later, harvest the spleen, prepare a single-cell suspension, and fuse with the desired plasmacytoma cell line (*UNIT 11.7*).
4. Plate cells, suspended in HAT medium, into 96-well cell culture plates (~10 to 20 plates depending upon past history of fusion frequency) as described in *UNIT 11.7*.
5. About 10 to 14 days after the fusion, screen the hybridomas for specific antibody production, using 100 μl of cell culture medium and a standard ELISA procedure (*UNIT 11.2*).
*If an impure antigen is used, a secondary screen, using a microimmunoblot assay (*UNIT 10.8*) might be necessary.*
6. Add back 100 μl of HAT medium to the positive wells. After 1 to 2 days of incubation, perform the ELISA-elution assay as described in the following steps.

Screen for polyol responsiveness by the ELISA-elution assay

7. Coat a microtiter plate with antigen (30 to 100 ng/well, contained in 50 μl of PBS) for 1 hr at room temperature. Remove the antigen solution and then block with 1%

nonfat dry milk at 200 μl /well by incubating for at least 2 hr at room temperature, or overnight at 4°C.

8. Remove the blocking solution. Add 50 μl of the cell culture medium from antigen-specific antibody positive wells to each of two wells of the microtiter plate.

One well will serve as the buffer control, the other well will serve as the polyol-responsive test well.

9. Incubate at room temperature 1 to 1.5 hr, then wash wells three times with PBST. Remove residual PBST.
10. To one well, add 100 μl of 1 \times TE buffer, pH 7.9. To the other well add 100 μl of 1 \times TE buffer, pH 7.9, containing the polyol/salt combination.

For screening, a combination of 0.75 M ammonium sulfate and 40% (v/v) propylene glycol works well. This combination seems to identify more polyol-responsive MABs than the 1 M NaCl and 50% (v/v) ethylene glycol originally reported.

11. Incubate 20 min at room temperature, tapping the plate about every 5 min to ensure mixing of the solution in the wells, then wash wells three times with PBST. Remove residual PBST.
12. Add 50 μl of the proper dilution (usually 1:1000) of HRPO-conjugated anti-mouse IgG antibody in 1% non-fat dried milk. Incubate 1 hr at room temperature.
13. Wash plate eight times with PBST. Remove residual PBST.
14. Add 100 μl of OPD substrate. Allow color to develop for 1 to 5 min.

CAUTION: OPD is a carcinogen. Use appropriate care to avoid contact. Other substrates for HRPO can be used, but OPD seems to be the most sensitive.

15. Add 50 μl of 1 M H_2SO_4 to stop the reaction. Stop each control and test reaction in parallel.

Different hybridomas will produce MABs that have different titers and affinities. Therefore, different reaction times (1 to 5 min) might be needed for the individual antibodies. Other substrates may require use of different stop solutions.

16. Read the reactions on a microtiter plate reader at 490 nm.

A MAb is considered to be polyol-responsive if the OD reading of the well treated with the polyol/salt is 50% or less than the OD reading of the control well. The above wavelength is for OPD; other substrates may require a different wavelength.

17. Clone the polyol-responsive MAb-producing hybridomas at least twice by limiting dilution (UNIT 11.8). Freeze the hybridomas for future antibody production (UNIT 11.9).

Save the cell culture supernatant. It can be used for optimizing the elution conditions and determining the isotype of the MAB.

Optimize elution conditions by ELISA-elution assay

18. Coat with antigen and block a microtiter plate (see step 7) for each of the polyol-responsive MABs.

19. Prepare the desired polyol/salt combinations in 1 \times TE buffer, pH 7.9.

These solutions can be prepared at many different concentrations. Generally a range of each polyol and salt is assayed. Convenient salt concentrations are 0 M, 0.1 M, 0.25 M, 0.5 M, and 0.75 M and convenient polyol concentrations are 0%, 10%, 20%, 30%, 40%, and 50% (v/v). It is sometimes possible to use higher salt concentrations, but some salts are not soluble at high concentration in the higher percentages of polyols. These solutions

can be made ahead and stored in the refrigerator, but should be warmed up to room temperature before use.

20. Add 50 μ l of the cell culture supernatant to each well, and incubate 1 to 1.5 hr at room temperature. Wash the wells three times with PBST.
21. Set up a grid on the microtiter plate so that all each polyol/salt combination is tested in duplicate. Run several different combinations of polyol/salt on one plate.
22. Add 100 μ l of each polyol/salt solution to each of two wells. Incubate 20 min at room temperature, tapping the plate about every 5 min to ensure mixing of the solution in the wells. Wash the plate three times with PBST. Remove any residual PBST. Continue with the ELISA-elution assay (steps 12 to 16).
23. Average the OD readings for the duplicate samples and plot the value as a function of polyol/salt concentrations.

A typical set of data is shown in Figure 11.18.1.

Prepare the MAb and MAb-conjugated resin

24. Isotype each of the MAbs using a commercially available isotyping kit (or see UNIT 11.3).

Knowledge of the isotype is helpful for designing the purification of the MAb. The cell culture supernatant from freezing the hybridomas can be used for this assay.

25. Prepare ascites fluid from the hybridoma (UNIT 11.10).

Because some research institutes have placed restrictions on the production of ascites fluid in mice, alternative methods of large-scale production of MAbs should be considered (UNIT

Figure 11.18.1 Optimization of eluting conditions using the ELISA-elution assay. Two different salts at several concentrations were tested with two different polyols. Sodium chloride (NaCl) and ammonium sulfate (AS) were used at the indicated concentrations. Ethylene glycol (EG) and propylene glycol (PG) were used at 40% (v/v).

11.10). The scale of the MAb production should be such that ~5 to 10 mg of purified MAb can be produced.

26. Purify mouse IgG_{2a} and IgG_{2b} on staphylococcal protein A-agarose (UNIT 11.11).

Mouse IgG₁ does not bind well to protein A, but can be purified to ~80% purity by chromatography on DE-52 cellulose. Add saturated (at 4°C) ammonium sulfate solution to achieve a 45% ammonium sulfate cut of the ascites fluid. Stir on ice bath ~30 min. Centrifuge to collect the precipitate, dissolve the precipitate in 1/2 volume of 50 mM Tris-Cl, pH 7.0, and 25 mM NaCl, and dialyze overnight against this buffer. Centrifuge to clarify. Equilibrate a 5-ml column of DE-52 in the same Tris buffer. Apply the material to the DE-52 column and collect the flowthrough fractions. Most mouse IgG₁ MAbs (and some of the IgG_{2a} and IgG_{2b} MAbs) flow through DE-52 under these conditions.

27. Determine the amount of MAb (in mg) by taking an absorbance reading at 280 nm and applying the following formula:

Absorbance × dilution factor/1.38 × volume of MAb solution (ml)

28. Calculate the amount of MAb needed for the conjugation, using an estimate of 2.5 mg MAb per ml of swollen resin.

Slightly lower amounts can be used, but increasing the amount of antibody will not necessarily increase the capacity of the resin. Hybridomas vary in the amount of MAb that is produced in the ascites fluid. This is usually in the range of 1 to 10 mg/ml with most hybridomas producing between 1 to 3 mg/ml. Thus ~5 to 10 ml of ascites fluid will generally suffice for preparation of a useful amount of MAb-conjugated resin.

29. Calculate the amount of cyanogen bromide-activated Sepharose needed to prepare the desired amount of resin.

Other matrices with other coupling chemistries can be used. However, because cyanogen bromide-activated Sepharose performs well and is relatively inexpensive, the protocol is described for this resin. 1 g of dried Sepharose swells to ~3.5 ml of resin. Thus, 1 g would require 8.75 mg of MAb. The volumes described below are useful for 3.5 ml of Sepharose.

30. Dialyze (APPENDIX 3C) the appropriate amount of purified MAb against bicarbonate coupling buffer overnight at 4°C and centrifuge 15 min at 6000 × g, 4°C, to clarify.
31. Swell the appropriate amount of cyanogen bromide-activated Sepharose in 1 mM HCl for ~15 min at room temperature.
32. Wash the Sepharose on a 30-ml sintered glass filter with ~200 ml of 1 mM HCl. Quickly wash the resin with ~20 ml of bicarbonate coupling buffer and transfer to the solution (~10 ml) containing the MAb.
33. Mix the solution, end-over-end, on a laboratory rotator for 2 hr at room temperature.
34. Collect the resin on the sintered glass filter, reserving the flowthrough to determine the amount of MAb coupled. Take the absorbance of the flowthrough at 280 nm and estimate the percentage of coupling, again assuming that 1 mg MAb/ml will give an absorbance at 280 nm of 1.38.
35. Transfer the resin to a solution of 1 M ethanolamine, pH 8.3. For 3.5 ml of resin, use ~10 ml of ethanolamine solution.
36. Mix the solution, end-over-end, on a laboratory rotator for 2 hr at room temperature.
37. Collect the resin on the sintered glass filter and wash with ~100 ml bicarbonate coupling buffer.
38. Wash the resin on the sintered glass filter with ~100 ml acetate washing buffer.

39. Repeat steps 37 and 38 twice. Wash and resuspend in bicarbonate coupling buffer (~10 ml).
40. Add 1/100 vol of 2% NaN₃ and store at 4°C.

Purify target protein on MAb-conjugated resin

41. Prepare the crude material from which the protein is to be purified by an appropriate method to maintain stability of the protein.

Immunoaffinity chromatography (UNIT 10.11A) is generally one step in a protein purification protocol. Frequently, it is the only chromatography step necessary. The initial steps in the purification procedure will vary with the nature of the material. Usually, some initial steps must be taken to remove nucleic acids to lower viscosity. In addition, generally some fractionation step might be used to reduce the volume of the material. See Chapter 10 introduction for guidelines on how to structure a protein purification procedure. The references contain protocols for preparing material from yeast (Edwards et al., 1990), wheat germ and calf thymus (Thompson et al., 1990), and bacteria (Thompson et al., 1992; Thompson and Burgess, 1994).

42. Pack a 10-ml disposable polypropylene column with the antibody-Sepharose (UNIT 10.11A). Apply the crude material to the MAb-conjugated resin.

Alternatively, this step can be performed in batch mode.

43. Wash the resin with the appropriate buffer containing ~0.5 M salt but no polyol.
44. Move the resin to room temperature. If the material had been applied to the MAb-conjugated resin in a batch mode, pour the resin into a small column.
45. Elute the column with 1× TE buffer, pH 7.9, containing the salt/polyol.

Care should be taken to apply the polyol/salt solution gently to a well-packed column to avoid causing the resin to float due to the high density of the polyol/salt solution. For reasons that are not clear, the polyol/salt elution is more effective at room temperature than at 4°C. However, if lability of the protein is a concern, all steps up to the elution step can be performed at 4°C. Fractions containing the protein can also be put in an ice bath as they come off the column. Therefore, the protein is usually at room temperature for less than 30 min.

46. Perform a quick protein assay such as a Bradford assay (UNIT 10.1) and pool the peak fractions.
47. Dialyze the protein (APPENDIX 3C) against two changes of an appropriate buffer, for 2 hr each at 4°C, to remove salt and polyol.

It is necessary to remove the salt and polyol to avoid interference in subsequent biological or biochemical assays. A buffer should be chosen that will maintain the stability and activity of the particular protein.

Regenerate and store MAb-conjugated resins

48. Wash the resin with ~10 ml of 1× TE buffer containing 2 M KSCN.

This can be performed in either batch or column mode, but the MAb-conjugated resin should not be exposed to KSCN for longer than ~20 min.

49. Wash the resin with 1× TE buffer containing 100 mM NaCl and 0.02% NaN₃.
50. Store the MAb-resin at 4°C.

MAb-conjugated Sepharose can be stored up to ~6 months at 4°C. After ~6 months, some leaching of MAb from the resin can be detected. Most MAb-conjugated Sepharose preparations can be used ~10 times. After ~10 uses, the column usually still works but more contaminants seem to be recovered in the product.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetate washing buffer

To 900 ml H₂O, add:
13.6 g sodium acetate trihydrate
29.22 g NaCl
Adjust to pH 4.0 at 23°C with glacial acetic acid
Add H₂O to 1000 ml
Store up to 6 months at room temperature

Bicarbonate coupling buffer

To 900 ml H₂O, add:
8.4 g NaHCO₃
29.22 g NaCl
Adjust to pH 8.3 at 23°C with 1 N NaOH
Add H₂O to 1000 ml
Prepare fresh

Citrate buffer, 0.1 M

Solution A: 29.4 g sodium citrate, dihydrate in 1000 ml H₂O
Solution B: 21.0 g citric acid, monohydrate in 1000 ml H₂O
Add solution B to ~500 ml of solution A until pH 5.0 is achieved. Filter sterilize and store up to 1 year at 4°C.

EDTA, 0.2 M, pH 7.9

74.4 g disodium EDTA dihydrate
700 ml H₂O
Adjust to pH 7.9 at 23°C with 10 M NaOH
Add H₂O to 1000 ml

Ethanolamine, 1 M, pH 8.3

To 80 ml of bicarbonate coupling buffer (see recipe), add 6 ml ethanolamine. Adjust pH to 8.3 at 23°C with 6 M HCl. Add coupling buffer to 100 ml. Prepare fresh.

Nonfat dry milk, 1%

5 g nonfat dried milk
50 ml 10× PBS (see recipe)
450 ml H₂O
Store up to 1 week at 4°C

OPD substrate

10 mg *o*-phenylenediamine (OPD)
10 ml H₂O
10 ml 0.1 M citrate buffer (see recipe)
20 µl 30% H₂O₂
Prepare fresh

PBST

100 ml 10× PBS (see recipe)
900 ml H₂O
1 ml Tween 20
Store up to 2 months at room temperature

Phosphate-buffered saline (PBS), pH 7.4, 10×

To 900 ml H₂O, add:
80.0 g NaCl
2.0 g KCl
21.6 g Na₂HPO₄·7H₂O
2.0 g KH₂PO₄
Add H₂O to 1000 ml
Store up to 6 months at room temperature

TE buffer, pH 7.9, 10×

25 ml 2 M Tris·Cl, pH 7.9 (see recipe)
0.5 ml 0.2 M EDTA, pH 7.9 (see recipe)
Add H₂O to 100 ml with H₂O
Store up to 1 year at room temperature

Tris·Cl, 2 M, pH 7.9

242.2 g Tris base
500 ml H₂O
Adjust to pH 7.9 at 23°C with 6 M HCl
Add H₂O to 1000 ml

COMMENTARY

Background Information

The development of practical methods for generating MABs has renewed interest in adapting immunoaffinity chromatography techniques for protein purification. Most early studies focused on low-affinity MABs. However, in order for a MAB to effectively capture an antigen from a dilute solution it must be a high-affinity antibody. Most high-affinity antigen-antibody interactions are difficult to disrupt, requiring conditions that are generally denaturing to proteins, such as extremes of pH or 6 M urea. About 5% to 10% of mouse MABs are polyol-responsive antibodies (Thompson et al., 1992) which release the antigen in the presence of a combination of low-molecular-weight polyol and a nonchaotropic salt. In addition to being gentle and protein-stabilizing, these reagents are very inexpensive and can be used economically on a large scale.

This procedure can be used to purify labile, multi-subunit enzymes, such as eukaryotic RNA polymerase II (Edwards et al., 1990; Thompson et al., 1990) and bacterial RNA polymerase (Thompson et al., 1992; Marshak et al., 1996). In fact, the immunoaffinity chromatography step was the critical purification step for the eventual crystallization of the yeast RNA polymerase II (Cramer et al., 2000). It has also been used for purification of eukaryotic transcription factors expressed in bacteria (Thompson and Burgess, 1994, 1999).

In some cases, it is desirable to follow the immunoaffinity step with a high-resolution ion-exchange step to remove any minor contaminants. Sepharose has some nonspecific binding capacity, and some batches of Sepharose seem to have higher nonspecific binding than others.

Using the ELISA-elution assay, it is possible to screen for polyol responsiveness at the master-well stage of hybridoma production. Thus, if the goal is to isolate this type of MAB, valuable time can be saved by identifying the MAB early in the process. In addition, the ELISA-elution assay can also be used to quickly screen different polyol/salt combinations and to help optimize eluting conditions. Some polyol-responsive MABs respond to a variety of polyol/salt combinations (Thompson et al., 1990, 1992). However, some MABs are more limited in their response (Thompson and Burgess, 1999). It is worth noting that polyol-responsive MABs are not limited to a particular sub-class of mouse IgG.

Critical Parameters and Troubleshooting

One of the most critical parameters of this procedure is that the epitope for the MAB must be accessible in solution. The ELISA-elution assay can generate some false positives. That is, a MAB might appear to be polyol-responsive in this assay, but it does not capture the antigen from solution. This is probably due to distortion

of the antigen on the polystyrene surface, resulting in exposure of epitopes that are not accessible in solution. It is wise to examine the ability of the MAb to remove the antigen from solution early in the identification procedure. This can be done with a simple immunodepletion assay using cell culture supernatant (Thompson and Burgess, 1994).

When a MAb is screened from ascites fluid or other concentrated source of antibody, care must be taken to ensure that the MAb concentration is in the linear range. Otherwise a false negative might result due to overloading of the MAb. Thus, a 50% reduction might not be noticed, resulting in a false negative.

Another critical parameter is that the elution of the antigen from the immobilized MAb is much more efficient at room temperature than at 4°C. However, with careful planning it is possible to limit the time that the protein is exposed to the higher temperature.

High levels of reducing agents in buffers can result in reduction of the disulfides in the MAb. When the antigen is eluted with the polyol/salt, some immunoglobulin chains can be detected in the protein product. To avoid this problem, the material should be applied in buffer that does not contain reductant. In most cases, reductant can be added to each fraction as it comes off the column. In cases where reducing agent is required for enzyme stability, the 0.05 to 0.1 mM DTT can be used in the column buffers, but this might result in decreasing the life of the column and recovery of some MAb chains in the product.

Anticipated Results

Approximately 5% to 10% of MAbs are polyol-responsive; therefore, the probability of isolating one from a standard fusion is quite high. In most cases, the immunoaffinity chromatography step is the only chromatography step necessary for purification of the protein, resulting in a more rapid purification procedure. Because the protein is eluted in salt and a polyol, the product is in a solution that is generally protein-stabilizing.

Time Considerations

The ELISA-elution assay takes ~0.5 days to perform. However, when screening hybridoma

at the master-well stage, the cells need to incubate ~1 day between the initial screen for specific antibody and the ELISA-elution assay. Thus, this adds ~2 days to the hybridoma production.

Production of large amount of MAb by ascites fluid production usually takes 2 to 3 weeks.

The purification and conjugation of the MAb takes 2 days. Because the MAb can start to leach off the resin upon extended storage, the resin should be used within 6 months of conjugation.

CHAPTER 12

DNA-Protein Interactions

INTRODUCTION

For several decades, DNA-binding proteins have been studied because of their involvement in cellular processes such as replication, recombination, viral integration, and transcription. In recent years, the number of workers interested in the study of these proteins has greatly increased as the advent of recombinant DNA technology has led to the isolation of numerous biologically important genes. Many investigators are interested in how transcription of these genes is controlled in response to environmental or developmental signals, and have started to characterize the DNA sequences responsible for this regulation. This analysis has naturally led to the detection, isolation, and characterization of the proteins that bind to these regulatory sequence elements. This chapter summarizes the techniques currently used to characterize DNA-protein interactions and to isolate DNA-binding proteins.

The preparation of cell extracts from either the nucleus or cytoplasm is often the first step in studying these proteins and their interactions (*UNIT 12.1*). The resulting preparations can be used directly in a variety of functional studies, or as the starting point for the purification of proteins involved in gene regulation. In the past two decades many advances have been made in the technologies used for detecting DNA-binding proteins and for purifying those proteins. Perhaps the most widely applied technology has been the mobility shift assay (*UNIT 12.2*), whereby proteins are detected by their ability to retard the mobility of a labeled DNA fragment through a nondenaturing gel. This technique—originally developed to characterize the interaction of purified prokaryotic proteins with DNA—has been refined to allow detection of numerous DNA-binding proteins in crude extracts from a wide variety of cells. Because the mobility shift assay is simple and rapid, it is typically the method of choice when purifying DNA-binding proteins.

After detection of a DNA-binding protein, it is often necessary to determine its binding specificity. Guesses about the binding site can be verified by using mutated DNA fragments as either cold competitor or as labeled probe in the mobility shift assay. Alternatively, one can chemically modify the DNA template, and ask how these alterations affect binding of a specific protein. The most widely used of these modification, or “interference,” techniques is methylation interference (*UNIT 12.3*). This technique allows direct detection of nucleotides that are in close contact with the binding protein. Here, guanine and adenine residues are methylated at an average of one modification per DNA molecule. Modified DNA molecules bound to a specific protein are then separated from those molecules that are not bound via the mobility shift assay. Molecules that are methylated at nucleotides which are important for binding will be underrepresented in bound DNA.

While methylation interference tends to be more informative than most protection techniques, DNase I protection mapping (or “footprinting”) can provide another level of information (*UNIT 12.4*). In these procedures, protein is first bound to DNA and then the DNA is cleaved either by DNase or chemical agents. Footprinting typically reveals, without perturbing, the general region(s) of DNA to which a protein binds. Footprinting is rapid and sensitive once it is optimized for a particular interaction and can be used as a routine assay in purification. The footprinting assay can also be used as a quantitative

technique to determine both the binding curves for individual proteins, as well as cooperative interactions among proteins bound to multiple sites along DNA.

After detection and preliminary characterization of a DNA-binding protein, investigators frequently wish to purify the protein. This can be accomplished using standard chromatography techniques (Chapter 10) and assaying the fractions for presence of the protein by mobility shift gel electrophoresis or footprinting. Another procedure that has proved to be very powerful in these purification schemes is the use of an affinity column containing large amounts of DNA specifying the binding site for the factor (*UNIT 12.10*).

These affinity columns take advantage of the extraordinary specificity that a protein has for its cognate binding site. When such a column is used, protein is applied to it in the presence of high levels of competing, nonspecific DNA, and proteins recognizing specific sequence motifs on the affinity column partition onto those sequences as the column is loaded. In an alternative procedure, protein is first fractionated on a standard, nonspecific DNA column (e.g., DNA-cellulose), and then applied in high salt to the specific affinity column. Specific protein-DNA complexes are frequently stable to moderate salt concentrations, while many nonspecific protein-DNA complexes are disrupted in high salt. A high degree of purification can therefore be achieved using a standard DNA-cellulose column and a DNA affinity column in tandem.

Similar degrees of purification can be accomplished through the use of biotinylated DNA fragments that contain the binding site for a protein and column matrices that are coated with streptavidin (*UNIT 12.6*). In this procedure, a biotinylated DNA fragment containing a specific sequence motif is mixed with crude or partially purified protein and an excess of competitor DNA. As with the affinity column described above, the specific protein will partition onto the DNA fragment containing the binding site. The specific DNA fragment—as well as the attached protein—is then fished out of this mixture using streptavidin and a column matrix, and the specific protein is eluted with high salt. This protocol is relatively easy to optimize, as the success or failure of several of the steps can be monitored using mobility shift gels. It is also extremely flexible, as one single type of column matrix is compatible with any biotinylated DNA probe, and thus can be used to purify numerous different DNA-binding proteins.

To help ensure that the appropriate protein has been purified, it is useful to know the size of the protein that interacts with a specific DNA sequence. In addition, regulatory proteins can be modified in the cell in response to environmental or developmental signals; therefore, knowing the apparent size of a DNA-binding protein under various conditions is also important as this information can provide insight into regulatory events concerning that protein.

The size of a DNA-binding protein can be determined by covalently crosslinking the protein to its regulatory sequence using UV light and resolving the protein complexes on an SDS polyacrylamide gel (*UNIT 12.5*). This procedure works even for impure proteins in crude extracts. Crosslinking can be accomplished by irradiating a protein solution containing a specific labeled DNA probe. Alternatively, protein-DNA complexes can first be separated on a mobility shift gel and then irradiated. This latter protocol increases confidence that the identified protein is actually part of an appropriate complex. In both protocols, it is critical to verify that the crosslinked protein interacts specifically with a given sequence motif, for example by performing competition studies with unlabeled DNA fragments.

In many instances, an important goal is to clone the gene that encodes a DNA-binding protein, thus allowing detailed genetic characterization of the protein. This can be

accomplished by purifying the binding protein to homogeneity, sequencing it, and using that sequence to identify a cDNA clone (see Chapter 6); however, despite the recent advances in purification techniques, the above approach can be extremely time consuming, particularly if the DNA-binding protein is present at very low levels. An alternative approach is to use the sequence known to be recognized by the protein to directly identify a cDNA clone (*UNITS 12.7 & 12.12*). In *UNIT 12.7*, a library that expresses inserted cDNAs in *E. coli* is plated out, and proteins expressed in plaques produced by recombinant phages are transferred to nitrocellulose filters. These filters are then probed with a specific labeled sequence in order to detect clones that express a given DNA-binding protein. Success of this protocol relies on the assumption that the protein as expressed in *E. coli* will be capable of specifically binding DNA. For example, if the protein binds DNA as a heterodimer, or requires a particular covalent modification to bind to its site, it will not be detectable using this approach.

A second approach to isolate a cDNA clone for a sequence-specific DNA binding protein is to take advantage of the powerful reporter gene and expression strategies that have been developed for use in yeast. *UNIT 12.12* describes the “one hybrid” approach in which a cDNA library of proteins that are fused to a transcriptional activation domain is screened. This library is introduced into yeast strains that contain a reporter gene whose expression is regulated using the candidate DNA binding sequence. Expression of a protein that binds to this sequence will result in activation of the reporter gene, which in turn allows for isolation of the yeast colonies that express the reporter. These yeast colonies are screened further for the presence of proteins that bind to the sequence of interest. This technique offers the advantage that the DNA binding proteins are expressed *in vivo*, and thus binding conditions do not require optimization and the expressed proteins do not need to be denatured and renatured.

Using the above mentioned techniques, one can identify and purify DNA-binding regulatory proteins. Once these proteins are pure it is important to characterize their ability to interact with DNA. Information on both the sequence-specificity for binding and the “strength,” or affinity, of the binding interaction are useful. Binding affinity can be measured using DNase footprinting (*UNIT 12.4*), however in many instances it is simpler to use filter binding (*UNIT 12.8*). Double-stranded DNA flows through nitrocellulose, while protein or protein-DNA complexes are retained. Filter binding provides a simple and sensitive means of characterizing the interaction of purified protein with a known regulatory sequence. Competition experiments using filter binding allow rigorous determination of the relative affinities that several sequences have for one protein. In addition, kinetic measurements can be performed that allow a good estimate of the binding constant and off-rate for any given protein-DNA interaction.

Filter binding is also a useful procedure for determining the DNA-binding properties of pure protein with unknown functions. Frequently (e.g., with developmentally important genes or with oncogenes) a gene product that is biologically important is known to reside in the nucleus, but its precise function is obscure. Filter binding can be used to screen regions of DNA for those sequences that interact with these proteins. If such sequences are identified by filter binding, more detailed analyses—such as footprinting or methylation interference—can be used to further characterize the binding site.

In many instances, it is worthwhile to identify the optimal DNA sequence for binding by a specific protein. Strategies that use PCR have been developed to “select” DNA fragments that bind to a given protein from a large collection of DNA fragments (*UNIT 12.11*). Initially, a large group of DNA fragments is bound to the protein of interest and bound fragments are separated and amplified by PCR. The procedure is repeated several times until a pool of DNA fragments are isolated that can bind to the protein of interest.

Determining the sequences of a number of the individual DNA fragment in this pool, and then comparing those sequences, usually yields a consensus DNA binding sequence.

Once a cloned gene encoding a DNA-binding protein is identified, it is possible to synthesize radiolabeled protein by *in vitro* transcription and translation (*UNIT 10.7*). The resulting labeled protein can then be used to detect and analyze DNA-protein interaction (*UNIT 12.9*). The striking advantage of this approach is the possibility for constructing mutations in the cloned gene which can affect the DNA binding properties of the expressed gene.

The protocols described in this chapter can therefore be used to detect and characterize specific DNA-protein interactions, to purify specific DNA-binding proteins, and to clone the genes for these proteins. Using these protocols, one can start with a defined regulatory sequence motif and isolate the gene that encodes the factor responsible for regulation. The characteristics of the regulatory protein can be determined, and the clone of the regulatory gene can be dissected to define functional domains of the regulatory protein. These procedures have been widely applied in mammalian systems where there is very little that can be done to dissect gene regulation by classical genetic means, and have developed to the point where it is feasible, though certainly still difficult, to dissect complex regulatory loops at the molecular level.

Robert E. Kingston

Preparation of Nuclear and Cytoplasmic Extracts from Mammalian Cells

Extracts prepared from the isolated nuclei of cultured cells are functional in accurate *in vitro* transcription and mRNA processing. Thus, such extracts can be used directly for functional studies and as the starting material for purification of the proteins involved in these processes. In the basic protocol described below, reproducible extracts from different preparations of nuclei are generated. The conditions described are optimized to produce transcriptionally active extracts from HeLa cells. The first support protocol describes how to optimize the basic protocol to increase the yield of specific proteins or activities from different cell types. The second support protocol describes the preparation of the cytoplasmic (S-100) fraction.

BASIC PROTOCOL

PREPARING NUCLEAR EXTRACTS

To prepare nuclear extracts, tissue culture cells are collected, washed, and suspended in hypotonic buffer. The swollen cells are homogenized and nuclei are pelleted. The cytoplasmic fraction is removed and nuclei are resuspended in a low-salt buffer. Gentle dropwise addition of a high-salt buffer then releases soluble proteins from the nuclei (without lysing the nuclei). Following extraction, the nuclei are removed by centrifugation, the nuclear extract (supernatant) is dialyzed into a moderate salt solution, and any precipitated protein is removed by centrifugation.

Materials

- Mammalian (i.e. HeLa) cells from spinner cultures or monolayer cultures
- Phosphate-buffered saline (PBS; *APPENDIX 2*)
- Hypotonic buffer
- Low-salt buffer
- High-salt buffer with 1.2 M KCl
- Dialysis buffer
- Liquid nitrogen
- Beckman JS-4.2 rotor (or equivalent)
- 50-ml graduated conical polypropylene centrifuge tubes (or 15-ml tubes for smaller extract volumes)
- Glass Dounce homogenizer (type B pestle)
- Beckman JA-20 rotor (or equivalent)
- Magnetic stirrer *or* tiltboard
- Dialysis membrane tubing ($\leq 14,000$ MWCO; *APPENDIX 3*)
- Conductivity meter
- Additional reagents and equipment for trypan blue exclusion (*UNIT 11.5*) and Bradford protein assay (*UNIT 10.1*)

NOTE: Perform this procedure at 0° to 4°C, preferably in a cold room. Use precooled buffers and equipment. All centrifugations are done at 4°C with precooled rotors.

Isolate the nuclei

- 1a. *Collect cells from spinner cultures.* Centrifuge cells in 1-liter plastic bottles 20 min in a Beckman JS-4.2 rotor at 3000 rpm ($1850 \times g$). Decant the supernatants and discard. Pool cells in 50-ml graduated conical centrifuge tubes (one tube for every 2 to 3 liters of cells). Proceed to step 2.

The density of the spinner culture should be $5-10 \times 10^8$ cells/liter.

- 1b. *Collect cells from monolayer cultures.* Remove the culture medium from confluent

monolayer cultures. Wash the cells by pipetting sufficient PBS to cover them, swirling gently, and pouring off the PBS. Scrape the cells into fresh PBS and pool in a graduated conical centrifuge tube. Proceed to step 2.

2. Pellet the cells by centrifuging 10 min in a JS-4.2 rotor at 3000 rpm. Proceed to step 3a for spinner cultures or step 3b for monolayer cultures.
- 3a. *Spinner cultures.* Decant the supernatants and discard. Using the graduations on the tube, measure the packed cell volume (pcv). Resuspend the cells in a volume of PBS ~5 times the pcv. Centrifuge the cells 10 min in a JS-4.2 rotor at 3000 rpm. Proceed to step 4.
- 3b. *Monolayer cultures.* Decant the supernatants and discard. Using the graduations on the tube, measure the pcv. Proceed to step 4.
4. Rapidly resuspend the cell pellets in a volume of hypotonic buffer ~5 times the pcv. Centrifuge the cells 5 min in a JS-4.2 rotor at 3000 rpm and discard supernatant.

Do this step quickly because proteins can leak out of the cell at this point and be discarded with the supernatant. This step removes salt from the PBS solution so that efficient swelling can occur in the next step; however, some swelling will occur during this step.

5. Resuspend the packed cells in hypotonic buffer to a final volume of 3 times the original pcv (step 3) and allow to swell on ice 10 min.

For example, if an original pcv of 10 ml has swelled to 20 ml in step 4, only 10 ml of additional buffer is required at this step. The cells should swell at least 2-fold.

6. Transfer the cells to a glass Dounce homogenizer. Homogenize with ten up-and-down strokes, using a type B pestle.

Perform the homogenization slowly, especially the down strokes. After homogenization, check for cell lysis in a microscope. Lysis can be observed by addition of trypan blue to an aliquot of cells (UNIT 11.5). The dye is excluded from intact cells but stains the nuclei of lysed cells. Lysis should be >80% to 90%.

7. Transfer cells to centrifuge tubes. Collect the nuclei by centrifuging 15 min in a JS-4.2 rotor at 4000 rpm (3300 × g). Remove the supernatant and save for S-100 cytoplasmic extract preparation (second support protocol).

Extract the nuclei

8. Using the graduations on the tubes, measure the packed nuclear volume (pnv) from step 7. Resuspend the nuclei in a volume of low-salt buffer equal to ½ pnv.

Resuspension of the nuclei with a small volume of low-salt buffer allows thorough rapid mixing of the nuclei during the addition of the high-salt buffer (step 9). If necessary, clumps of nuclei can be resuspended with one or two strokes in a Dounce homogenizer using a type B pestle.

9. In a dropwise fashion, while stirring gently, add a volume of high-salt buffer equal to ½ the pnv (from step 8). Homogenize in Dounce if necessary.

The high-salt buffer must be added dropwise with frequent or continuous mixing. If it is added too quickly, local concentration of salt can become high and some nuclei will lyse. After adding high-salt buffer, the nuclei can be homogenized with two to five up-and-down strokes in a glass Dounce homogenizer (type B pestle) to prevent clumping in large volumes. It is not always necessary for very small volumes (2 to 3 ml).

The final concentration of potassium chloride should be ~300 mM.

10. Allow the nuclei to extract for 30 min with continuous gentle mixing.

Mixing can be done using very gentle stirring on a magnetic stirrer or by tilting on a tiltboard.

11. Pellet the extracted nuclei by centrifuging 30 min in a Beckman JA-20 rotor at 14,500 rpm ($25,000 \times g$). Draw off the resulting supernatant and measure its conductivity (see step 12). This is the nuclear extract.

Dialyze and store the extract

12. Place the nuclear extract in dialysis tubing. Seal at least one end of the dialysis bag with a clip; the bag can then be opened to compare the conductivity of the contents with that of the dialysis buffer to determine whether further dialysis is necessary. Dialyze against 50 vol of dialysis buffer until the conductivities of the extract and buffer are equal (i.e., when the extract reaches 100 mM KCl).

Conductivity is checked by diluting 5 to 10 μ l of the extract to 1 ml water. Read the conductivity of this dilution directly with a conductivity meter and compare it to that of an equivalent dilution of dialysis buffer.

Dialyze the extract for the minimum amount of time needed to achieve the desired salt concentration: 75 to 100 ml of nuclear extract require ~5 hr of dialysis, whereas 2 ml of extract requires <1 hr. Use the support protocol for optimizing nuclear extraction to determine this. To decrease the dialysis time, use tubing with the largest reasonable surface area for the volume. Dialyzing against dialysis buffer without KCl can also reduce dialysis time. In this instance, the conductivity of the extract should be checked frequently and the dialysis stopped when the conductivity equals that of the dialysis buffer (with 100 mM KCl). This method requires extreme care as a very rapid decrease in the salt concentration and/or dialysis to <100 mM KCl can result in increased protein precipitation.

13. Remove the extract from the dialysis bag and check the conductivity a final time to ensure that dialysis is complete. Centrifuge the extract 20 min in JA-20 rotor at 14,500 rpm. Discard the pellet.

This will remove protein and nucleic acid that precipitates when the potassium chloride concentration is lowered during dialysis.

14. Determine the protein concentration of the supernatant. Aliquot into tubes if desired and rapidly freeze by submerging in liquid nitrogen. Store the extracts at -80°C .

Protein concentration can be determined using the Bradford assay (UNIT 10.1). If all of the extract is not going to be used at one time (i.e., for protein purification), divide the extract into aliquots before freezing to avoid unnecessary freezing and thawing. In general, avoid more than five cycles of freezing/thawing; however, the stability of specific proteins may differ. Thaw frozen extracts on ice.

OPTIMIZATION OF NUCLEAR EXTRACTION

This protocol describes a simple method to optimize the salt concentration during nuclear extraction for specific applications (see critical parameters). Extracts made with higher or lower potassium chloride concentrations can then be assayed in transcription, splicing, gel-shift analysis (*UNIT 12.2*) to determine the optimum extraction conditions for specific cells and applications.

Additional Materials

High-salt buffer with 0.8, 1.0, 1.2, 1.4, and 1.6 M KCl

1. Perform steps 1 to 8 of the basic protocol.

As in the basic protocol, perform all steps at 0° to 4°C and use precooled buffers and equipment.

2. After resuspending the nuclear pellet in low-salt buffer ($\frac{1}{2}$ pnv; step 8 of basic protocol), divide the suspension into five aliquots of equal volume.

Before aliquoting, be certain that the nuclei are completely resuspended. Homogenize with one or two strokes in a Dounce homogenizer using type B pestle if necessary.

3. Add $\frac{1}{3}$ aliquot vol of high-salt buffer with frequent or continuous mixing to each aliquot, as follows: add high-salt buffer with the lowest KCl concentration (0.8 M) to the first aliquot and add high-salt buffer with increasing KCl concentrations (up to 1.6 M) to subsequent aliquots.

It is critical to add this buffer in the cold room with gentle continual mixing on a magnetic stirrer.

4. Secure the tubes containing the extracting nuclei on a tiltboard and gently mix 30 min.
5. Remove the nuclei by centrifuging 30 min in JA-20 rotor at 14,500 rpm.
6. Decant the extracts (supernatants) and dialyze against dialysis buffer (as in step 12 of the basic protocol).

Dialyze all the extracts until the one with the highest KCl concentration approaches the conductivity of the dialysis buffer (100 mM KCl).

Centrifuge the extracts 20 min in JA-20 rotor at 14,500 rpm.

7. Check the conductivity of each extract, and determine the protein concentration of the supernatants (see steps 13 and 14 of basic protocol).
8. Assay the extracts directly or aliquot into tubes. Freeze in liquid nitrogen before storing at -80°C .

PREPARATION OF THE CYTOPLASMIC (S-100) FRACTION

The basic protocol also yields a cytoplasmic extract that may contain proteins of interest (e.g., RNA polymerase III transcription factors). This protocol describes the preparation of the S-100 fraction from this cytoplasmic extract. It is practical to prepare and dialyze the S-100 fraction and the nuclear extract simultaneously.

Additional Materials

Cytoplasmic extract (step 7, basic protocol)

10× cytoplasmic extract buffer

Beckman Type 50 fixed-angle rotor (or equivalent)

1. Carefully measure the volume of the cytoplasmic extract (supernatant from step 7 of the basic protocol). Add 0.11 vol of 10× cytoplasmic extract buffer and mix thoroughly.

As in the basic protocol, perform all steps at 0° to 4°C and use precooled buffers and equipment.

2. Centrifuge 1 hr in a Beckman Type 50 rotor at 40,000 rpm (100,000 × g).
3. Decant the supernatant containing the cytoplasmic (S-100) fraction and place it in dialysis tubing. Dialyze S-100 fraction against dialysis buffer until the conductivity of the former reaches that of dialysis buffer (100 mM KCl).

As with the nuclear extract, dialyze for the minimum amount of time necessary (see step 12, basic protocol).

4. Remove the S-100 fraction from the dialysis tubing and centrifuge 20 min in a Beckman JA-20 rotor at 14,500 rpm (25,000 × g) to pellet precipitated material.
5. Decant the supernatant, check the conductivity, and determine the protein concentration (steps 12 to 15 of the basic protocol). Aliquot into tubes, freeze in liquid nitrogen, and store at −80°C.

REAGENTS AND SOLUTIONS

NOTE: All solutions can be stored at 4°C for a couple of weeks. However, Dithiothreitol (DTT) and phenylmethylsulfonyl fluoride (PMSF) must be added to buffers immediately before use. PMSF (molecular weight 174.2) is dissolved in anhydrous isopropanol (Sigma #405-7) as a 0.2 M stock. The stock solution is stable for 9 months. PMSF is not stable in aqueous solution, and should be added to the solutions indicated below drop by drop with vigorous stirring to go into solution. Additional PMSF may be added again partway through a long dialysis.

A less expensive alternative to HEPES is Tris buffer, which can be used in place of HEPES in the solutions below. However, the pH of Tris buffers changes dramatically with temperature. For example, a Tris stock solution that is pH 7.9 at 4°C will drop to approximately pH 7.3 at room temperature. When using extracts prepared in Tris for functional studies (e.g., transcription or splicing) it is necessary to increase the pH of the extract at 30°C by adding HEPES, pH 8.4 (room temperature), to a final concentration of 40 mM.

10× cytoplasmic extract buffer

0.3 M HEPES, pH 7.9 at 4°C
1.4 M KCl
0.03 M MgCl₂

Dialysis buffer

20 mM HEPES, pH 7.9 at 4°C
20% glycerol
100 mM KCl
0.2 mM EDTA
0.2 mM PMSF*
0.5 mM DTT*

**Add ingredients immediately before use (see introductory note to reagents and solutions).*

High-salt buffer

20 mM HEPES, pH 7.9 at 4°C
25% glycerol
1.5 mM MgCl₂
0.8, 1.0, 1.2, 1.4 or 1.6 M KCl
0.2 mM EDTA
0.2 mM PMSF*
0.5 mM DTT*

*Add ingredients immediately before use (see introductory note to reagents and solutions).

Hypotonic buffer

10 mM HEPES, pH 7.9 at 4°C
1.5 mM MgCl₂
10 mM KCl
0.2 mM PMSF*
0.5 mM DTT*

*Add ingredients immediately before use (see introductory note to reagents and solutions).

Low-salt buffer

Prepare high-salt buffer, substituting 0.02 M KCl for 1.2 M KCl.

COMMENTARY

Background Information

Crude extracts from cultured mammalian cells were first used to demonstrate accurate initiation and termination of transcription from exogenously added purified DNA by RNA polymerase III (Weil et al., 1979a). Subsequently, cell-free soluble systems were developed from cultured cells that could accurately initiate transcription from purified genes by RNA polymerase II. These include a high-speed supernatant from a low-salt extraction of cells that was supplemented with purified RNA polymerase II (Weil et al., 1979b) and a high-salt extract of whole cells that contained endogenous polymerase II (Manley et al., 1980).

In order to take advantage of the presumed nuclear localization of transcriptional components, Dignam et al. (1983a) developed a procedure for preparing a soluble extract from isolated mammalian nuclei. This preparation was shown to support accurate transcription initiation from several class II genes by endogenous RNA polymerase II and accessory factors. Although 5S gene transcription by RNA polymerase III required supplementation with the cytoplasmic (S-100) fraction or the gene-specific factor TF IIIA, these extracts were sufficient for accurate transcription from tRNA and adenovirus VA genes by RNA polymerase III (Dignam et al., 1983b). Subsequent analyses

demonstrated that these extracts were also competent for *in vitro* pre-mRNA splicing (Krainer et al., 1984).

This protocol represents modifications of the original procedure of Dignam et al. (1983a). It employs KCl instead of NaCl and has the advantage of a normalized salt concentration during the nuclei extraction. This is achieved by adjusting the buffer volume in the nuclear extraction step to the volume of the nuclear pellet. These modifications result in more reproducible extracts from separate preparations of nuclei.

Nuclear extracts prepared from HeLa cells using this procedure support accurate initiation of transcription by RNA polymerase II and III from purified cloned promoters. Furthermore, regulatory promoter elements that function *in vivo* often regulate transcription in nuclear extracts. The presence in these extracts of proteins that bind to such promoter elements can be determined by gel-shift, methylation protection, and footprinting assays. These extracts will also accurately splice pre-mRNA into mature mRNA products. In addition to supplying a rapid functional assay of promoter elements and sequences required for RNA processing, these extracts provide starting material for purification and mechanistic analysis of the proteins involved in transcription and splicing.

Critical Parameters

In the preparation of nuclear extracts it is essential that denaturation of proteins or proteolysis be avoided as this will cause a loss of protein activity. In order to minimize these possibilities the protocols described are performed at 0° to 4°C, preferably in a cold room. In addition, fresh phenylmethylsulfonyl fluoride (PMSF; 0.2 mM final) is added to the buffers just prior to use to further inhibit proteolysis. While these treatments appear adequate for many mammalian cell types, in some instances, additional protease inhibitors may be necessary. For example, transcriptionally active nuclear extracts from yeast cells are prepared in the presence of 1 mM PMSF, 2 μM pepstatin A, and 0.6 μM leupeptin (Lue and Kornberg, 1987).

The approach described here is designed to generate reproducible preparations of extracts; however, there will be some variation in the activity of extracts prepared from separate cultures or prepared at different times. These variations can arise from several factors, including the volume and density of cells, the packed cell and nuclear volumes, and the amount of time needed to perform individual steps and to complete the procedure. Keeping a record of these factors allows one to directly compare the preparation of separate extracts and to correlate these parameters with any variations in activity. A flow chart for this purpose is presented in Figure 12.1.1. We recommend that this page be copied, filled in during each extract preparation, and kept in laboratory notebooks.

The preparation of nuclear extracts has two common pitfalls—the relevant proteins are inefficiently extracted from the nuclei or an excessive amount of nonspecific inhibitory proteins are also extracted. The significance of these problems depends upon the application for which the extract is intended. For example, if one is trying to purify a particular DNA-binding protein that is much more efficiently extracted with higher salt concentrations, the unwanted proteins also extracted can be removed with additional chromatographic procedures. Of course, if the protein of interest is efficiently solubilized at low KCl concentrations, contamination with proteins extracted at higher salt will be avoided.

If the extracts are to be used for direct functional analysis (i.e., transcription or splicing) where multiple proteins are involved, extraction conditions that achieve the maximum activity should be determined. In the case of

transcription analysis, increasing the KCl concentration during extraction of HeLa cells increases the transcriptional potential of the extracts up to the point where the nuclei begin to lyse during extraction. Nuclear lysis results in the release of chromosomal proteins that nonspecifically bind to DNA and thus inhibit transcriptional analysis. The conditions described in the basic protocol are chosen to give high transcriptional and splicing activity while remaining safely below salt concentrations where nuclei become fragile and lyse. Thus, these conditions are chosen to give reproducible, high-activity extracts. It should be noted that even under these conditions a significant fraction of inhibitory nonspecific DNA binding proteins are contained in the extracts. These nonspecific proteins inhibit transcription at low template concentrations (Abmayr et al., 1988). Contaminating proteins can be titrated by using an excess of template or nonspecific DNA.

Anticipated Results

Using this protocol it is possible to consistently produce extracts of 8 to 12 mg protein/ml. The high protein concentration in the extracts results in a high yield of transcription factors and nonspecific DNA binding proteins.

Time Considerations

The entire procedure should be completed in one day. It will require ~3 to 5 hr to prepare the extracts prior to dialysis, depending on the volume of cells and the amount of time required to centrifuge spinner cultures or scrape monolayer cells. Approximately 4 to 6 hr are required for dialysis. It is important to stop the dialysis and complete the procedure on the same day, rather than dialyze overnight. Dialysis time can be reduced by using dialysis buffer without KCl. In this instance it is necessary to check the conductivity of the extract frequently during dialysis. The dialysis should be stopped promptly when the extract reaches the conductivity of dialysis buffer with 100 mM KCl. After the dialysis is complete, centrifugating, freezing, and storing the extract can be completed in ≤45 min.

Mobility Shift DNA-Binding Assay Using Gel Electrophoresis

The DNA-binding assay using nondenaturing polyacrylamide gel electrophoresis (PAGE) provides a simple, rapid, and extremely sensitive method for detecting sequence-specific DNA-binding proteins. Proteins that bind specifically to an end-labeled DNA fragment retard the mobility of the fragment during electrophoresis, resulting in discrete bands corresponding to the individual protein-DNA complexes. The assay can be used to test binding of purified proteins or of uncharacterized factors found in crude extracts (see Basic Protocol). This assay also permits quantitative determination of the affinity, abundance, association rate constants, dissociation rate constants, and binding specificity of DNA-binding proteins. Three additional protocols describe a competition assay using unlabeled competitor DNA (see Alternate Protocol 1), an antibody supershift assay (see Alternate Protocol 2), and multicomponent gel shift assays (see Alternate Protocol 3).

STRATEGIC PLANNING

The utility of this technique is underscored by the many proteins that have been characterized using this assay. It has become clear that there is no single protocol that works best for all proteins. Rather, several variables can be changed to optimize binding. There are several options available for the design of the DNA probe, the binding reaction conditions, and the gel running conditions.

Protein-DNA binding is affected by a number of factors, including ion concentration and pH. Many of the salt, buffer, and glycerol components needed in the binding reaction may be contributed by the buffer contained in the protein extract. If only a small volume of protein extract is used, these components can be supplied by including the appropriate amount of buffer. Typical binding reaction conditions are 12% glycerol, 20 mM HEPES (pH 7.9) or 20 mM Tris·Cl (pH 7.9), 60 to 150 mM KCl, 1 mM EDTA, and 1 mM DTT. However, the DNA binding assay is compatible with a wide variety of binding conditions. Each parameter must be titrated for the specific protein-DNA interaction to be studied (see Critical Parameters).

Inclusion of BSA or other carrier protein in the binding reaction seems to improve the stability of some complexes during electrophoresis. Other reagents that have been reported to affect formation or stability of some protein-DNA complexes are nonionic detergents, polycations such as spermine and/or spermidine, and ATP. However, every protein-DNA complex is likely to have an idiosyncratic response to different binding conditions. Also, the optimal binding conditions for a purified protein may be different from the optimal binding conditions for the same protein in a crude extract.

As with the binding reaction, there are several variables for the nondenaturing gel—acrylamide concentration, buffer, and other components. Typical gels for this assay are in the range of 4% to 5% acrylamide. Early protocols used a high ratio of acrylamide to bisacrylamide (80:1), resulting in very soft gels. However, it is often preferable to run gels with a 40:1 acrylamide/bisacrylamide ratio, which gives a more cohesive gel. There are even published mobility shift experiments that resolve very large complexes on agarose gels (Lieberman and Berk, 1994).

Many gel buffers have been successfully used for mobility shift assays. The stability of protein-DNA complexes can be strongly affected by the choice of buffer, so it is worth trying different systems for the protein of interest. The most common buffers used are

**BASIC
PROTOCOL**

Tris-acetate (TAE), Tris-glycine, and Tris-borate (TBE) electrophoresis buffers at 0.25×, 0.5×, 1.0×, or 2.0× concentration. The gel running buffer should match the buffer in the gel. If low-ionic-strength buffer ($\leq 0.25\times$) is used, the buffer should be recirculated while running the gel. Although not required for stable electrophoresis of all protein-DNA complexes, glycerol in the gel at 2.5% (v/v) final concentration may help stabilize some interactions. At least one protein (the eukaryotic TATA-binding protein) also requires 3 to 5 mM Mg^{2+} in the gel and running buffer to allow it to bind stably to DNA during migration through the gel.

MOBILITY SHIFT ASSAY

This protocol can be divided into four stages: (1) preparation of a radioactively labeled DNA probe containing a particular protein binding site; (2) preparation of a nondenaturing gel; (3) a binding reaction in which a protein mixture is bound to the DNA probe; and (4) electrophoresis of protein-DNA complexes through the gel, which is then dried and autoradiographed.

Materials

10× electrophoresis buffer, e.g., TAE or TBE electrophoresis buffer (*APPENDIX 2*) or Tris-glycine electrophoresis buffer (see recipe)

30% (w/v) ammonium persulfate, prepared fresh
N,N,N',N'-tetramethylethylenediamine (TEMED)

Nondenaturing gel mix (see recipe)

Bulk carrier DNA, e.g., poly(dI-dC)·poly(dI-dC)

BSA

Protein preparation containing DNA-binding protein (crude extract or purified fraction)

10× loading buffer with dyes (*UNIT 2.5*)

Constant-temperature water bath

Two-head peristaltic pump

10- μ l glass capillary pipet (optional)

Clay-Adams screw-top loader (optional)

Whatman 3MM filter paper (or equivalent)

Additional reagents and equipment for digesting DNA with restriction endonucleases (*UNIT 3.1*), labeling DNA fragments with Klenow fragment (*UNIT 3.5*) or polynucleotide kinase (*UNIT 3.10*), agarose and nondenaturing polyacrylamide gel electrophoresis (*UNIT 2.5A* or *UNIT 2.7*), recovery of DNA from gels (*UNIT 2.6* & *UNIT 12.4*), oligonucleotide synthesis (*UNIT 2.11*), PCR (*UNIT 15.1*), ethanol precipitation (*UNIT 2.1*), ethidium bromide dot quantitation (*UNIT 2.6*), and autoradiography (*APPENDIX 3A*)

Prepare the DNA probe

DNA fragments from 20 to 300 bp long may be used as probes. However, longer fragments are likely to contain binding sites for multiple proteins, which may make interpretation of the gel difficult. The DNA probe can be prepared in one of several ways.

- 1a. *For restriction endonuclease fragments:* Isolate a small DNA fragment containing the binding site of interest from a plasmid using a standard restriction endonuclease digestion (*UNIT 3.1*). Label the fragment by filling in a 5' overhang with the Klenow fragment of *Escherichia coli* DNA polymerase and ^{32}P -labeled nucleotide (*UNIT 3.5*) or by end labeling using polynucleotide kinase (*UNIT 3.10*). Separate the fragment from the plasmid by gel electrophoresis (*UNIT 2.5A* or *UNIT 2.7*).

Kinased probes should be avoided in experiments using crude protein preparations that might contain phosphatase activity.

Agarose gels are good for resolving fragments as small as 50 bp. Fragments can be recovered using low melting temperature agarose or DEAE paper (UNIT 2.7 & UNIT 12.4). For smaller DNA fragments, nondenaturing polyacrylamide gels can be used (UNIT 2.7).

- 1b. *For synthetic oligonucleotides:* Synthesize and anneal (UNIT 2.11) complementary oligonucleotides to generate a double-stranded DNA fragment containing the binding site of interest. Label the probe using polynucleotide kinase (UNIT 3.10).

The kinase reaction can be performed before annealing to label only one strand, or after annealing to label both strands. Alternatively, the oligonucleotides can be designed to leave an overhang that can be filled in with labeled nucleotide and Klenow fragment of E. coli DNA polymerase I (UNIT 3.5).

- 1c. *For PCR fragments:* Generate a DNA fragment containing the binding site of interest by polymerase chain reaction (PCR; UNIT 15.1). End-label one of the primers with polynucleotide kinase (UNIT 3.10) before the PCR reaction, or label the double-stranded PCR product after purification.

2. Following isolation of the probe, determine its concentration by ethidium bromide dot quantitation (UNIT 2.6).

Concentrations in the range of 2 to 50 ng/μl are convenient.

3. Count 1 μl for Cerenkov counts in a scintillation counter to determine specific activity (cpm/μl).

A typical binding reaction will contain about 5,000 to 20,000 cpm and about 10 to 100 fmol probe (10 fmol DNA in a final reaction volume of 10 μl gives a total DNA concentration of 1 nM). If desired, probes can be stored up to 4 to 6 weeks at 4°C before proceeding with the experiment.

Prepare the nondenaturing gel

4. Dilute 10× electrophoresis buffer to prepare enough 1× electrophoresis buffer to fill the tank.

5. Assemble washed glass plates and 1.5-mm spacers for casting the gel (UNIT 2.7).

All traces of detergent must be removed because detergent will disrupt protein-DNA interactions.

6. Add 150 μl of 30% ammonium persulfate and 70 μl TEMED to 60 ml nondenaturing gel mix prepared using the same buffer as that used for electrophoresis. Swirl gently to mix.

The amounts of ammonium persulfate, TEMED, and nondenaturing gel mix can be scaled up or down as necessary depending on the size and number of gels.

7. Pour the gel mix between the plates and insert a comb. Allow the gel to completely polymerize for 20 min.

For optimal results, use a comb with teeth that are ≥7 mm wide.

8. Remove the comb and bottom spacer and attach the plates to the electrophoresis tank after filling the lower reservoir with 1× electrophoresis buffer. Fill the upper reservoir of the tank with 1× electrophoresis buffer. With a bent-needle syringe, remove any air bubbles trapped beneath the gel and flush out the wells (UNIT 2.7). Prerun the gel 30 to 60 min at 100 V.

For low-ionic-strength buffers (≤0.5×), use a pump with two heads and a flow rate of 5 to 30 ml per min to exchange buffer between the upper and lower reservoirs. Recirculation of the buffer is essential to prevent polarization due to the low buffering capacity of the buffer.

Prepare the binding reactions

9. While the gel is prerunning, assemble the binding reaction by combining the following in a 0.5-ml or 1.5-ml microcentrifuge tube:
 - 5,000 to 20,000 cpm radiolabeled probe DNA (0.1 to 0.5 ng, ≥ 10 fmol)
 - 0.1 to 2 μ g nonspecific carrier DNA
 - 300 μ g/ml BSA
 - $\geq 10\%$ (v/v) glycerol
 - Appropriate buffer and salt
 - DNA-binding protein (~15 μ g crude extract or ~5 to 25 ng purified protein)
 - Adjust the final reaction volume to 10 to 15 μ l with water or buffer.

The protein should be added last.

10. Mix gently by tapping the bottom of the tube with a finger.
 - Avoid introducing bubbles in the mix.*
11. Incubate the binding reaction mix 15 to 30 minutes in a constant-temperature water bath.
 - Optimal incubation temperatures for different proteins can vary from room temperature to 37°C.*

Run the gel

12. Load each binding reaction into the appropriate well of the prerun gel using either a 10- μ l glass capillary pipet and Clay-Adams screw-top loader, or a pipettor. Load a small volume of 10 \times loading buffer with dyes into a separate well.

The dyes are used to monitor the progress of electrophoresis.

There is no stacking gel in this system, so precise loading with little mixing with the gel buffer is necessary to obtain sharp bands on the gel. Allow the sample to fall along one side of the well to prevent dilution and avoid bubbles in the well.

13. Electrophorese at ~30 to 35 mA for the minimum time required to give good separation of free probe and the protein-DNA complexes. Stop the gel before the bromphenol blue approaches the bottom of the gel (~1.5 to 2 hr for a 15- to 20-cm gel).

Longer run times may cause a weaker signal due to partial dissociation of complexes during electrophoresis.

Bromphenol blue migrates at approximately the same position as a 70-bp DNA probe. For probes <70 bp, do not run the bromphenol blue to the bottom of the gel.

If electrophoresis is performed at room temperature, the glass plates should be allowed to become only slightly warm. Decrease the voltage if the plates become any hotter. To run the gel faster, put the apparatus in a cold room. Higher voltages may then be used without heating the glass plates.

Analyze the gel

14. Remove the glass plates from the gel box and carefully remove the side spacers.
15. Using a spatula, slowly pry the glass plates apart, allowing air to enter between the gel and the glass plate.

The gel should remain attached to only one of the plates. Prying the plates apart too quickly may tear the gel or cause it to stick to both plates. If this occurs or if the gel has become distorted, squirt a stream of water underneath it. This will reduce the stickiness of the gel. Be careful not to let the gel slide off the plate.

16. Lay the glass plate with the gel attached on the bench with the gel facing up. Place three sheets of Whatman 3MM filter paper cut to size on top of the gel.

17. Support both sides of the gel sandwich and carefully flip it over so that the filter paper is on the bottom and the glass plate is on the top.
18. Carefully lift up one end of the glass plate. Peel the filter paper with the gel attached to it from the plate.
19. Cover the gel with plastic wrap and dry under vacuum with heat.
20. Autoradiograph the dried filter overnight without an intensifying screen or 2 to 3 hr with an intensifying screen (*APPENDIX 3A*).

COMPETITION MOBILITY SHIFT ASSAY

One of the most powerful aspects of the mobility shift DNA-binding assay is the ease of assessing the sequence specificity of protein-DNA interactions using a competition binding assay (Carthew et al., 1985; Singh et al., 1986). This is necessary because most protein preparations will contain both specific and nonspecific DNA binding proteins. For a specific competitor, the same DNA fragment (unlabeled) as the probe can be used. The nonspecific competitor can be essentially any fragment with an unrelated sequence, but it is useful to roughly match the probe and specific competitor for size and configuration of the ends. For example, some proteins bind blunt DNA ends nonspecifically. These would not be competed by circular plasmid or a fragment with overhangs, leading to the false conclusion that the protein-DNA complex represented specific binding. Perhaps the best control competitor is a DNA fragment that is identical to the probe fragment except for a mutation(s) in the binding site that is known to disrupt function (and presumably binding).

Additional Materials (also see Basic Protocol)

Unlabeled specific and nonspecific competitor DNA fragments

For this protocol, follow steps 1 to 8 of the Basic Protocol to prepare the probe and gel, modify the binding reaction as indicated in step 9, and proceed with steps 10 through 20 of the Basic Protocol.

- 9a. Assemble binding reactions (see Basic Protocol, step 9). In addition to the labeled DNA probe, add increasing amounts of unlabeled specific and nonspecific competitor DNAs. Add DNA-binding protein last.

Assuming there is not a huge excess of binding protein to probe, typical amounts of competitor are 5×, 10×, and 50× molar excess relative to the labeled probe.

Sequence-specific complexes will show a clear differential response to the specific and nonspecific competitors.

ANTIBODY SUPERSHIFT ASSAY

Another useful variation of the mobility shift DNA-binding assay is to use antibodies to identify proteins present in the protein-DNA complex (Kristie and Roizman, 1986).

Addition of a specific antibody to a binding reaction can have one of several effects. If the protein recognized by the antibody is not involved in complex formation, addition of the antibody should have no effect. If the protein that forms the complex is recognized by the antibody, the antibody can either block complex formation, or it can form an antibody-protein-DNA ternary complex and thereby specifically result in a further reduction in the mobility of the protein-DNA complex (supershift). Results may be different depending upon whether the antibody is added before or after the protein binds DNA (particularly if there are epitopes on the DNA-binding surface of the protein).

**ALTERNATE
PROTOCOL 1**

**ALTERNATE
PROTOCOL 2**

**DNA-Protein
Interactions**

12.2.5

Additional Materials (also see Basic Protocol)

Antibody specific for DNA-binding protein
Nonspecific control antibody

For this protocol, follow steps 1 to 8 of the Basic Protocol to prepare the probe and gel, modify the binding reaction as indicated in step 9, and proceed with steps 10 through 20 of the Basic Protocol.

9a. Assemble binding reactions (see Basic Protocol, step 9). Add a small volume of antibody ($\leq 1 \mu\text{l}$) to the binding mix. To a second tube of binding reaction, add an equivalent amount of nonspecific control antibody.

The amount of antibody used should be the minimum needed to produce an observable effect, and inclusion of a control antibody reaction is critical, because the salts and other proteins in the antibody preparation may nonspecifically affect stability or mobility of the protein-DNA complexes. Antibody supershifts have been successfully performed using crude sera, purified polyclonal antibodies, and monoclonal antibodies. In general, however, the more pure the antibody preparation, the clearer the results will be.

**ALTERNATE
PROTOCOL 3**

MULTICOMPONENT MOBILITY SHIFT ASSAYS

The mobility shift assay can be used to study multicomponent assemblies of DNA-binding complexes. Indeed, many of the transcription factors studied by mobility shift assays are actually homo- or heterodimers. There are many cases in which a sequence-specific DNA-binding protein (A) acts as a platform for the association of other proteins (B and C) which themselves do not bind specific sequences (see Fig.12.2.1). This phenomenon can be observed as a supershift of the primary DNA-protein complex into a new discrete complex that is dependent upon all of the factors.

In essence, assays for multicomponent complexes are no different from the Basic Protocol. However, some additional points should be considered:

1. The concentration of factors may need to be high. Although the dissociation constant (K_d) for a sequence-specific DNA-binding protein is often very high (10^{-9} to 10^{-12} M),

Figure 12.2.1 Hypothetical autoradiogram of a mobility shift binding experiment analyzing a multicomponent complex (see Alternate Protocol 3). In this experiment, factor A provides sequence-specific DNA binding. Factors B and C associate with the factor A-DNA complex.

the constants for subsequent protein-protein interactions may be lower. Therefore, it may be necessary to saturate the probe for binding of factor A to reach a concentration where the ABC complex can form.

2. A mobility shift is not necessarily due to association of a factor. For example, factor C may be a kinase whose function is necessary for the association of factor B with the DNA-A complex. Antibody supershift experiments or other protein-protein interaction assays may be useful for showing physical association of a factor with a particular complex.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Nondenaturing gel mix

For 60 ml:

6.0 ml 10× TAE or TBE electrophoresis buffer (APPENDIX 2) or Tris-glycine electrophoresis buffer (see recipe)

8.1 ml 30% (w/v) acrylamide

3.0 ml 2% (w/v) bisacrylamide

42.9 ml H₂O

Prepare fresh for each use

CAUTION: Acrylamide monomer is neurotoxic. Gloves should be worn when handling the solution, and the solution should not be pipetted by mouth.

Tris-glycine electrophoresis buffer, 10×

30.28 g Tris base (0.25 M final)

142.7 g glycine (1.9 M final)

3.92 g EDTA (10 mM final)

H₂O to 1 liter

Check that pH is ~8.3

Store up to several months at room temperature

COMMENTARY

Background Information

Several methods exist for detecting the sequence-specific binding of proteins to DNA, including nitrocellulose filter binding (UNIT 12.8), DNase I footprinting (UNIT 12.4), methylation protection, methylation interference (UNIT 12.3), and mobility shift gel electrophoresis, the approach presented here. The DNA-binding assay using mobility shift polyacrylamide gel electrophoresis (PAGE) is based on the observation that DNA-protein complexes migrate through polyacrylamide gels more slowly than unbound DNA fragments. This assay is generally simpler, faster, and more sensitive than other methods. Thus, it is an ideal assay for monitoring the purification of DNA-binding proteins. More importantly, the sensitivity of this assay enables femtomole quantities of DNA-binding proteins to be detected routinely. It is quite remarkable what large complexes can be resolved with acrylamide gels. For example,

the eukaryotic RNA polymerase II or RNA polymerase III transcription complexes (each of total molecular weight well over 500 kDa) can be resolved on 4% acrylamide gels.

In addition to providing quantitative information on the amount of DNA bound by the protein, the use of mobility shift PAGE provides additional information on the number and type of proteins bound. Each species of protein bound to the probe generates a complex of distinct mobility and specificity so that interactions of several proteins binding to a single DNA fragment can be observed. Even if multiple proteins recognize overlapping sites on the DNA fragment, the complexes formed by each can be resolved and characterized. If there are multiple forms of a protein that bind (for example, several phosphorylation states), these can often be distinguished using this assay.

This assay was originally developed for kinetic and equilibrium analyses of purified pro-

karyotic gene-regulatory proteins (Fried and Crothers, 1981, 1984a,b; Garner and Revzin, 1981; Hendrickson and Schleif, 1984). It was modified by the addition of bulk carrier DNA (*Escherichia coli* DNA) to the binding reaction, permitting detection of DNA-binding proteins in crude extracts (Strauss and Varshavsky, 1984). Subsequently, a synthetic alternating copolymer was used instead of heterologous DNA to facilitate the identification of sequence-specific DNA-binding proteins (Carthew et al., 1985; Singh et al., 1986). Apparently, the large mass of alternating copolymer presented a large number of nonspecific binding sites for DNA-binding proteins in the extract, but presented considerably fewer sequence-specific binding sites relative to heterologous-sequence DNA.

Interestingly, protein-DNA complexes with short half-lives (<1 min) can be easily detected despite the fact that electrophoresis takes significantly longer than this. Thus, kinetic stability is not a requirement for detection of protein-DNA complexes. The mobility shift DNA-binding assay is often more sensitive than the nitrocellulose filter-binding assay because the kinetically labile complexes dissociate during washing of the filter. For example, *lac* repressor-operator complexes formed in the presence of IPTG can be detected by the mobility shift assay but not by filter binding (Hendrickson and Schleif, 1984).

Although some dissociation of complexes during nondenaturing gel electrophoresis undoubtedly occurs, complexes within the gel are remarkably stable. At least two factors stabilize protein-DNA complexes in the gel. One of these is the low ionic strength of the buffer, which can increase binding affinity. The second factor is the "caging effect" (Fried and Crothers, 1981; Garner and Revzin, 1981). The gel matrix may provide a cage so that dissociated components cannot diffuse away and instead rapidly recombine with each other. Therefore, the separation achieved during electrophoresis is dependent upon the fraction of free and bound probe molecules as the binding reaction enters the gel.

Because the mobility shift procedure can be performed under conditions in which the DNA probe concentration is in large excess over that of the DNA-binding protein, it can be used to obtain thermodynamically rigorous physical constants of DNA-binding proteins, such as relative affinity, association rate constants, and dissociation rate constants (Riggs et al., 1970; Fried and Crothers, 1981; Chodosh et al.,

1986). The abundance of a protein in a crude extract can also be easily measured using this assay by increasing the concentration of DNA probe in the binding reaction until the amount of complex formed no longer increases (Chodosh et al., 1986). At this DNA concentration, all of the particular DNA-binding protein molecules present in the sample will be bound. By comparing the amount of probe in the protein-DNA complex to a set of standard dilutions of free probe included on the same gel, the number of moles of protein in the reaction can be calculated, assuming a 1:1 stoichiometry of binding, because the specific activity of the probe is known.

Critical Parameters and Troubleshooting

Binding reaction and gel electrophoresis conditions may affect the results obtained in this assay. Binding reaction conditions that may be varied include monovalent and divalent salt concentrations, pH, presence or absence of nonionic detergents, protein concentration, DNA concentration, and type and concentration of bulk carrier DNA.

At a fixed protein concentration, if too little carrier DNA is included in the reaction, all of the probe will be bound and will not enter the gel. Conversely, if too much carrier DNA is included, none of the probe will be bound. An appropriate amount of carrier DNA is one that is sufficient to prevent nonspecific proteins from binding to the probe, yet not so great as to prevent the specific binding of proteins that recognize sequences within the DNA probe. Most sequence-specific DNA-binding proteins have nonspecific DNA affinities several orders of magnitude below that for the recognized site. In practice, when synthetic DNA polymers are used as carrier DNA, the range of carrier DNA concentrations that will permit the detection of specific DNA-binding proteins is quite broad.

The type of carrier DNA chosen is of great importance. Optimally, the sequence should bear little resemblance to the specific binding site. Thus, if the putative binding site is TATAT-GTA, the synthetic alternating copolymer poly(dA-dT)-poly(dA-dT) would be a poor choice for a carrier DNA, whereas the synthetic polymer poly(dG-dC)-poly(dG-dC) would be a much better choice. If the binding site sequence of a putative DNA-binding protein is unknown, at least two synthetic DNA carriers of different structure should be tested. In general, heterologous-sequence DNA, such as *E. coli* or salmon sperm DNA, will reduce the

amount of specific protein-DNA complex because binding sites of varying affinities will fortuitously occur at some frequency.

The conditions under which gel electrophoresis is performed can greatly influence the results obtained. The mobility of a protein-DNA complex through a nondenaturing polyacrylamide gel is determined primarily by the size and charge of the protein bound to the DNA fragment and by the conformation of the protein-DNA complex. The mobility of the protein-DNA complex is only slightly affected by changes in the size of the DNA fragment used as probe. As a result, changing gel conditions such as acrylamide percentage, acrylamide/bisacrylamide ratio, and pH can significantly alter the mobility of a given protein-DNA complex. In some cases this alteration may be sufficient to permit the resolution of two protein-DNA complexes, allowing the DNA-binding specificity of each to be independently and unambiguously ascertained. Use of high-ionic-strength buffer systems can also enhance the resolution of protein-DNA complexes. As a result of these features, novel protein-DNA complexes may be obtained by varying the pH of the buffer system (Staudt et al., 1986). Interestingly, the mobility of a protein-DNA complex can be affected by the position of the binding site relative to the ends of the DNA fragment (Zinkel and Crothers, 1987). This is presumed to result from conformational effects such as protein-induced bending of the DNA fragment.

As previously noted, many buffer systems may be used with the mobility shift DNA-binding assay. The Tris-glycine system, in particular, has several advantages. The high ionic strength makes recirculation of buffer unnecessary. Because of the higher ionic strength, a smaller amount of bulk carrier DNA (approximately 2- to 10-fold lower) is required to abolish nonspecific binding of proteins to the probe than with low-ionic-strength systems. Moreover, the resulting bands tend to be sharper than those of the low-ionic-strength systems, allowing better resolution of protein-DNA complexes. Furthermore, the higher pH of the Tris-glycine system alters the mobility of some protein-DNA complexes, permitting detection of novel protein-DNA complexes (Staudt et al., 1986). However, although many protein-DNA interactions may survive the high ionic strength of this buffer system, some do not. Therefore, it is helpful to try both low- and high-ionic-strength buffer systems for each putative protein-DNA interaction.

For further discussion of important binding reaction conditions, see *UNIT 12.8*, Critical Parameters. A guide to troubleshooting these procedures is provided in Table 12.2.1.

Anticipated Results

Figure 12.2.2 shows a typical autoradiogram from a mobility shift assay. Lane 1 contains only the DNA probe and poly(dI-dC)-poly(dI-dC) with no added protein. A single band representing the unbound probe is seen. In lanes 2 to 5, an increasing amount of protein from a crude extract is added to a constant amount of probe and poly(dI-dC)-poly(dI-dC). In lanes 2 and 3, two discrete complexes (B1 and B2) migrate through the gel more slowly than the band corresponding to the free probe. As more protein is added to the reaction, the intensities of the B1 and B2 bands increase and the amount of free probe decreases (compare lanes 2 and 3). As even more protein is added (lanes 4 and 5), there is little or no free probe remaining. Moreover, complexes B1 and B2 are no longer observed. Because many different nonspecific DNA-binding proteins are bound, most of the probe migrates very slowly and diffusely or does not enter the gel.

The reaction shown in lane 6 is identical to that shown in lane 5, except that a larger excess of poly(dI-dC)-poly(dI-dC) has been added. Because more protein was added in lane 6 relative to that in lane 3, the intensities of the bands representing complexes B1 and B2 are greater in lane 6 than in lane 3. Note that if a more purified preparation of B1 were used in the binding reaction, all of the probe in the reaction could be specifically bound and would migrate in complex B1, rather than at the top of the gel.

In lanes 7 to 9, a competition binding experiment (see Alternate Protocol 1) is used to determine whether complexes B1 and B2 represent specific protein-DNA complexes. Lane 7 is a standard binding reaction that contains probe, protein, and poly(dI-dC)-poly(dI-dC). Lane 8 is the same as lane 7, except that a 50-fold molar excess of an unlabeled DNA fragment identical to the probe (i.e., a specific competitor) is added prior to the addition of protein. Lane 9 is the same as lane 8, except that an unlabeled DNA competitor fragment containing sequences different from the probe (i.e., a nonspecific competitor) was added.

Formation of complex B1 is competed by the specific unlabeled DNA fragment (lane 8), but not by the nonspecific DNA fragment (lane 9). Therefore, complex B1 results from the

Table 12.2.1 Troubleshooting Guide for Mobility Shift Assays

Problem	Possible cause	Possible remedies
No specific complexes observed	Not enough protein or probe (amounts $<K_d$ or below level of detection)	Titrate up the amount of protein and/or probe.
	Protein binds nonspecific competitor DNA	Try a different DNA—e.g., poly(dG-dC) instead of poly(dI-dC).
	Gel buffer system incompatible with binding	Try a different gel buffer system.
Probe smeared or stuck in the well; no free probe observed	Binding conditions not appropriate	Try different salt and buffer conditions in binding reaction.
	Protein/probe ratio too high	Titrate down the amount of protein or increase nonspecific competitor DNA. Small amounts of detergent may also help.
Complexes seen but a smear is observed leading down to the free probe	Complex too big for gel system	Try lower percentage of acrylamide or lower acrylamide/bisacrylamide ratio.
	Complexes dissociating during electrophoresis	Run gel slower or at lower temperature; try different gel buffer system.
Complexes indistinct, bands fuzzy	Poor loading technique	Increase glycerol in binding reaction; load sample as sharp band; minimize time sample sits in well before current is turned on.
	Gel run too fast or too long	Reduce voltage or running time.
	Multiple protein species due to modifications	Multiple species may be due to phosphorylation or other modifications; test for alterations upon phosphatase treatment. Multiple species may be better resolved by running gel longer or under different conditions.
	Protein or probe degraded	Try protease inhibitors in protein preparation; check protein for nucleases.

specific binding of a molecule in the extract to the DNA probe. Formation of complex B2 is not competed by either the specific competitor or the nonspecific competitor. Complex B2 results from the nonspecific binding of a molecule in the extract to the DNA probe. This is typical behavior for a nonspecific DNA-protein interaction.

Time Considerations

Following preparation of the DNA probe, the DNA-binding assay itself is extremely rapid. It may take 4 to 5 hr to complete the experiment from the time the gel is poured to the time it is dried onto filter paper. Only a small fraction of this time is labor intensive. Thus, several DNA-binding gels can be run simultaneously while other experiments are being per-

formed. Furthermore, the results are often available within 2 to 3 hr after completion of the experiment.

Methylation and Uracil Interference Assays for Analysis of Protein-DNA Interactions

UNIT 12.3

Interference assays identify specific residues in the DNA binding site that, when modified, interfere with binding of the protein. The protocols use end-labeled DNA probes that are modified at an average of one site per molecule of probe. These probes are incubated with the protein of interest, and protein-DNA complexes are separated from free probe by the mobility shift assay (UNIT 12.2). A DNA probe that is modified at a position that interferes with binding will not be retarded in this assay; thus, the specific protein-DNA complex is depleted for DNA that contains modifications on bases important for binding. After gel purification, the bound and unbound DNA are specifically cleaved at the modified residues and the resulting products analyzed by electrophoresis on polyacrylamide sequencing gels and autoradiography. In methylation interference (first basic protocol), probes are generated by methylating guanines (at the N-7 position) and adenines (at the N-3 position) with DMS; these methylated bases are cleaved specifically by piperidine. In uracil interference (second basic protocol), probes are generated by PCR amplification (UNIT 15.1) in the presence of a mixture of TTP and dUTP, thereby producing products in which thymine residues are replaced by deoxyuracil residues (which contains hydrogen in place of the thymine 5-methyl group). Uracil bases are specifically cleaved by uracil-*N*-glycosylase to generate apyrimidinic sites that are susceptible to piperidine. These procedures provide complementary information about the nucleotides involved in protein-DNA interactions.

METHYLATION INTERFERENCE ASSAY

Methylation interference identifies guanines and adenines in the DNA binding site that, when methylated, interfere with binding of the protein. The protocol described below uses a single end-labeled DNA probe that is methylated at an average of one site per molecule of probe. The labeled probe is a substrate for a protein-binding reaction. DNA-protein complexes are separated from the free probe by the mobility shift DNA-binding assay (UNIT 12.2). A DNA probe that is methylated at a position that interferes with binding will not be retarded in this assay. Therefore, the specific DNA-protein complex is depleted for DNA that contains methyl groups on purines important for binding. After gel purification, DNA is cleaved with piperidine. Finally, these fragments are electrophoresed on polyacrylamide sequencing gels and autoradiographed. Guanines and adenines that interfere with binding are revealed by their absence in the retarded complex relative to a lane containing piperidine-cleaved free probe. This procedure offers a rapid and highly analytical means of characterizing DNA-protein interactions.

Materials

- DNA containing protein-binding site
- TE buffer, pH 7.5 to 8.0 (APPENDIX 2)
- Dimethyl sulfate (DMS)
- DMS reaction buffer
- DMS stop buffer
- 10 mg/ml tRNA solution
- 0.3 M sodium acetate/1 mM EDTA, pH 5.2
- 1 M piperidine (dilute from 10 M piperidine stock)
- Stop/loading dye (UNIT 7.4)
- 90° to 95°C water bath

Additional reagents and materials for mobility shift DNA-binding assay (UNIT 12.2), phenol extraction and ethanol precipitation (UNIT 2.1), nondenaturing

Supplement 36

polyacrylamide gel electrophoresis and electroelution of DNA fragments onto DEAE membranes (UNIT 2.7), autoradiography (APPENDIX 3), and denaturing polyacrylamide gel electrophoresis for sequencing (UNIT 7.6)

Prepare methylated DNA probe

1. Prepare a DNA probe labeled at one end (as for mobility-shift assay).
2. Suspend $\sim 10^6$ cpm of probe in 5 to 10 μl TE buffer. Add 200 μl DMS reaction buffer and 1 μl DMS. Mix well by vortexing. Incubate 5 min at room temperature.

CAUTION: DMS is a powerful poison and must be used in a fume hood with careful handling. Liquids containing DMS should be disposed of in a designated DMS waste bottle and pipet tips that come into contact with DMS should be placed in a separate DMS solid-waste bottle for disposal by institutional safety officials.

3. Add the following to the probe mixture:

40 μl DMS stop buffer
1 μl 10 mg/ml tRNA solution
600 μl 100% ethanol.

Mix and incubate ~ 10 min in a dry ice/ethanol bath. Microcentrifuge 10 min at top speed, 4°C. Carefully remove supernatant with a drawn-out Pasteur pipet and dispose in liquid DMS waste bottle.

4. Resuspend pellet in 250 μl of 0.3 M sodium acetate/1 mM EDTA. Keep the tube on ice. Add 750 μl of 100% ethanol, mix, and ethanol precipitate as in step 3.
5. Repeat ethanol precipitation once exactly as in step 4. Wash pellet once in 70% ethanol and microcentrifuge 10 min again. Carefully remove supernatant, invert tube on tissue, and air dry 10 min.
6. Measure the pellet for Cerenkov counts in a scintillation counter to determine cpm. Resuspend pellet in TE buffer at $\sim 20,000$ cpm/ μl .

The DNA can be difficult to resuspend, particularly with excessive drying of the pellet. Heating, vortexing, and pipetting up and down aid resuspension.

Bind methylated probe to protein and isolate DNA-protein complex and free probe

7. Set up a DNA-binding reaction as described in step 9 of the UNIT 12.2 basic protocol, but scaled up ~ 5 -fold (use 10^5 cpm of probe in 50 μl).

The degree of scale-up is dependent on the relative proportion of protein-DNA complex obtained. A 5-fold scale-up is sufficient for most DNA-binding activities.

8. Load binding reaction on three lanes of a native (nondenaturing) polyacrylamide gel. Electrophorese the binding reaction using the procedure for the mobility-shift assay.
9. Autoradiograph gel, cut out bands corresponding to the protein-DNA complex and free probe, and purify DNA from gel by electroelution onto a DEAE membrane.

Cleave DNA-protein complex with piperidine

10. Resuspend pellet in 100 μl of 1 M piperidine. Place in a 90° to 95°C water bath for 30 min. Put a glass plate over tubes to keep tops from popping open. Carefully remove from water bath and place on dry ice.
11. Make holes in the tops of the tubes with a large needle and lyophilize samples in a vacuum evaporator (e.g., Speedvac) for ~ 1 hr or until dry. Add 100 μl of distilled water. Freeze and lyophilize again. Repeat addition of water, freezing, and lyophilizing. Measure sample for Cerenkov counts to determine cpm.

Analyze fragments on DNA sequencing gels

12. Add sufficient stop/loading dye to pellet so that 1 to 2 μl will contain the sample to be loaded. Heat 5 min at 95°C. Quickly chill on ice.

For an overnight exposure with intensifying screen, 3000 cpm is sufficient. It is critical to equalize the number of counts applied from the DNA-protein complex and from the free probe to allow accurate comparison between samples.

13. Load the samples from the free probe and bound complex on a 6% or 8% polyacrylamide/urea sequencing gel. Electrophorese samples as for a sequencing gel and expose gel for autoradiography.

URACIL INTERFERENCE ASSAY

Uracil interference identifies thymines in a DNA binding site that, when modified, interfere with binding of the protein. Probes generated by PCR amplification in the presence of TTP and dUTP incorporate deoxyuracil in place of thymine residues. PCR products are incubated with the binding protein and resulting complexes are separated from unbound DNA. The DNA recovered from the protein-DNA complex is treated with uracil-*N*-glycosylase and piperidine, and the products are then electrophoresed on a denaturing polyacrylamide gel (Fig. 12.3.1).

Materials

DNA containing protein-binding site
Oligonucleotide primers specific for sequences flanking the binding site on the two complementary DNA strands
2 mM 4dNTP mix (UNIT 3.4)
0.5 mM dUTP
Taq polymerase buffer (UNIT 3.4) and *Taq* polymerase (UNIT 3.5)
TE buffer, pH 7.5 to 8.0 (APPENDIX 2)
Uracil-*N*-glycosylase (Perkin Elmer-Cetus)
1 M piperidine (diluted from 10 M piperidine stock)
Stop/loading dye (UNIT 7.4)
90° to 95°C water bath

Additional reagents and equipment for end-labeling DNA with T4 polynucleotide kinase (UNIT 3.9), polymerase chain reaction (UNIT 15.1), phenol extraction and ethanol precipitation (UNIT 2.1), nondenaturing polyacrylamide gel electrophoresis and electroelution of DNA onto DEAE membranes (UNIT 2.7), denaturing polyacrylamide gel electrophoresis (UNIT 7.6), mobility shift DNA-binding assay (UNIT 12.2), and autoradiography (APPENDIX 3)

Prepare deoxyuracil-substituted DNA probe

1. ³²P-label the 5' ends of oligonucleotide primers with T4 polynucleotide kinase.

Primers should be designed for PCR amplification (UNIT 15.1) and should contain sequences that flank the protein-binding site and are on opposite strands (Fig. 12.3.1).

2. Set up two parallel 50- μl PCR reactions containing the following ingredients:

5 μl DNA fragment containing protein-binding site (0.2 pmol)
5 μl of one ³²P-labeled oligonucleotide primer (20 pmol)
5 μl of other oligonucleotide primer (unlabeled; 20 pmol)
5 μl 2 mM 4dNTP mix
5 μl 0.5 mM dUTP
5 μl 10 \times *Taq* polymerase buffer
19 μl H₂O
1 μl *Taq* polymerase (5 U).

BASIC PROTOCOL

DNA-Protein Interactions

12.3.3

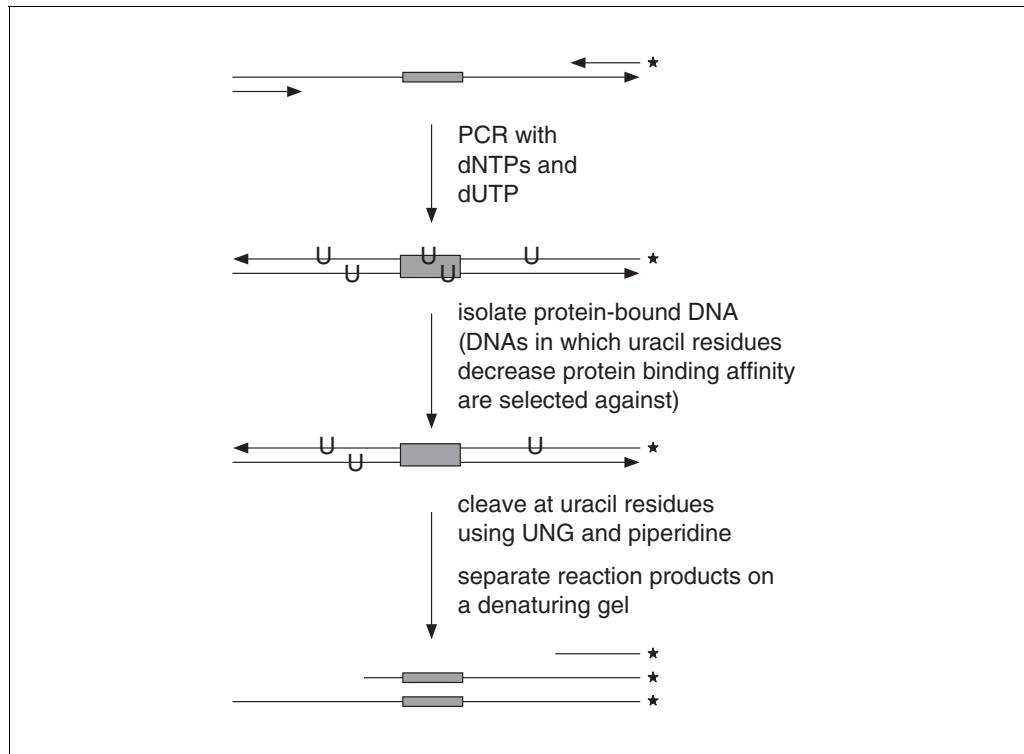

Figure 12.3.1 Uracil interference. An oligonucleotide or restriction fragment (long arrow) containing a protein-binding site (hatched box) is amplified by PCR using one unlabeled primer (short arrow) and one 5'-labeled primer (asterisk) in the presence of dGTP, dATP, dCTP, dTTP, and dUTP, producing reaction products in which deoxyuracil is randomly substituted for thymine on both strands. This collection of DNA molecules is incubated with the protein of interest and DNA molecules containing deoxyuracil substitutions that do not interfere with protein binding are selected by purifying the DNA-protein complex away from unbound DNA. The resulting DNA is cleaved at uracil residues using uracil-*N*-glycosylase followed by piperidine, and the reaction products are separated on a denaturing polyacrylamide gel. (Reprinted from Pu and Struhl, 1992, by permission of Oxford University Press.)

Carry out 8 cycles of PCR amplification.

The two PCR reactions, which differ with respect to which oligonucleotide primer is ³²P-labeled, result in binding-site probes that are specific for the individual DNA strands. The precise conditions for carrying out PCR amplification will depend on the length and base-composition of the primers (UNIT 15.1). Additional PCR cycles can be carried out if sufficient product is not generated.

3. Purify PCR products by electrophoresis on a native (nondenaturing) polyacrylamide gel followed by phenol extraction and ethanol precipitation.
4. Measure pellet for Cerenkov counts in a scintillation counter to determine cpm. Resuspend in TE buffer at ~20,000 cpm/μl.

Isolate protein-DNA complex and free probe

5. Carry out a DNA-binding reaction using 10⁵ cpm of probe in 50 μl. Electrophorese the binding reaction on a native (nondenaturing) polyacrylamide gel.

If the amount of the protein-DNA complex is not sufficient, the binding reaction can be scaled up further and multiple gel lanes can be used.

6. Autoradiograph gel, cut out bands corresponding to the protein-DNA complex and free probe, and purify DNA from gel slices. Resuspend each DNA sample in 25 μ l TE buffer.

The exposure time depends on the quantity of protein-DNA complex. An exposure time of 1 hr is usually sufficient, although longer exposures (12 hr) may be necessary in some cases.

Cleave DNAs at uracil residues and analyze on sequencing gels

7. Set up the following uracil-*N*-glycosylase reaction (50 μ l final):

19 μ l H₂O
5 μ l 10 \times *Taq* polymerase buffer
25 μ l DNA (from step 6)
1 μ l uracil-*N*-glycosylase (1 U).

Incubate 60 min at 37°C. Stop the reaction by ethanol precipitation.

8. Resuspend DNA pellets in 100 μ l of 1 M piperidine. Incubate 30 min in a 90° to 95°C water bath. Place a glass plate over tubes to keep tops from popping open. After piperidine cleavage, place tubes on dry ice.
9. Make holes in tops of tubes with a large needle and lyophilize samples in a vacuum evaporator (e.g., Speedvac) for 1 hr or until dry. Add 100 μ l water, freeze, and lyophilize again. Repeat addition of water, freezing, and lyophilizing. Measure the samples for Cerenkov counts.
10. Add stop/loading dye to the pellet. Heat 5 min at 95°C and quickly chill on ice. Electrophorese samples from free probe and bound complex on a 6% or 8% sequencing gel and autoradiograph.

To easily compare the samples, it is critical to equalize the number of counts prior to electrophoresis. For an overnight exposure with an intensifying screen, 3000 cpm is sufficient.

REAGENTS AND SOLUTIONS

DMS reaction buffer

50 mM sodium cacodylate, pH 8.0
1 mM EDTA, pH 8.0
Store at 4°C

DMS stop buffer

1.5 M sodium acetate, pH 7.0
1 M 2-mercaptoethanol
Store at 4°C

COMMENTARY

Background Information

Methylation interference was used initially by Siebenlist and Gilbert (1980) to study the interaction of RNA polymerase and the T7 promoter. This technique utilized the chemistry developed for the G reaction in DNA sequencing (Maxam and Gilbert, 1980). The principle of uracil interference was established by Goeddel et al. (1978), who synthesized oligonucleotides in which individual thymine residues

were replaced by uracil (for a review, see Levarie, 1987). To simultaneously analyze all the thymines in a given DNA fragment, randomly distributed deoxyuracil substitutions are introduced by PCR in the presence of dUTP, and uracil-specific cleavage is accomplished by treatment with uracil-*N*-glycosylase and piperidine (Pu and Struhl, 1992). Both interference methods have been coupled with the mobility shift DNA-binding assay (*UNIT 12.2*), re-

sulting in relatively rapid analyses of the contact sites for DNA-binding proteins.

Interference assays and DNase I protection assays (*UNIT 12.4*) are the two procedures typically used to map regions of DNA-protein interaction. Interference assays have several advantages over DNase I protection. First, interference analyses are not hindered by incomplete binding, because all of the probe in a retarded complex is bound by protein. In contrast, DNase I protection experiments require protein titrations to fully saturate probe DNA. Another disadvantage of DNase I digestions is that protein exchange from the binding site during the digestion can lead to cutting within the binding site. Finally, interference assays allow the determination of specific nucleotides that are in relatively close contact with the DNA-binding protein. As a result, much more information is obtained about the binding site than from the comparatively large protected region produced by a DNase I footprint. Methylation interference has determined single nucleotide differences in binding site specificities that could not be determined by DNase I protection (Baldwin and Sharp, 1988).

Although interference does not measure direct protein contacts with nucleotides, it permits detection of nucleotides that are closely apposed to the proteins. DMS methylates guanine residues at the N-7 position that protrudes into the major groove, and also at the N-3 position of adenines that protrudes into the minor groove. Adenines can be detected in this assay but these reactions are much weaker than the G reactions (Maxam and Gilbert, 1980). Uracil substitutions result in substitution of hydrogen for thymine 5-methyl groups, which lie in the major groove and are involved in short-range hydrophobic interactions.

In another interference procedure (Brunelle and Schleif, 1987), depurinated and depyrimidinated DNA probes are substrates in the binding reaction. Bound and free probes are separated by native (nondenaturing) gel electrophoresis and cleaved by piperidine, allowing detection of proteins closely apposed to T and C, as well as G and A, residues.

Critical Parameters

Maximizing the amount of specific complex is critical for DNA-binding activities of lower abundance or affinity. Before beginning the methylation interference, it is necessary to optimize conditions for the mobility shift DNA-binding assay. The degree of scale-up is important in generating enough cpm for analysis.

It is important to analyze protein-DNA interactions on both strands. In some cases no contacts are detected on one strand of the probe.

Troubleshooting

In methylation interference, a very large DNA pellet is sometimes observed after the first ethanol precipitation. If this occurs, fresh DMS stop buffer should be made or less 2-mercaptoethanol should be used in the buffer. It is also important to solubilize this methylated DNA pellet completely in TE buffer. Heating at 65°C, vortexing, and repeated pipetting may be required as well.

To obtain an interpretable gel following piperidine cleavage, the DNA probe must be free of acrylamide impurities and be labeled at one end only. The DNA probe should be modified at an average of only one guanine per molecule. If the DMS-reacted DNA has no uncleaved probe at the top of the gel and a nonhomogeneous ladder of bands, the time of the DMS reaction should be reduced. For uracil interference, it is crucial that the PCR reaction and the uracil-*N*-glycosylase cleavage proceed efficiently. The DNA probe should be modified at an average of only one uracil per molecule. To achieve this, it may be necessary to alter the dTTP:dUTP ratio in the PCR reaction.

Anticipated Results

For methylation interference, it is assumed that guanines and adenines are located in the binding site and are positioned close to the DNA-binding activity. The bound lane in the sequencing gel has some missing bands relative to the free probe lane. Adenine contacts may be detected upon careful examination (Fig. 12.3.2). Uracil interference experiments should look similar except that missing bands will correspond to thymine residues in the original DNA fingerprint.

Time Considerations

Preparation of a probe labeled on a single end requires a full day's work. This includes enzymatic treatments and electrophoresis required for probe purification. Ethanol precipitations are convenient stopping points. Methylation requires ~1 to 2 hr. The mobility shift binding assay and exposure require 3 to 5 hr, but may take 12 hr if longer exposure times are necessary. DNA isolation requires ~2 hr. Piperidine cleavage and lyophilization require 3 to 5 hr. Electrophoresis requires 2 to 3 hr followed by a 12- to 24-hr exposure. Thus, a total time of ~3 days is required to perform the procedure.

Figure 12.3.2 Hypothetical autoradiogram of a methylation interference experiment, as described in Anticipated Results. Guanines and adenines that interfere are indicated by asterisks.

DNase I Footprint Analysis of Protein-DNA Binding

UNIT 12.4

Deoxyribonuclease I (DNase I) protection mapping, or footprinting, is a valuable technique for locating the specific binding sites of proteins on DNA. The basis of this assay is that bound protein protects the phosphodiester backbone of DNA from DNase I-catalyzed hydrolysis. Binding sites are visualized by autoradiography of the DNA fragments that result from hydrolysis, following separation by electrophoresis on denaturing DNA sequencing gels. Footprinting has been developed further as a quantitative technique to determine separate binding curves for each individual protein-binding site on the DNA. For each binding site, the total energy of binding is determined directly from that site's binding curve. For sites that interact cooperatively, simultaneous numerical analysis of all the binding curves can be used to resolve both the intrinsic binding and cooperative components of these energies.

The unit is divided into three parts. The basic protocol covers DNase I footprint titration and involves (1) preparation of a singly end-labeled DNA restriction fragment, (2) equilibration of the protein with DNA, (3) exposure of the equilibrium mixture to DNase I, and (4) electrophoretic separation on gels of the denatured hydrolysis products, followed by autoradiography. The support protocol describes (1) densitometric analysis of the autoradiograms to obtain binding data and (2) numerical analysis of the binding data to yield binding curves and equilibrium constants for the interactions at each of the separate sites. An alternate protocol describes the qualitative use of footprinting to identify DNA-binding proteins in crude extracts.

DNASE I FOOTPRINT TITRATION

Materials

- Plasmid DNA containing protein-binding sites (UNIT 1.6)
- Appropriate restriction endonucleases (UNIT 3.1)
- 100% and ice-cold 70% ethanol
- TE buffer (APPENDIX 2)
- Aqueous [α - 32 P]dNTP (3000 to 6000 Ci/mmol; UNIT 3.4)
- 10 \times Klenow fragment buffer (UNIT 3.4)
- Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
- 5 mM 4dNTP mix (UNIT 3.4)
- Deoxyribonuclease I (DNase I; EC 3.1.4.5)
- Assay buffer A or B
- Dry ice
- DNase I stop solution
- DNase I storage buffer
- Formamide loading buffer (UNIT 7.4)
- 10-ml plastic disposable tubes
- Silanized 1.5-ml microcentrifuge tubes (APPENDIX 3)
- Regulated water bath ($\pm 0.1^\circ\text{C}$)
- 12 \times 7.5-in. glass or stainless-steel tray
- Plastic microcentrifuge tube rack with open sides
- Gel comb for DNA sequencing gel with 6-mm lanes spaced on 12-mm centers
- Hamilton syringes with blunt-tip needles (29 G for 0.4-mm gels)
- Additional reagents and equipment for CsCl gradient centrifugation (UNIT 1.7), restriction enzyme digestion (UNIT 3.1), ethanol precipitation (UNIT 2.1), spin col-

Supplement 7

umn procedure (UNIT 3.4), agarose gel electrophoresis (UNIT 2.5A), electroelution (UNIT 2.6), autoradiography (APPENDIX 3), denaturing polyacrylamide gel electrophoresis (UNIT 2.12), and reversed-phase or ion-exchange chromatography (Elutip-d or DEAE-cellulose, respectively; UNIT 2.6)

Prepare singly ^{32}P end-labeled DNA

Plasmid DNA is prepared by the alkaline lysis method (UNIT 1.6), followed by two sequential CsCl gradient centrifugations (UNIT 1.7). Exposure of the plasmid to shortwave UV illumination should be minimized to prevent nicking of the DNA.

1. Digest ~5 pmol plasmid with a restriction enzyme that generates a 3'-recessed end, 25 to 100 bp from the first protein-binding site (Fig. 12.4.1).
2. Ethanol precipitate the DNA, wash once with 1 ml of cold 70% ethanol, and dry pellet in a Speedvac evaporator. Dissolve pellet in 5 μl TE buffer.

Standard precautions for handling aqueous ^{32}P -labeled nucleotides should be followed throughout the remaining steps (UNIT 3.4).

3. Add 50 μCi each of the appropriate aqueous [^{32}P]dNTPs, 5 μl of 10 \times Klenow fragment buffer, and water to 49 μl . Add 1 μl Klenow fragment (5 to 10 Kunitz units), mix gently, microcentrifuge, and incubate 25 min at room temperature (UNIT 3.5).

To generate end-labeled DNA with high specific radioactivity, perform the Klenow "fill in" reaction of the 3'-recessed end using only [α - ^{32}P]dNTPs.

4. Add 2 μl of 5 mM 4dNTP mix, mix, and incubate 5 min.

The cold chase ensures that all the labeled fragments have the same number of base pairs.

5. Remove unincorporated nucleotides with spin column procedure (UNIT 3.4). Ethanol precipitate DNA as in step 2.

6. Digest with a second enzyme to generate a restriction fragment labeled only at one end and on one strand (Fig. 12.4.1).

The second restriction site should be >150 bp beyond the protein-binding site most distal to labeled end of fragment.

7. Purify the labeled binding-site-containing DNA using agarose gel electrophoresis, followed by electroelution and reversed-phase chromatography.

Because the DNA fragment is radiolabeled, staining the gel with ethidium bromide (as described in UNIT 2.6) is unnecessary. Instead, wrap the gel in a single layer of plastic wrap. Autoradiograph the gel for 5 to 15 min and use the developed film as a template for excising the band containing the binding site from the gel.

Reversed-phase (using Elutip-d) or ion-exchange (using DEAE-cellulose) chromatography of the labeled DNA is essential for removing impurities and obtaining high-quality footprints (see UNIT 2.6).

Figure 12.4.1 Correct positioning of protein-binding sites from the restriction cuts used to generate a linear, singly end-labeled fragment. Black boxes represent protein-binding sites. Asterisks (*) represent [^{32}P]dNTP incorporated in the Klenow labeling reaction.

- Ethanol precipitate DNA as in step 2. Dissolve DNA in 100 μl TE buffer, pH 8.0. Store at 4°C. Do not freeze.

Recovery of the small quantity of labeled DNA is improved by extending the -70°C precipitation for several hours.

- Determine radioactivity of the DNA by dissolving a 0.5- μl aliquot in an aqueous scintillation cocktail and counting.

Up to 80% of theoretical label incorporation has been achieved using this procedure. This figure, along with the specific radioactivity of the [^{32}P]dNTPs and the number of bases filled in, can be used to estimate the molar concentration of binding-site DNA. Storage of labeled DNA for longer than 2 weeks results in unacceptable background levels due to radiochemical nicking of the DNA.

Equilibrate protein with DNA

- Prepare $(n + 2) \times 180 \mu\text{l}$ assay buffer in a 10-ml disposable plastic tube, where n is the number of binding reactions in the experiment. Determine the volume of ^{32}P -labeled DNA to yield 10,000 to 15,000 cpm/lane. Add the ^{32}P -labeled DNA to assay buffer. Vortex gently.

The necessary number of binding-reaction mixtures (i.e., data points) for an experiment depends on the relative affinities of the binding sites if multiple sites are present, and whether the shapes of the binding curves need to be well defined. We routinely assay 18 to 24 binding-reaction mixtures. An absolute upper limit is dictated by the number of sequencing gel lanes (see commentary).

*The assay buffer used (e.g., A or B) depends on the nature of the protein, the protein-DNA system, and the questions being addressed. In all cases, millimolar concentrations of Mg^{++} and Ca^{++} are required for DNase I activity. Also, although the specific binding affinity of most DNA-binding proteins decreases with increasing monovalent cation concentration, the specificity (ratio of specific site to nonspecific affinities) often increases. Assay buffers A and B are examples of buffers used in DNA-binding studies of the *E. coli* Gal and λ cI repressors, respectively.*

- Aliquot 180 μl of assay buffer containing ^{32}P -labeled DNA into each of $n + 1$ silanized 1.5-ml microcentrifuge tubes. The extra tube is a control to which no DNase I is added.
- Prepare a series of serial protein dilutions that cover the range of concentrations to be analyzed.

The ligand concentrations should span a range from 0% to $\geq 99\%$ saturation of all of the protein-binding sites. This requires a concentration range of four orders of magnitude for even a single DNA-binding site. Site heterogeneity increases the required range. The final ligand concentrations in the binding-reaction mixtures should define an evenly spaced, logarithmic series with at least several points to define each asymptote of the titration curves (plotted versus log ligand concentration; Fig. 12.4.2).

- Pipet the desired amount of protein dilution (2 to 20 μl) into each tube. Add assay buffer (without ^{32}P -labeled DNA) to a final total volume of 200 μl per tube.

To have a sufficient amount of ^{32}P -labeled DNA for fragment detection and still keep the concentration of the DNA low, use 200- μl volumes (see commentary).

Propagation of pipetting errors can be a problem in steps 12 and 13. Accuracy is critical: wipe the outside surface of the pipet tip so that no liquid adheres to the surface.

- Gently mix each tube and microcentrifuge briefly. Equilibrate samples in a regulated water bath 30 to 45 min at the desired temperature.

Figure 12.4.2 Footprint titration curve showing the proper range and spacing of protein concentrations. The upper and lower limits of the titration curve are indicated by dashed lines. See Equation 1 for a definition of f .

This equilibration time is a general guideline. Equilibration of the protein-DNA mixture should be verified by conducting assays using different equilibration times.

Perform DNase I footprint titration

15. Prepare an ethanol-dry ice bath in a glass or stainless-steel tray. Place a plastic microcentrifuge tube rack in the bath. The liquid level should cover tubes to just below their tops. Prepare an excess of DNase I stop solution (700 μ l is required per tube) and place in the bath to cool.
16. Prepare ≥ 500 μ l dilute DNase I solution in assay buffer *without* BSA and calf thymus DNA. Place solution in regulated water bath with samples and allow it to equilibrate.

The necessary DNase I concentration not only depends on the supplier but also on the storage and assay conditions. Routinely, 2 mg/ml enzyme is stored in DNase storage buffer at -70°C with no loss of activity. Repeated freezing and thawing drastically reduces activity (requiring storage in small aliquots); therefore, DNase I concentration must be determined empirically (see critical parameters).

Expose equilibrium mixture to DNase I

17. To start DNase I exposure, pipet exactly 5 μ l dilute DNase I into the first tube, vortex gently but quickly to mix, set timer to 2 min, and immediately return tube to the regulated bath.

To obtain titrations of high quality, maintain uniform DNase I exposure. To minimize differences, carry out all manipulations in the same order and at the same pace for each tube.

18. After precisely 2 min, rapidly add 700 μ l DNase I stop solution to the tube. Vortex vigorously to mix the viscous stop solution. Place tube in ethanol-dry ice bath.

The exposure time and DNase I concentration can be varied (between, but never within, experiments) as long as the product of the two (and hence, the number of DNA nicks produced) remains constant. The thermodynamic validity of the method depends on avoiding significant perturbation of the binding equilibria; thus, overall exposure time is not an issue.

19. Repeat steps 17 and 18 for each tube.

20. Add stop solution to the extra tube prepared in step 11 (without DNase I).

This tube provides a control for the presence of excessive background nicking of the DNA. Such nicking can occur upon preparation or over-long storage of labeled DNA.

21. Precipitate DNA in ethanol–dry ice bath for ≥ 15 min. Start timing when last tube is placed in the bath.

The minimum time required for quantitative precipitation under these conditions is 15 min. Longer times are not deleterious.

22. Microcentrifuge tubes 15 min. Carefully remove supernatant with a pipet. Add 1 ml cold 70% ethanol. Microcentrifuge again 5 min. Remove supernatant very carefully with a pipet; the pellet is frequently very loosely attached to the tube at this point. Repeat wash step. Dry pellets in a Speedvac evaporator (~10 to 15 min).

23. Resuspend DNA in 5 μ l formamide loading buffer. Pipet buffer onto the upper inside surface of tube and tap the tube to allow buffer to settle. Vortex vigorously and microcentrifuge several seconds. Repeat twice.

Quantitative resuspension of the pellet is mandatory but can be very difficult. Incomplete resuspension results in substantial variations in the amount of DNA loaded onto each lane. The difficulty appears to be in getting the DNA pellet and loading buffer in physical contact. High microcentrifuge speeds and commercially available silanized tubes facilitate good pellet formation. Vigorous vortexing also helps and does not appear to damage the DNA at this step of the procedure.

24. If the sequencing gel is not to be run immediately, store samples overnight below -70°C .

Isolate and autoradiograph denatured hydrolysis products

25. Prepare and pre-electrophorese a polyacrylamide DNA sequencing gel (UNIT 2.12).

The percentage of acrylamide depends on the size of the fragments to be separated, i.e., on the distance between the first binding site and the labeled end, and on the size of the binding-site region. In most cases, 6% to 8% is optimal. For systems with widely separated binding sites, 0.4- to 1.2-mm-thick gels are desirable.

For quantitative analysis the spacing between lanes of commercial combs (usually 3 mm) is insufficient to prevent bleeding of density across lanes when using ^{32}P . This can produce significant errors in analysis and is easily avoided by using a sample comb with 6-mm lanes and 6-mm spacing. Such combs can be cut by most university machine shops or custom ordered from commercial suppliers.

26. While pre-electrophoresing the gel, heat samples at 90°C in a dry-block heater 5 to 10 min, followed by immediate quenching in wet ice. When the temperature of the gel reaches 50° to 55°C , disconnect the power supply. Load samples carefully, being sure to take up all of the loading buffer in each tube. Either Hamilton syringes with blunt-tip needles (29 G for 0.4-mm gels) or thin micropipet tips are suitable. Care should be taken to prevent cross contamination of the wells.

It is essential that the temperature of the dry-block heater not exceed 90°C . Higher temperatures cause large portions of the DNA to remain in the sample wells and also cause streaking.

27. Electrophorese until the protein-binding sites migrate to, or just below, the middle of the gel. Fix (gradient gels only) and dry gel using standard procedures (*UNIT 2.12*).
28. Autoradiograph the dried gel with preflashed Kodak X-Omat AR film and a single calcium tungstate intensifying screen at -70° to -85°C as described in *APPENDIX 3*. Set the preflashed side of the film against the gel.

Preflashing the X-ray film is essential for overcoming threshold behavior of the film and achieving linear response to radioactivity (APPENDIX 3). With 10,000 to 20,000 cpm loaded per lane and 25% to 50% of the DNA nicked at least once, 24- to 48-hr exposures are required. The optical density (OD) range analyzable is highly dependent on the type of densitometer used (see below). An absolute limit to the darkest area to be analyzed is dictated by the significant deviation of the response of Kodak X-Omat AR film from linearity, >1.6 OD. Make two or three autoradiograms of each gel (at different exposure levels) to ensure a correct exposure.

29. Develop films under consistent and controlled conditions.

It is suggested that films be developed by hand in a standard temperature-regulated 5-gallon tank with Kodak GBX developer and fixer for the times recommended by the manufacturer (i.e., 4 min at 70°F). Automatic X-ray film processors or other developers or stabilizers have not been tested with regard to either image or background uniformity or optical density linearity.

30. Store films carefully with interleaved paper. Scratches, fingerprints, and dirt will appear as optical signals, indistinguishable from ^{32}P . The autoradiograms are now ready for quantitation.

SUPPORT PROTOCOL

QUANTITATION OF PROTEIN-BINDING EQUILIBRIA BY DENSITOMETRIC AND NUMERICAL ANALYSES

This protocol outlines the resolution of binding curves from autoradiograms and the numerical analyses of those curves to obtain equilibria binding constants. The steps involved are (1) digitization of the autoradiogram, (2) integration of optical density over the bands corresponding to binding site(s), (3) correction of integrated optical density for film background optical density, (4) standardization of corrected, integrated optical density to the total amount of DNA loaded onto each lane, and (5) calculation of fractional protection of the sites, proportional to fractional saturation.

Accurate densitometric analysis is critical to obtaining thermodynamically valid individual site-binding curves. The common practice of visually estimating titration half-points from autoradiograms is unacceptable for a number of reasons. First, the eye responds to light intensity, whereas optical density—the quantity proportional to the concentration of labeled DNA in a given band—is the log of the intensity. Thus, visual estimates of titration half-points are usually systematically wrong. Second, autoradiograms that look acceptable show appreciable saturation of dark bands. Films that are within the linear densitometric range appear light or washed out, making the intensity differences difficult to estimate. Third, visual inspection allows no estimate of the precision of the experimental data or derived binding constants. Fourth, visual estimation is not objective. There is a tendency to group estimated half-points into classes (i.e., relative dissociation constants of 1, 2, and 25) which may obscure real differences in the data. Finally, in cooperative systems, the half-point of a titration corresponds to no single equilibrium binding constant (Ackers et al., 1983).

Required hardware includes a two-dimensional optical scanning device and a micro- or minicomputer with a high-resolution graphics display. Although some investigators rely on one-dimensional analog traces of each of the separate film lanes, we consider

two-dimensional scanning to be essential for accurate quantitation. Two-dimensional scanning avoids the systematic error that is made when either the maximum peak height or the area of a one-dimensional slice through a band is equated with the total material in the band. Two-dimensional scanning also minimizes the effect of electrophoretic abnormalities, e.g., band skewing and distortion.

The variety of appropriate scanning devices currently in use include flat bed scanners (e.g., some laser scanners), flying spot detectors (e.g., rotating drum scanners), charge coupled devices (CCD) or photodiode array-imaging cameras, and video cameras. The digital image consists of an array of values corresponding to the diffuse optical density of picture elements (pixels). The pixels must be small enough to resolve closely spaced bands clearly. Spatial resolution of 250 to 200 μm is optimal. The scanner must resolve at least 256 levels of gray. This optical resolution is adequate to quantitate 0 to 1.6 OD when the levels represent equal optical density increments, such as those produced by flying spot or laser scanning devices. Camera devices, however, measure transmitted intensity (I) rather than optical density. The transformation to optical density ($\text{OD} = \log I/I_0$) must be computed. I_0 , the incident intensity, is determined by scanning the light source with no film present. The log transformation reduces the range that can be scanned to 0 to 1.0 OD (100% to 10% transmission) but benefits from the greater sensitivity of the scanner in that range.

For analysis, the film image should be displayed on a graphic display monitor with a minimum of 16 gray or color levels. Display devices with 256 levels are preferred. Spatial resolution $\geq 1024 \times 1024$ pixels is preferred, although lower resolution display devices can be used.

Computer software to expedite both film scanning and analysis is available for PC/DOS and VAX/VMS computers. Information concerning these programs can be obtained by contacting the authors. Also, some commercially available image-analysis software packages have functions that can be used for the analysis of titration autoradiograms. The protocol described can be implemented using such systems.

1. Use a film-scanning device to construct a two-dimensional digital image of the film.
2. Integrate the optical density in each lane (i.e., at each ligand concentration) for the protected DNA bands in each binding site (Fig. 12.4.3). The integrated optical density is the sum of the optical density values of the individual pixels within a contour defining the band.

Protected bands are easily identified by visual inspection. In principle, any protected bands can be chosen to follow the titration. It is best to consider all protected bands by analyzing contiguous groups of bands as single blocks (Fig. 12.4.3). This simplification is appropriate whenever all the bands included titrate equivalently.

Choose the ends of blocks by drawing boundaries at the minimum density level between bands of similar maximum density that can be visualized in all lanes (i.e., even at high protection). It is crucial that each block include precisely the same bands in every lane of the film. If there are multiple, closely spaced binding sites, ensure that the protection of bands near the edge of one site is not influenced by binding of the neighboring site.

3. Correct the integrated optical density value of each block in each lane for the local film background optical density. This can be calculated using the image-analysis software as follows:
 - a. Define small rectangles in the center of the interlane space and at the position of each block (Fig. 12.4.3).

Figure 12.4.3 Portion of a footprint titration autoradiogram showing the different blocks that need to be defined for analysis. "Std." denotes a standard block used to correct for variations in the DNA loaded onto each lane. O₁ and O₂ denote protein-binding sites 1 and 2, respectively. The insert shows regions for a standard block for which background determinations will be made.

- b. Calculate a histogram plot of the pixel optical density values in each rectangle and define the local background as the most probable pixel optical density.
- c. For each block and lane, average the background values on either side of the lane.
- d. Multiply this average value by the number of pixels in the block.
- e. Subtract the product from the integrated optical density to give the corrected integrated optical density for that block.

The variability in the background density of the film is large enough to warrant local determination of background and correction of the integrated optical densities (a to e above).

4. Standardize corrected, integrated optical density values for binding-site blocks to total DNA in the lane.
 - a. Choose one or more blocks, excluding titrating sites or very hypersensitive bands, to represent the total DNA concentration in a lane.
 - b. Follow steps 2 and 3 to determine the corrected, integrated optical density for these standard blocks.
 - c. Calculate the optical density ratio ($D_{\text{site}}/D_{\text{std}}$) for each binding-site block. If more than one standard block is chosen, take the sum of their values as D_{std} .

It is practical and sufficient to choose two large standard blocks (Fig. 12.4.3), one nearer the origin of electrophoresis than the binding site(s) and one farther away. Carefully check each standard for systematic, ligand concentration-dependent

variations that invalidate its use. Variations might indicate nonspecific protein binding (decreasing density with increasing ligand), redistribution of DNase I on the DNA fragment (increasing density with increasing ligand) as binding sites are saturated and protected (Dabrowiak and Goodisman, 1989), or poor experimental technique.

5. Convert OD ratios to fractional protection (f), according to

$$f = 1 - \left\{ \frac{(D_{n,site}/D_{n,std})}{(D_{r,site}/D_{r,std})} \right\} \quad (1)$$

where n refers to any lane with finite protein ligand concentration and r refers to a reference lane (that must be included in every experiment) in which no protein ligand has been added to the reaction mixture. Plot data, f versus [ligand], for each binding-site block to define the binding curves (Fig. 12.4.2).

If outlined protocols are followed and if control experiments (see Brenowitz et al., 1986a) demonstrate no effect of exposure to DNase I on the protein–DNA binding equilibria, then f yields the fractional saturation (Y). Observed values of f frequently do not span the entire range, 0 to 1. One reason for this is the failure to account for nicking of the DNA prior to DNase I exposure (i.e., $D_{n,site} > 0$, even at saturating ligand concentration). Therefore, in analyzing data, it is best to treat f as defining a transition curve, proportional to the binding curve, and to include both curve endpoints (u and l for upper and lower endpoints, respectively) as adjustable parameters (Fig. 12.4.2).

For a single binding site or multiple sites that do not interact cooperatively, the binding curve is the familiar Langmuir isotherm given by

$$\bar{Y} = \frac{k[P]}{1 + k[P]} \quad (2)$$

where $[P]$ is the free protein concentration and k is the microscopic equilibrium association constant (the more complex case of multiple, interacting binding sites is discussed in the commentary). Thus, the equation used to analyze the data is

$$f = m \times \left\{ \frac{k[P]}{1 + k[P]} \right\} + b \quad (3)$$

with $m = 1/(u - l)$ and $b = 1/(l - u)$ and other units as defined above. Methods of nonlinear least-squares parameter estimation (Johnson and Frasier, 1985) should be used to estimate k , l , and u , along with their confidence limits and the variance of the fit. Pay particular attention to the pattern of residuals (i.e., difference between fitted and observed f) in evaluating the goodness of fit of the nonlinear least-squares parameter estimation.

DNASE FOOTPRINTING IN CRUDE FRACTIONS

DNase footprinting is frequently used to locate proteins in crude fractions, thus providing an assay for use during purification. The purpose of this type of footprinting is usually to locate a particular binding activity, not to characterize the strength of the interaction. Thus one first establishes conditions under which a complete footprint can be observed, and then assays fractions of a crude extract for that activity. For this purpose, it is necessary to develop conditions that allow binding of the protein of interest to a specific site, but that do not allow substantial nonspecific binding. This is accomplished by varying conditions such that nonspecific DNA-binding proteins are inhibited from binding to the labeled DNA containing the site of interest—i.e., by including substantial amounts of competitor DNA in the reaction, or by increasing the salt concentration of the reaction.

ALTERNATE PROTOCOL

DNA-Protein Interactions

12.4.9

1. Prepare singly ^{32}P end-labeled DNA as in steps 1 to 9 of the basic protocol.
2. Characterize dilutions of stock DNase I for a concentration of DNase I that will produce ~50% non-nicked DNA. Set up a 200- μl reaction containing probe and assay buffer, but no added protein, as described in step 10 of the basic protocol. Add 5 μl of diluted DNase I, mix gently, and microcentrifuge briefly.

The amount of DNase I required will vary with lot and storage conditions, but is frequently ~0.1 mg/ml in the dilute solution added to the reaction. Assay composition can dramatically affect DNase I activity; see critical parameters.

3. Incubate 2 min and stop as described in step 18 of the basic protocol. Ethanol precipitate and analyze products on a sequencing gel.
4. Perform a footprinting reaction as described in the basic protocol. Instead of using varying amounts of protein, however, use a constant amount of a crude fraction that is known to contain the activity of interest. Perform a set of assay conditions as described in Table 12.4.1, in order to find a condition that produces a footprint.

The goal of this experiment is to find conditions for the specific binding of the protein of interest without interference from nonspecific DNA-binding proteins. In the experiment described in the table, poly(dI-dC) concentration is varied in an attempt to find an optimal concentration that will “soak up” contaminating nonspecific proteins. A similar protocol can be used to vary salt concentration (e.g., try 200 mM, 300 mM, 500 mM, and 800 mM) or calf thymus DNA concentration. It may also be prudent to vary extract concentrations, as the level of any DNA-binding protein can vary dramatically.

It is important to vary DNase I concentration above that needed for appropriate digestion of labeled DNA when no crude fraction is present. This is because DNase digestion is inhibited in many crude fractions.

Table 12.4.1 Assay Conditions for Footprinting in Crude Fractions

Reaction no. ^a	10 \times assay buffer (μl)	Probe (cpm)	Crude fraction (μl)	Poly(dI-dC) (μg)	DNase (μl) ^b
1	20	10-20k	0	0.4	5 (1 \times)
2	20	10-20k	12	0.1	5 (1 \times)
3	20	10-20k	12	0.4	5 (1 \times)
4	20	10-20k	12	2.0	5 (1 \times)
5	20	10-20k	12	10.0	5 (1 \times)
6	20	10-20k	0	0.4	5 (4 \times)
7	20	10-20k	12	0.1	5 (4 \times)
8	20	10-20k	12	0.4	5 (4 \times)
9	20	10-20k	12	2.0	5 (4 \times)
10	20	10-20k	12	10.0	5 (4 \times)
11	20	10-20k	0	0.4	5 (16 \times)
12	20	10-20k	12	0.1	5 (16 \times)
13	20	10-20k	12	0.4	5 (16 \times)
14	20	10-20k	12	2.0	5 (16 \times)
15	20	10-20k	12	10.0	5 (16 \times)

^aReaction volume is 200 μl .

^bDilutions are shown in parentheses. 1 \times refers to the dilution that leaves 50% unnicked DNA (step 2 of alternate protocol). 4 \times and 16 \times refer to higher concentrations (as indicated) of DNase I.

REAGENTS AND SOLUTIONS

Assay buffers A and B

Assay buffer A:

10 mM Tris-Cl
5 mM MgCl₂
1 mM CaCl₂
2 mM dithiothreitol (DTT)
50 µg/ml bovine serum albumin (BSA)
2 µg/ml calf thymus DNA
100 mM KCl
Titrate to pH 8.0

Assay buffer B:

10 mM bis-Tris-Cl
2.5 mM MgCl₂
1 mM CaCl₂
0.1 mM EDTA
200 mM KCl
100 µg/ml BSA
2 µg/ml calf thymus DNA
Titrate to pH 7.0

DNase I stop solution

For each 200-µl binding-reaction mixture:

645 µl 100% ethanol
5 µl tRNA stock solution (1 mg/ml)
50 µl saturated ammonium acetate
Store at -20°C for up to 1 to 2 weeks

DNase I storage buffer

50 mM Tris-Cl, pH 7.2
10 mM MgSO₄
1 mM DTT
50% glycerol
Store DNase I in small aliquots at -70°C

COMMENTARY

Background Information

In both prokaryotes and eukaryotes the binding of proteins to specific DNA sequences is critical to the regulation of many cellular processes. In addition, cooperative interactions among bound proteins (perhaps also with non-DNA-binding proteins) are known to be critical to the regulation of transcription, replication, and recombination. A key to understanding the molecular mechanism by which these proteins regulate cellular processes is the measurement of the free energy of binding of these proteins to DNA and the free energies that describe the cooperative interactions occurring among them.

The DNase I footprint titration method, with subsequent quantitative analysis, has been shown to yield thermodynamically valid individual site-binding curves for site-specific protein-DNA interactions. In systems containing multiple sites, these curves can be used to resolve intrinsic binding constants, describing the binding of a protein to a site in the absence of other sites, and constants that describe the cooperative interactions among proteins bound

to multiple sites. The power of the method is that it is, in principle, not limited by the number of sites or the number of proteins.

The method is based on the fact that DNase I probes, *without perturbing*, the equilibrium distribution of binding protein with DNA. Control experiments show that DNase I does not perturb the equilibrium between *cI*- and Gal-repressors and their respective binding sites under the solution conditions we have studied. This conclusion may not be valid, however, for all systems under all experimental conditions. Thus, control experiments must be conducted for new systems and drastically new conditions. Some general considerations are discussed in critical parameters.

DNase I protection mapping, or footprinting, was developed as a qualitative technique to locate the specific protein-binding sites on DNA (Galas and Schmitz, 1978). Subsequently, it was used to compare the relative affinities of *cI* repressor to multiple binding sites (Johnson et al., 1979). Using the data of Johnson et al., Ackers et al. (1982) resolved the intrinsic binding and cooperative free energies

for the binding of *cI* repressor to the O_R operator of the bacteriophage λ . A general theory for individual site-binding curves has been developed (Ackers et al., 1983). The fact that quantitative DNase I footprint titrations yield thermodynamically valid individual site-binding curves for site-specific protein-DNA interactions was demonstrated by Brenowitz et al. (1986a,b). A discussion of the use of the footprint titration method (and other popular binding methods) to determine the intrinsic binding and cooperativity constants for systems of multiple, interacting sites has been presented (Senear et al., 1986). Quantitative footprint titration methods for studying drug-DNA interactions have been developed in parallel with the work on proteins presented in this protocol (Dabrowiak and Goodisman, 1989).

Other probes. As a probe of the occupancy of protein-binding sites, DNase I has several advantages over high-resolution probes such as Fe-EDTA (Tullius et al., 1987) or methidium-propyl-EDTA (MPE) (Hertzberg and Dervan, 1982). First, the uniform footprint produced by DNase I yields large density changes on the autoradiogram that can be accurately quantitated. This facilitates the precise determination of binding curves. Second, divalent cations are known to bind tightly to DNA, are frequently involved in protein structure and self-assembly, and are physiologically important. Unlike MPE and Fe-EDTA, DNase I can be used conveniently with (and requires) divalent cation-containing buffers. Third, the fact that DNase I is an enzyme specific for DNA precludes the possibility of degradation of the binding protein by promiscuous free radicals. Thus, DNase I may be particularly valuable for the analysis of binding proteins sensitive to degradation.

The single base-pair resolution of Fe-EDTA and MPE make these reagents important tools if detailed structural information is desired. There is no a priori reason that they cannot be used to monitor protein or drug titrations with single basepair resolution.

Other binding methods. A virtue of footprinting for quantitative analysis is that protein binding is determined at equilibrium. Unlike other methods, such as the mobility shift assay (UNIT 12.2), the manipulations required to separate and visualize liganded and unliganded DNA are performed after the binding and DNase I-catalyzed reactions are quenched. This feature of the method provides for its application over a wide range of precisely controlled experimental conditions.

In contrast, the use of the mobility shift assay

to obtain titration curves that separately represent each protein-DNA complex with exactly n bound proteins requires that the protein-DNA complexes do not dissociate in the gel during electrophoresis and that their distribution remains unchanged. It has been noted that quantitation of the unbound DNA band is less affected by dissociation of protein-DNA complexes in the gel. If only the unbound DNA is quantitated, however, all of the information concerning potential cooperative free energies is lost. For a theoretical discussion of the determination of cooperativity constants from the mobility shift assay, see Senear et al. (1986).

Critical Parameters

Protein purity. Meaningful determination of absolute equilibrium binding constants requires that the protein and DNA concentrations be known. Thus, the binding protein must be chemically pure, and both its DNA-binding form and specific DNA-binding activity must be known. Only relative binding affinities can be obtained from the analysis of crude extracts or partially purified protein (see alternate protocol).

Concentration of DNA-binding site(s). Accurate determination of equilibrium binding constants requires that the free protein concentration in each equilibrium mixture be known. The relationship of free to total protein is

$$[P]_f = [P]_t - [P-DNA] \quad (4)$$

where $[P]_f$ is free protein, $[P]_t$ is total protein, and $[P-DNA]$ represents DNA-bound protein. The simplest way to deal with this problem is to maintain low concentration of DNA-binding sites in the reactions, so that $[P-DNA]$ is negligible and Equation 4 reduces to

$$[P]_f = [P]_t \quad (5)$$

Because the concentration of specific binding-site-containing DNA in the assay is dictated by the radioactivity needed for good autoradiography, it is important to achieve high specific activity in labeling. Choosing restriction sites such that the Klenow fill-in reaction adds four radiolabeled deoxyribonucleotides to the DNA is useful. By using high-specific-activity nucleotides (3000 or 6000 Ci/mmol), 15,000 to 20,000 dpm/200 μ l assay mixture is achieved with 1 to 10 pM in binding-site DNA. For this simplest case of a protein ligand binding to a single site on the DNA, this concentration can be safely ignored if the dissociation equilibrium constant is 50 to 500

pM or greater. In some cases, DNA-binding proteins self-polymerize before binding to DNA. It is then necessary to calculate the free polymer concentration as the free ligand, $[P]_f$. However, the polymer concentration is buffered by the monomer with which it is in equilibrium, allowing higher concentrations of binding-site-containing DNA to be used or higher affinity binding to be analyzed.

It is also possible to make the correction to $[P]_f$ from $[P]_t$, if the total concentration of binding-site-containing DNA ($[DNA]_t$) in the reactions is known or can be estimated accurately, because

$$[P-DNA] = \bar{Y} \times [DNA]_t \quad (6)$$

where \bar{Y} (being the dependent variable in the experiment) represents the fractional saturation of the binding site(s). For systems with multiple binding sites, \bar{Y} is the sum of the Y_s for each of the individual sites. The procedure is to solve for $[P-DNA]$, hence, $[P]_f$, iteratively. At each iteration of the nonlinear least-squares procedure used to fit the Y values observed (see below), the fitted $Y(s)$ is used to correct each $[P]_t$ to $[P]_f$ for the next iteration. The limitations to this approach are the accuracy with which $[DNA]_t$ is known, the sophistication of the least-squares program used, and the available computing power.

DNase I concentration. The general requirement for frequency of single-stranded nicks introduced into the DNA is an average of one per DNA fragment. Based on a random distribution of nicks and fragments, this corresponds to ~50% of the fragments containing nicks and ~50% left intact (Table 12.4.2). This relaxes the more widely held (and stringent) interpretation of “single-hit kinetics,” in which no molecule is nicked more than once. This

interpretation leads to a very small fraction of DNA molecules being nicked during the assay, so that a significant proportion of the density on the autoradiogram represents nicks introduced during preparation and handling of the DNA more than by DNase I activity. More nicking greatly improves the experimental signal-to-noise ratio. Although this results in molecules being nicked more than once, our experimental results (Brenowitz et al., 1986a,b) indicate no effect on the binding equilibria, as long as the (intact) specific-site-containing DNA molecule is at least an order of magnitude longer than the binding sites. The fraction of uncut DNA following DNase I exposure is readily determined by comparison of the uncut DNA (top band following electrophoresis) from DNA exposed, and not exposed, to DNase I. Quantitation of the amount of DNA in this band can be accomplished by autoradiography (very short exposures) and densitometry, or the bands can be physically excised, dissolved in scintillant, and counted. The latter might be more accurate, but hydrolyzable analogs of bisacrylamide must be used to cast the gels, and acrylamide quenching of fluorescence can be a problem. The distribution of number and average number of nicks per fragment are calculable, based on Poisson statistics (Table 12.4.2).

Nonspecific carrier DNA. Nonspecific carrier calf thymus DNA is included in the assay buffer to maintain the DNase I substrate concentration constant. In the absence of carrier, binding of ligand to the DNA leads to increased nicking of the fragment outside of the binding sites (Dabrowiak and Goodisman, 1989). In our hands, carrier DNA eliminates this effect and hence, the need to apply empirical corrections. It is crucial that the carrier concentration be sufficiently low to avoid nonspecific binding of

Table 12.4.2 Calculated Distribution of DNase I Nicks Among Fragments^a

Uncut ^b (%)	Singly nicked ^c (%)	Multiply nicked ^c (%)	Ave. no. nicks/ fragment ^d
10	23.1	67.0	2.3
20	32.2	47.8	1.6
30	36.1	34.0	1.2
50	34.7	15.3	0.7
75	21.6	3.4	0.3
90	9.5	0.5	0.1

^aCalculated for a 682-bp fragment, before DNase I exposure.

^bExperimentally measured percentage of fragments left after exposure to DNase I.

^cPercentages were calculated assuming a Poisson distribution of nicks.

^dAverage number of nicks per labeled strand calculated assuming a Poisson distribution of nicks.

the protein ligand. Although we have used only calf thymus DNA in our experiments, other carriers including synthetic polynucleotides, e.g., poly(dI-dC), which might exhibit lower affinities for site-specific DNA-binding proteins, should also be effective. Binding to the carrier DNA can be monitored by conducting parallel nitrocellulose filter-binding assays (UNIT 12.8).

Assay buffer conditions. An advantage of DNase I footprinting is its applicability over a broad range of binding reaction conditions. Limitations are of two types: the binding affinity of the protein ligand, and the enzymatic activity of DNase I. The limits of high- and low-binding affinity that can be studied by DNase I footprinting have been outlined above. The extremes of temperature, pH, and salt concentration corresponding to these limits are easily determined for any particular protein-DNA system by conducting preliminary binding experiments, e.g., using filter binding (UNIT 12.8) or mobility shift (UNIT 12.2) methods. In the presence of millimolar amounts of Ca⁺⁺ and Mg⁺⁺, the specific activity of DNase I varies by only severalfold from pH 5 to 9 (most active near pH 7), from 4° to 37°C and from 50 to 200 mM KCl. Simultaneous extremes have not been tested. Changes in DNase I activity of only severalfold are easily compensated by adjusting the DNase I concentration and/or the exposure time. Although DNase I is active in the presence of Mg⁺⁺ alone or Ca⁺⁺ (and some other divalent cations), its activity varies dramatically with solution conditions. Under some conditions, the variations in activity (decreases) may be too great to be compensated without unacceptably high DNase I concentrations.

Analysis of binding to multiple, interacting sites. The footprint titration method is best suited to analyze binding to multiple, cooperatively interacting sites on DNA. No other

method provides the information necessary to separately resolve the microscopic equilibrium constants for intrinsic binding and cooperativity. The key feature of cooperativity is that the binding of ligand to one site depends on the fractional occupancy of all other interacting sites. The individual site-binding curves for this situation and the equations that describe them reflect this fact.

To formulate the binding expressions, first consider all possible configurations of liganded and nonliganded sites (Table 12.4.3). For each configuration, the microscopic equilibrium (association) constants for each of the macromolecular interactions are defined. In Table 12.4.3, the Gibbs free-energy changes associated with the interactions are substituted for equilibrium constants. These are related by the well-known thermodynamic relation, $\Delta G = -RT \ln(k)$. The ΔG s are of two types: binding of ligand to one site in the absence of binding to others (ΔG_i) and the excess (or cooperative) energy for binding to two (or more) site(s) simultaneously (ΔG_{ij}). The fractional probability of any one of the configurations is related to its relative Gibbs energy according to

$$f_s = \frac{\exp(-\Delta G_s / RT) \times [P]^j}{\sum_{s,j} \exp(-\Delta G_s / RT) \times [P]^j} \quad (7)$$

where ΔG_s is the sum of ΔG_i 's and ΔG_{ij} 's for state (configuration) s , R is the gas constant, T is the absolute temperature, and j is the number of ligands bound to s . The denominator is the summation of such terms over all states, s . Y_i (fractional saturation of site i) is the sum of probabilities of all configurations with ligand bound to i , e.g., for two sites (Table 12.4.2):

$$\bar{Y}_1 = f_1 + f_3 \quad (8)$$

$$\bar{Y}_2 = f_2 + f_3 \quad (9)$$

Table 12.4.3 Binding-Site Configurations and Associated Energy States of Protein Bound to Two Sites

Species	Binding sites		Free energy contributions ^a	Total free energy ^a
	1	2		
1	—	—	(Ref. state)	ΔG_{s1}
2	P_2	—	ΔG_1	ΔG_{s2}
3	—	P_2	ΔG_2	ΔG_{s3}
4	P_2 —	P_2	$\Delta G_1 + \Delta G_2 + \Delta G_{12}$	ΔG_{s4}

^aFree energies (kcal/mol), where $\Delta G_{12} = \Delta G_{total} - (\Delta G_1 + \Delta G_2)$; i.e., the cooperative free energy ΔG_{12} is the difference between binding to both sites simultaneously and to each site independently.

Table 12.4.4 Analysis of Gal Repressor with Wild-Type Operator^a

ΔG_1^b	ΔG_2^b	ΔG_{12}^b	s^c
-12.9 ± 0.5	-13.2 ± 0.4	-0.03 ± 0.7	0.065

^aFree energies in kcal/mol.

^b ΔG_1 and ΔG_2 refer to the intrinsic free energies to sites O_1 and O_E , respectively. The monomer-to-dimer association free energy of Gal repressor is -11.6 kcal/mol.

^cSquare root of the variance.

Substituting the expressions developed using Equation 7 into Equations 8 and 9 yields

$$\bar{Y}_1 = \frac{k_1 [P] + k_1 k_2 k_{12} [P]^2}{1 + (k_1 + k_2)[P] + k_1 k_2 k_{12} [P]^2} \quad (10)$$

and

$$\bar{Y}_2 = \frac{k_2 [P] + k_1 k_2 k_{12} [P]^2}{1 + (k_1 + k_2)[P] + k_1 k_2 k_{12} [P]^2} \quad (11)$$

Systems with more than two sites are treated in an analogous manner. These larger systems introduce the complication of more than one possible pattern of cooperative interaction. Consider, e.g., three interacting sites. With all sites occupied, cooperativity might reflect any of several combinations of the strictly pairwise interactions (ΔG_{12} , ΔG_{13} , ΔG_{23}), or a unique interaction unrelated to these (ΔG_{123}). In general, it will not be possible to infer a unique pattern from binding data alone; the model will rest on extra-thermodynamic information or on a priori assumptions.

If there are multiple specific-binding sites, simultaneous numerical analysis of the data for all sites, according to the appropriate set of binding expressions, is necessary (be sure to include all transition endpoints). In principle, it should be possible to resolve all parameters in this manner; however, infinite numerical correlation between parameters usually precludes such resolution. It can be a challenge to even conclusively demonstrate cooperativity. To resolve the binding and cooperativity terms, it is usually also necessary to analyze binding data for reduced valency mutants (i.e., DNA fragments in which mutations in one or more sites eliminate site-specific binding to those sites). It is then necessary to demonstrate that alterations in the mutated sites have no intrinsic effect on the remaining sites. A complete description of the procedures necessary to analyze the interactions of protein ligands with multiple specific sites on DNA is beyond the scope of this article. Refer to Senear et al. (1986) for a complete discussion of the issues outlined above.

Anticipated Results

The individual site-binding curves resolved from *E. coli* Gal-repressor binding to its two-site wild-type operator—converted to fractional saturation by numerical determination of the endpoints—are shown in Figure 12.4.5. Note that the protein concentration range covers six orders of magnitude and includes a significant number of points at the upper and lower ends of the binding curve. Numerical analysis of this binding data with Equations 10 and 11 yields the *intrinsic* binding and cooperative free energies shown in Table 12.4.3. As discussed above, improved resolution of the cooperative free energies can be obtained by the simultaneous analysis of binding curves of protein and wild-type DNA (such as those shown in Fig. 12.4.4) and binding curves determined for protein binding to reduced valency DNA.

Time Considerations

Following preparation of the end-labeled DNA, the footprint titration assay will take ~6 to 8 hr to complete. The footprint assay and preparation of the samples for electrophoresis is labor intensive and can be performed in 3 to 4 hr. Electrophoresis usually takes ~2.5 hr, with fixing and drying the gels requiring the remaining time. It is convenient to cast the sequencing gels the day before conducting the assay.

UV Crosslinking of Proteins to Nucleic Acids

UNIT 12.5

Irradiation of protein-nucleic acid complexes with ultraviolet light causes covalent bonds to form between the nucleic acid and proteins that are in close contact with the nucleic acid. Thus, UV crosslinking may be used to selectively label DNA-binding proteins based on their specific interaction with a DNA recognition site. As a consequence of label transfer, the molecular weight of a DNA-binding protein in a crude mixture can be rapidly and reliably determined.

The procedure can be divided into 3 stages: (1) Extract containing the protein of interest is incubated with a radioactive, uniformly labeled DNA fragment that contains a high-affinity binding site for the protein; (2) protein-DNA complexes are crosslinked with UV irradiation and digested with nuclease, leaving only those labeled DNA fragments that are crosslinked and in close contact with the DNA-binding protein; and (3) the molecular weights of the crosslinked proteins are determined by SDS-polyacrylamide gel electrophoresis followed by autoradiography. One of the advantages of this technique is that proteins bound specifically to the DNA probe can be easily distinguished from those bound nonspecifically.

UV CROSSLINKING USING A BROMODEOXYURIDINE-SUBSTITUTED PROBE

**BASIC
PROTOCOL**

DNA molecules containing halogenated analogs of thymidine, such as bromodeoxyuridine (BrdU), are considerably more sensitive to UV-induced crosslinking compared to unsubstituted DNA. Although use of BrdU-substituted probes is not essential for detecting protein-DNA crosslinking by UV light, in many cases it is helpful. Of course, BrdU cannot be incorporated into RNA. For crosslinking to RNA, it is most convenient to generate labeled SP6 transcripts (UNIT 4.7) and crosslink as described in the alternate protocol of this unit.

Materials

- Single-stranded M13 vector with desired binding site (UNIT 1.15)
- 17-bp M13 universal primer (Pharmacia)
- 1× and 10× restriction endonuclease buffer (50 mM NaCl and 500 mM NaCl, respectively; UNIT 3.1)
- 3000 Ci/mmol [α -³²P]dCTP (UNIT 3.4)
- 50× dNTP/BrdU solution
- 0.1 M dithiothreitol (DTT)
- 25 U Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
- Ammonium acetate
- 100% ethanol
- TE buffer (APPENDIX 2)
- Buffered extract containing DNA-binding protein
- Bulk carrier DNA, e.g., poly(dI-dC)·poly(dI-dC)
- 0.5 M CaCl₂
- DNase I (Worthington)
- 1 U micrococcal nuclease (Worthington)
- 2× SDS/sample buffer (UNIT 10.2)
- Fluor (Du Pont NEN Enhance or equivalent)
- ¹⁴C-labeled protein markers (UNIT 10.2)

- DEAE membrane (Schleicher & Schuell NA45)
- 1.5-ml round-bottom screw-cap vial (Nunc or equivalent)

Supplement 36

16°, 37°, 68°, 90°, and 100°C water baths
UV transilluminator (305 nm, 7000 μW/cm²; Fotodyne)

Additional reagents and equipment for digesting with restriction nucleases (UNIT 3.1), labeling with Klenow fragment (UNIT 3.5), agarose gel electrophoresis (UNIT 2.5), mobility shift DNA-binding assay (UNIT 12.2), ethidium bromide dot quantitation (UNIT 2.6), SDS-polyacrylamide gel electrophoresis (UNITS 10.2 and 10.3), and autoradiography (APPENDIX 3)

Prepare the BrdU-substituted probe

1. Add 10 μg of single-stranded M13 vector containing a high-affinity binding site for the protein of interest, and an equimolar amount of the 17-bp M13 universal primer. Adjust final volume to 100 μl in 1× restriction buffer (50 mM NaCl). Heat 5 min at 90°C. Cool overnight at room temperature.

The M13 plasmid must contain a high-affinity protein-binding site. If a binding site has not been cloned into M13, an alternative is to anneal a 50-bp synthetic oligonucleotide (containing a high-affinity binding site for the protein of interest) to a complementary 15-bp synthetic oligonucleotide. The complementary region must be at the 3' end of the 50-bp oligonucleotide. This hybridized complex may be used as substrate for Klenow fragment. BrdU increases the efficiency of photochemical crosslinking. It also permits the use of longer UV wavelengths that are less damaging to protein. Moreover, in certain instances DNA-binding proteins recognize sites substituted with BrdU with a higher affinity than unsubstituted DNA.

2. Add the following to the hybridized mixture:

50 μl [α -³²P]dCTP (3000 Ci/mmol)
3.5 μl 50× dNTP/BrdU solution
1.75 μl 0.1 M DTT
7.5 μl 10× restriction buffer (50 mM NaCl, final concentration)
7 μl H₂O
5 μl (25 U) Klenow fragment.

Incubate 90 min at 16°C.

The radioactive dNTP should be chosen on the basis of the DNA sequence at the protein-binding site. Approximately 10 to 20 bp will remain in the immediate vicinity of the binding site following crosslinking and DNase digestion. The nucleotide appearing most frequently in the binding site (except for thymidine) should be chosen as the radioactive nucleotide. Similarly, choice of which strand to label should be based upon the nucleotide sequence of the binding site. If one strand of a binding site is highly rich in thymidine and cytidine residues, that strand should be labeled with BrdU and [α -³²P]dCTP. Of course, the unlabeled dNTP solution must be appropriately modified.

3. Heat-inactivate the Klenow fragment 10 min at 68°C.
4. Add 40 U restriction endonuclease(s) to generate a DNA fragment between 20 and 600 bp. Digest under appropriate conditions.

If protein-DNA complexes are not digested with nuclease following crosslinking, a small DNA probe (50 bp) should be used to minimize the effect of the crosslinked DNA on the mobility of the protein during SDS-polyacrylamide gel electrophoresis.

5. Add ammonium acetate to 0.3 M and precipitate with 2 vol of 100% ethanol. Resuspend in TE buffer.
6. Load onto an agarose gel containing 0.5 μg/ml ethidium bromide. Electrophorese and isolate the desired fragment using DEAE membrane as described in UNIT 2.7.
7. Determine the specific activity of the BrdU-substituted fragment using a scintillation counter and estimate the DNA concentration by ethidium bromide dot quantitation (UNIT 2.6).

Specific activities of 10^8 cpm/ μ g can easily be generated. Since high-specific-activity probes decay relatively rapidly, the probe should be used within 3 to 6 days. This probe can be used in the mobility shift DNA-binding assay (UNIT 12.2). Thus, the integrity and function of the probe can be tested.

Bind the protein to DNA

8. Set up the following binding reaction:

- 10⁵ cpm of uniformly labeled probe
- Buffered extract containing the binding protein
- 10 to 20 μ g of DNA carrier such as poly (dI-dC) \cdot poly(dI-dC).

Adjust volume to 50 μ l in a 1.5-ml round-bottom vial. Seal with plastic wrap held in place with a strip of Parafilm.

Determine conditions required to observe specific protein-DNA binding using the mobility shift assay (UNIT 12.2).

Crosslink the binding reaction with UV light and digest the unprotected DNA

9. Set the vial in a test-tube rack. Irradiate from 5 cm directly above by inverting a UV transilluminator of 305 nm and intensity 7000 μ W/cm² (see Fig. 12.5.1). Irradiate 5 to 60 min.

If a lower intensity UV source is used or if the distance is greater than 5 cm, time of exposure should be increased. Plastic wrap prevents evaporation of the sample during irradiation (which increases the temperature of the sample), but is UV transparent. The effect of UV dose on the protein extract and the probe alone can be monitored by the mobility shift DNA-binding assay (UNIT 12.2).

Figure 12.5.1 Experimental setup for UV crosslinking DNA-binding proteins to uniformly labeled DNA.

10. Add the following to each binding reaction:

- 1 μ l 0.5 M CaCl₂
- 4 μ g DNase I
- 1 U micrococcal nuclease.

Digest 30 min at 37°C.

Nuclease digestion generally spares the 10 to 20 bp protected by the crosslinked protein.

Electrophoresis and autoradiograph the crosslinked protein

11. Add an equal volume of 2× SDS/sample buffer to the binding reaction. Boil 5 min at 100°C.
12. Electrophorese sample through a discontinuous SDS-polyacrylamide gel of appropriate percentage (UNIT 10.2). Include a lane of radioactive protein markers such as ¹⁴C-labeled markers. To efficiently visualize ¹⁴C-labeled markers, the protein gel must be impregnated with a fluor such as Enhance before drying and autoradiography.
13. After running the gel, cut away the region that migrates with the dye front.

The bulk of digested nucleic acid products runs with the dye front and is intensely radioactive. If these products are not cut away, they can obscure signals from crosslinked proteins migrating toward the bottom of the gel.
14. Dry the gel and autoradiograph with an intensifying screen. Expose 1 to 3 days to visualize crosslinked proteins.

ALTERNATE PROTOCOL

UV CROSSLINKING USING A NON-BROMODEOXYURIDINE-SUBSTITUTED PROBE

Incorporation of BrdU into probes may have no effect upon the efficiency of UV crosslinking of proteins to sequences that do not contain thymidine residues. In addition, BrdU cannot be used to UV-crosslink proteins to RNA. In these instances, crosslinking may be performed with probes that do not contain BrdU. The procedure is similar to the basic protocol except for the steps noted below.

Additional Materials

50× dNTP/TTP solution
UV transilluminator (254 nm)

1. To prepare the uniformly labeled probe (step 2 of basic protocol), replace 50× dNTP/BrdU solution with 50× dNTP/TTP solution.

If crosslinking to RNA is desired, construct the template using SP6 RNA polymerase (UNIT 4.7).

2. The wavelength for crosslinking should be 254 nm instead of 305 nm (step 9 of basic protocol).
3. Irradiation time for crosslinking the protein may be varied from 5 min to 3 hr.

ALTERNATE PROTOCOL

UV CROSSLINKING IN SITU

A protocol has recently been described (Wu et al., 1987) in which UV crosslinking is performed as the final step in a mobility shift DNA-binding assay (UNIT 12.2). The most obvious advantage is that when multiple proteins bind to the probe, proteins present in individual protein–nucleic acid complexes can be visualized. This protocol is similar to the basic protocol except that after the binding reaction the mixture is loaded onto a low gelling/melting temperature agarose gel, electrophoresed, and irradiated. Complexes are visualized by autoradiography, excised, and melted in SDS gel solution. Samples are then resolved by SDS-PAGE as in the basic protocol.

Additional Materials

Low gelling/melting temperature agarose (UNIT 2.6)
1× TBE buffer (APPENDIX 2)
SDS gel solution

UV Crosslinking of Proteins to Nucleic Acids

12.5.4

1. Since DNA is not digested following crosslinking, short DNA probes (50 bp) should be prepared. Use the M13 system with appropriate restriction endonucleases or a small oligonucleotide primer that is complementary to the 3' end of a larger synthetic oligonucleotide. Follow steps 1 to 7 of the basic protocol.
2. Set up a standard 50- μ l binding reaction (step 8 of the basic protocol or as in the mobility shift assay, *UNIT 12.2*, scaled up 5 \times).

*Unlabeled competing DNA fragments can be added to the binding reaction to help define specific complexes and to determine which UV-crosslinked protein bands are unique to any complex (see *UNIT 12.2* and commentary to this unit).*

3. Load the binding reaction onto a 1% low gelling/melting temperature agarose gel cast in a cold room using 1 \times TBE buffer. Electrophorese at 4 V/cm for 2 to 3 hr.

Steps 3 and 4 are performed in a cold room to prevent the gel from melting due to the heat from electrophoresis and from the UV transilluminator.

4. Place the gel on plastic wrap on the surface of a 305-nm UV transilluminator. Irradiate in the cold room 5 to 30 min.
5. Autoradiograph the gel for 1 to 3 hr in a refrigerator. Excise the regions corresponding to specific protein-DNA complexes.
6. Add 10 μ l of SDS gel solution to each 50 μ l of gel slice. Boil the samples for 2 min.
7. Load the warm liquid samples onto a discontinuous SDS-polyacrylamide gel. Electrophorese and autoradiograph as in the basic protocol.

REAGENTS AND SOLUTIONS

50 \times dNTP/BrdU solution

2.5 mM dATP
2.5 mM dGTP
250 μ M dCTP
2.5 mM BrdU (5-bromo-2'-deoxyuridine triphosphate; Sigma)

50 \times dNTP/TTP solution

2.5 mM dATP
2.5 mM dGTP
250 μ M dCTP
2.5 mM TTP

SDS gel solution

0.3 M Tris-Cl, pH 6.8
6% sodium dodecyl sulfate
15% glycerol
70 mM dithiothreitol
Store at -20°C

COMMENTARY

Background Information

Crosslinking proteins to nucleic acids with UV light is a simple method for rapidly and accurately determining the molecular weight of a DNA-binding protein in a crude extract. Moreover, the specificity of the photoadduct can be rigorously determined by measuring the ability of an excess of unlabeled competitor DNA to compete for binding sites on the protein.

The goal of the UV crosslinking method is to specifically transfer a radioactive label from a DNA-binding site to the binding protein. Irradiation of DNA with UV light produces purine and pyrimidine free radicals. If a protein molecule is in close proximity to the free radical, a covalent bond can be formed, crosslinking the protein to the DNA.

In solution, pyrimidines are approximately 10-fold more sensitive to photochemical alteration than purines. Several amino acids are known to form photoadducts with pyrimidine bases, including cysteine, serine, methionine, lysine, arginine, histidine, tryptophan, phenylalanine, and tyrosine. Cells that have incorporated halogenated analogs of thymine—such as bromodeoxyuridine (BrdU)—into their DNA are several times more sensitive to UV-induced crosslinking with protein than normal cells. This is because replacement of the thymidine methyl group with the bromine atom creates a molecule more susceptible to free radical formation in the presence of UV light. Because the bromo group is approximately the same van der Waals radius as a methyl group, several cellular enzymes will use thymidine and BrdU interchangeably. Thus, it is quite simple to generate BrdU-substituted DNA probes.

Another important reason for using BrdU is that the longer wavelength of UV light used to crosslink these probes is less damaging to proteins than a shorter wavelength. In addition, substitution of BrdU into a binding site sometimes increases the affinity of the protein-DNA interaction being studied.

Literature Review

UV crosslinking has been used to study the interactions of several DNA-binding proteins with their DNA recognition sites. In 1972, Markowitz showed that UV irradiation induced the formation of DNA polymerase–DNA complexes that were resistant to high salt, phenol, heat, and 0.1 M NaOH. He concluded that a covalent bond between DNA and protein had

been formed. Lin and Riggs (1974) showed that *lac* repressor could be specifically crosslinked by UV irradiation to BrdU-substituted *lac* operator DNA. Hillel and Wu (1978) used photochemical crosslinking to demonstrate that in nonspecific T7 DNA–*E. coli* RNA polymerase complexes, subunits σ , β , and β' were crosslinked to DNA. However, in specific T7 DNA–RNA polymerase complexes only subunits σ and β were crosslinked to DNA. Simpson (1979) used UV irradiation to map the molecular interaction between *E. coli* RNA polymerase and the *lacUV5* promoter substituted with BrdU. More recently, UV crosslinking has been used to identify eukaryotic sequence-specific DNA-binding proteins present in crude extracts. Chodosh et al. (1986) specifically crosslinked the adenovirus major late transcription factor to its binding site, confirming the molecular weight of the molecule. Wu et al. (1987) used UV light to specifically label the *Drosophila* heat-shock activator protein.

Critical Parameters

Many critical parameters of this assay can be easily optimized using the mobility shift DNA-binding procedure (UNIT 12.2). If specific binding to the DNA probe can be detected in the mobility shift assay it should be possible to crosslink the protein to the probe. Particular parameters which may be varied include time of irradiation, BrdU substitution, binding conditions (especially ionic strength), and choice of radioactive dNTP. Some protein-DNA complexes are particularly sensitive to DNase, and thus protocols using only a very limited DNase digestion or no digestion may be tried.

Anticipated Results

Figure 12.5.2 represents the autoradiogram of a dried gel containing the results of a typical UV crosslinking experiment. The figure legend describes the components of each lane.

When probe DNA was irradiated in the absence of protein (lane 2) or when UV irradiation was omitted (lane 3), no nuclease-resistant labeled species were generated. However, when complete binding-reaction mixtures were irradiated and analyzed, at least two labeled species were generated, migrating at ~45 kDa and 26 kDa. Increasing the time of irradiation from 15 to 60 min increased the amount of label in these species (lanes 5 to 7).

Figure 12.5.2 Representation of autoradiogram of a typical UV crosslinking experiment. As described in commentary, procedure involves UV crosslinking of protein to DNA probe, digestion of free DNA with DNase, and electrophoresis by SDS-PAGE of the treated binding reactions. Molecular weights of ^{14}C -labeled protein markers in Lane 1 are indicated to the left. Lanes 2 through 10 each contained a ^{14}C -labeled DNA probe with a site for a binding protein X. Samples applied to the lanes differed as follows (see also anticipated results): **Lane 2**—no protein; **Lane 3**—no UV irradiation; **Lane 4**—5 min irradiation of complete binding reaction; **Lane 5**—15 min irradiation of complete binding reaction; **Lane 6**—30 min irradiation of complete binding reaction; **Lane 7**—60 min irradiation of complete binding reaction; **Lane 8**—60 min irradiation of complete binding reaction then proteinase K treatment; **Lane 9**—60 min irradiation of complete binding reaction plus 100-fold molar excess of unlabeled probe containing a binding site for protein X; **Lane 10**—60 min irradiation of complete binding reaction plus 100-fold molar excess of unlabeled mutant probe lacking a binding site for protein X.

When UV-irradiated binding-reaction mixtures were treated with proteinase K, no labeled species were observed following electrophoresis—suggesting that the labeled species were protein-DNA photoadducts (lane 8). Control reactions demonstrated that probe DNA irradiated for 60 min was still able to bind protein X (data not shown). Similarly, UV irradiation of protein X alone did not significantly reduce its ability to bind probe DNA (data not shown).

To distinguish whether polypeptides were bound specifically or nonspecifically, UV crosslinking was performed with an excess of unlabeled competitor DNA. This DNA contained (lane 9) or lacked (lane 10) a high-affinity binding site for protein X. If a labeled polypeptide results from the covalent crosslinking of protein X to its recognition sequence, competitor fragments containing this sequence should abolish formation of the corresponding labeled DNA-protein adduct. Conversely, competitor fragments that lack this sequence should not affect formation of the labeled DNA-protein adduct. Because a competitor fragment with the protein X binding site abolished formation of the 45-kDa labeled polypeptide but did not affect formation of the 26-kDa labeled polypeptide (lane 9), the 45-kDa labeled polypeptide represents the covalent crosslinking of protein X to its recognition sequence. This is confirmed in lane 10 where a competitor fragment lacking the protein X

binding site did not affect formation of either labeled polypeptide.

Treatment of irradiated binding mixtures with either greater amounts of nuclease or the same amount of nuclease for longer times (data not shown) did not alter the mobility of the 45-kDa species, suggesting that this was a limit digest. Since the covalent attachment of short oligonucleotides to proteins has only a minor effect on the mobility of proteins in gels, these experiments indicate that a 45-kDa protein binds specifically to the protein X binding site.

An important point to consider is that the efficiency of UV crosslinking is usually on the order of ~0.1% to 10%. Therefore, it is exceedingly rare to see more than one crosslinking event in a single complex. If a protein binds to its target site as a dimer, UV crosslinking will typically only transfer label to one of the two bound molecules. Thus, the observed molecular weight is likely to be that of the monomer.

Time Considerations

The basic protocol can be performed in ~7 to 10 hr. However, most of this time is not labor intensive. Autoradiography takes between 12 hr and 3 days depending on the specific activity of the probe, the efficiency of crosslinking, and the abundance and binding affinity of the protein.

Purification of DNA-Binding Proteins Using Biotin/Streptavidin Affinity Systems

UNIT 12.6

BASIC
PROTOCOL

Short fragments of DNA—either natural or formed from oligonucleotides—containing a high-affinity site for a DNA-binding protein provide a powerful tool for purification. The biotin/streptavidin purification system is based on the tight and essentially irreversible complex that biotin forms with streptavidin. The experimental design of this system is illustrated in Figure 12.6.1. First, a DNA fragment is prepared that contains a high-affinity binding site for the protein of interest. A molecule of biotinylated nucleotide is incorporated into one of the ends of the DNA fragment. The protein of interest is allowed to bind to the high-affinity recognition site present in the biotinylated fragment. The tetrameric protein streptavidin is then bound to the biotinylated end of the DNA fragment. Next, the protein/biotinylated fragment/streptavidin ternary complex is efficiently removed by adsorption onto a biotin-containing resin. Since streptavidin is multivalent, it is able to serve as a bridge between the biotinylated DNA fragment and the biotin-containing resin. Proteins remaining in the supernatant are washed away under conditions that maximize the stability of the DNA-protein complex. Finally, the protein of interest is eluted from the resin with a high-salt buffer.

Materials

Plasmid DNA with desired binding site
Appropriate restriction endonucleases (UNIT 3.1)
Biotin-11-dUTP (BRL)

Figure 12.6.1 Purification of DNA-binding proteins using the biotin/streptavidin affinity technique. The protocol involves the following steps: (1) a biotinylated, labeled DNA fragment is prepared containing a binding site for the protein to be purified; (2) the biotin-cellulose resin is prepared; (3) a binding reaction containing a crude protein fraction and the biotinylated probe is set up; (4) free streptavidin is added to the binding reaction; (5) the protein/biotinylated DNA fragment/streptavidin complex is bound to the biotin-cellulose resin; (6) unbound protein is removed by extensive resin washing; and (7) the protein is eluted from the resin with high-ionic-strength buffer. Each of these steps can be monitored and optimized in solution, using the mobility shift DNA-binding assay (see UNIT 12.2).

DNA-Protein
Interactions

12.6.1

Supplement 36

Labeled and unlabeled dNTPs (UNIT 3.4)
Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5)
TE buffer (APPENDIX 2)
Biotin-cellulose (Pierce)
Biotin-cellulose binding buffer
Bovine serum albumin (BSA)
Bulk carrier DNA [e.g., poly(dI-dC)·poly(dI-dC), salmon sperm DNA,
or *E. coli* DNA]
Biotin-cellulose elution buffer
Protein solution
Streptavidin (Celltech Ltd.; may be stored as 5 mg/ml stock for at least 2 months)
DEAE membrane (Schleicher & Schuell NA45)
0.025- μ m filter discs (Millipore VS)
Additional reagents and equipment for agarose gel electrophoresis (UNIT 2.5),
mobility-shift DNA-binding assay (UNIT 12.2), and ethidium bromide dot
quantitation (UNIT 2.6)

Prepare biotinylated, labeled DNA fragment

1. Digest 50 μ g of plasmid DNA in 100 μ l. The plasmid DNA must contain a binding site for the protein of interest and should be digested with one or more restriction endonucleases.

The same DNA probe used in the mobility shift DNA-binding assay (UNIT 12.2) can also be used to purify the protein.

2. Add the following to the probe mixture:

Biotin-11-dUTP to a final concentration of 20 μ M
Radioactive dNTP for incorporation into the 5' overhang
100-fold molar excess of corresponding unlabeled dNTP
Remaining two unlabeled dNTPs to a final concentration of 200 μ M
5 U Klenow fragment.

This reaction is identical to that used in the DNA-binding assay except biotinylated dUTP is incorporated into one end of the DNA fragment in place of TTP and the fragment is radiolabeled to low specific activity instead of to high specific activity.

3. Precipitate the biotinylated probe. Isolate the probe by agarose gel electrophoresis using DEAE membrane (UNIT 2.7).

Gel purification of the biotinylated fragment removes unreacted biotin-11-dUTP. This is essential because any free biotin-dUTP binds to streptavidin and then to the biotin-cellulose column, reducing the apparent capacity of both materials to react with protein.

4. Resuspend the probe in TE buffer and measure an aliquot for Cerenkov counts. Estimate the DNA concentration by ethidium bromide dot quantitation (UNIT 2.6).
5. Test the biotinylated probe to be certain it will efficiently bind to the protein of interest. Use a standard binding assay (UNIT 12.2) with the biotinylated fragment as probe.

Prepare biotin-cellulose resin

6. Place 200 μ l biotin-cellulose in a 1.5-ml microcentrifuge tube. Spin the resin for 30 sec in a microcentrifuge and remove the supernatant. Add to the pellet:

1.0 ml biotin-cellulose binding buffer
500 μ g/ml BSA
200 μ g carrier DNA.

Gently mix the tube 5 min on a rotating wheel.

This step blocks nonspecific protein and nucleic acid binding sites present on the biotin-cellulose resin.

7. Spin the resin, remove the supernatant, and resuspend pellet in 1.0 ml of biotin-cellulose elution buffer. Gently mix 5 min on a rotating wheel. Repeat this wash.

Washing removes molecules on the biotin-cellulose resin that might later be eluted from the resin by the biotin-cellulose elution buffer.

8. Spin the resin, remove the supernatant, and resuspend pellet in 1.0 ml of biotin-cellulose binding buffer. Repeat this wash.

This 1:6 dilution of pretreated biotin-cellulose is ready for use and can be stored for several months.

Set up binding reaction

9. Determine the molar concentration of the protein to be purified using the mobility-shift assay (UNIT 12.2).
10. Set up a standard binding reaction containing the protein to be purified, carrier DNA, and a 10-fold molar excess of biotinylated fragment relative to the protein to be purified. Allow the reaction to go to completion for ~15 min.

Use reaction conditions that optimize protein binding to its recognition site. The composition of the biotin-cellulose binding buffer should be the same as that optimized for protein-DNA binding.

11. Add a 5-fold molar excess of streptavidin relative to the biotinylated fragment. Continue the binding reaction for an additional 5 min at 30°C.

Bind protein/DNA/streptavidin complex to biotin-cellulose resin

12. In a separate tube, place 2 μ l pretreated biotin-cellulose (12 μ l of the 1:6 dilution) for each picomole of biotinylated DNA fragment in the binding reaction. Spin the resin and remove the supernatant.

One or two microliters of biotin-cellulose can easily be seen at the bottom of the microcentrifuge tube.

13. Transfer the binding reaction mix into the tube with the biotin-cellulose resin using a pipettor. Gently resuspend the resin and incubate on a rotating wheel for 30 min.

This incubation can be done either at 4°C or at room temperature, depending on the stability of the protein.

14. Spin the resin and remove the supernatant.

Using the mobility shift assay, the supernatant should be measured to determine what percentage of the biotinylated fragment and the protein has been removed from the supernatant. It is also useful to assay the supernatant from the binding reaction for a control DNA-binding protein to determine whether the protein of interest has been specifically depleted or whether multiple DNA-binding proteins have been depleted nonspecifically. The latter observation would suggest that the matrix is acting as a nonspecific DNA-affinity column. For some applications, a protein fraction specifically depleted for a particular DNA-binding protein is a valuable reagent.

Wash the resin

15. Resuspend the biotin-cellulose pellet in 500 μ l biotin-cellulose binding buffer. Mix by gently inverting the tube 1 to 2 min. Spin the resin and remove the supernatant. Repeat this procedure twice. The second time, transfer to a clean microcentrifuge tube.

Transferring the reaction avoids elution of proteins that were bound nonspecifically to the walls of the tube in the first binding incubation.

Elute the protein

16. Resuspend the biotin-cellulose pellet in at least an equal volume of biotin-cellulose elution buffer. Mix gently on a rotating wheel for 20 min.

The salt concentration in the biotin-cellulose elution buffer must be determined empirically. Successively higher salt concentrations may be tested until the concentration of eluted protein is maximal.

17. Spin the resin. Save the supernatant and assay for binding activity.

Small volumes of protein solutions can be dialyzed effectively on 0.025- μ m filter discs.

ALTERNATE PROTOCOL

PURIFICATION USING A MICROCOLUMN

Although the batch method in the basic protocol is rapid and well-suited for analytical-scale purification, larger volumes of biotin-cellulose resin can be better handled in a microcolumn. This method is also used to elute the protein in as small a volume (i.e., as high a concentration) as possible.

Additional Materials

Siliconized glass wool (APPENDIX 3)
1.0-ml pipet tip
Ring stand

1. Prepare the biotinylated DNA fragment and biotin-cellulose resin, and set up binding reaction, as described in steps 1 to 11 of basic protocol.
2. Place a small plug of siliconized glass wool in the bottom of a 1.0-ml pipet tip. Firmly attach the pipet-tip microcolumn to a ring stand.

Prewet the glass wool in biotin-cellulose binding buffer before insertion into the pipet tip to avoid trapping air bubbles which might denature proteins.

3. Add 500 μ l binding buffer to the microcolumn. Maintain a steady flow through the glass wool plug.

If the column does not flow smoothly, a pipettor can be gently inserted into the top of the microcolumn. Slightly depressing the plunger will start the column or increase the flow.

4. Add at least 40 μ l of 1:1 biotin-cellulose slurry to the microcolumn. Allow the buffer to run down to the surface of the resin.
5. Equilibrate the resin with 3 column-volumes of biotin-cellulose binding buffer if the resin has already been pretreated (steps 6 to 8 of basic protocol). If the resin has not been pretreated, wash sequentially with 3 column-volumes each of biotin-cellulose binding buffer, biotin-cellulose binding buffer with 500 μ g/ml BSA and 200 μ g/ml poly(dI-dC)-poly(dI-dC), and biotin-cellulose elution buffer. Finally, equilibrate with biotin-cellulose binding buffer.

The biotin-cellulose microcolumn can be washed very rapidly. Each wash takes 2 or 3 min. The drop size from the pipet tip is ~25 μ l but this will change with alterations in the ionic strength and protein concentration of the eluate.

6. Load the binding reaction mix (step 11 of basic protocol) onto the microcolumn and collect the flowthrough.

The column can be run as fast as 6 to 10 column-volumes/hr without affecting the amount of biotinylated fragment bound by the resin. If the flow rate is too slow, use a pipettor to apply pressure to the column. If the flow rate is too fast, plug the tip of the microcolumn with Parafilm in between drops.

7. Wash with 4 column-volumes of biotin-cellulose binding buffer. Discard the flow-through.
8. Wash with 3 column-volumes of biotin-cellulose elution buffer. Collect 2-drop fractions and assay.

Fractions as small as 5 μ l may be rapidly and effectively dialyzed on 0.025- μ m filter discs with minimal loss of volume and activity. Float a filter (shiny side up) in a petri dish on top of 20 ml dialysis buffer. Allow the filter 10 min to wet. Place the sample (5 to 100 μ l) to be dialyzed onto the surface of the filter. Surface tension will keep the sample confined in a drop unless there is a detergent in the sample. After 1 hr remove the sample. Once the protein has been eluted from the resin, the resin is effectively the same as a sequence-specific DNA-affinity microcolumn.

PURIFICATION USING STREPTAVIDIN-AGAROSE

When high-quality free streptavidin is not available or cellulose is an inappropriate resin, a simple variation on the basic protocol may be employed. In this protocol, the same biotinylated DNA fragment is used but is removed from solution directly by streptavidin-agarose (see Fig. 12.6.2).

Additional Materials

Streptavidin-agarose

1. Prepare biotinylated DNA fragment and resin (substituting streptavidin-agarose for biotin-cellulose), and set up binding reaction, as described in steps 1 to 11 of basic protocol.

Figure 12.6.2 Purification of DNA-binding proteins using streptavidin-agarose.

**ALTERNATE
PROTOCOL**

**DNA-Protein
Interactions**

12.6.5

2. In a separate tube, add 50 μl pretreated streptavidin-agarose (300 μl of the 1:6 dilution) for each picomole of biotinylated DNA fragment in the binding reaction. Spin the resin and remove the supernatant.
3. Transfer the binding-reaction mix into the tube with the streptavidin-agarose using a pipettor. Gently resuspend the resin and incubate on a rotating wheel for 30 min to 2 hr.
4. Wash and elute the protein as described in steps 14 to 17 of the basic protocol.

Like biotin-cellulose, streptavidin-agarose may also be used in a microcolumn. Follow the microcolumn alternate protocol.

REAGENTS AND SOLUTIONS

Biotin-cellulose binding buffer

12% glycerol
 12 mM HEPES-NaOH, pH 7.9
 4 mM Tris-Cl, pH 7.9
 60 mM KCl
 1 mM EDTA
 1 mM dithiothreitol (DTT)
 Store at -20°C upon addition of DTT

This is a typical binding buffer. The composition of binding buffer—especially with respect to pH, ionic strength, and the presence or absence of MgCl_2 —should be determined by those conditions which optimize the binding of the protein of interest to its recognition site.

Biotin-cellulose elution buffer

12% glycerol
 20 mM Tris-Cl, pH 6.8
 1 M KCl
 5 mM MgCl_2
 1 mM EDTA
 1 mM DTT
 200 $\mu\text{g}/\text{ml}$ bovine serum albumin (BSA)
 Store at -20°C upon addition of DTT

This is a typical elution buffer. The composition of elution buffer—especially with respect to pH, ionic strength, and the presence or absence of MgCl_2 —should be determined by those conditions that maximize the dissociation rate of the protein from its recognition site. Another carrier protein, such as insulin or hemoglobin, may be substituted for BSA. The small size of insulin can be useful if protein gels will be run to determine the size of the regulatory factor.

COMMENTARY

Background Information and Literature Review

The biotin/streptavidin purification method works well because the interaction between biotin and avidin (or avidin-like proteins) is one of the strongest known noncovalent interactions. The dissociation constant for the streptavidin-biotin complex is $\sim 10^{-15}$ M. Avidin, from egg white, and streptavidin, from *Streptomyces avidinii*, are tetrameric proteins

containing four high-affinity binding sites for the vitamin biotin. Since streptavidin is multivalent, it is able to serve as a bridge between the biotinylated DNA fragment and the biotin-containing resin. The strong interaction is extremely useful for purification of DNA-binding proteins, because DNA-affinity columns with streptavidin/biotin bridges can be washed under a wide variety of conditions (i.e., 2 M KCl and 1% SDS) without remov-

ing either the streptavidin or the biotinylated DNA fragment from the matrix.

Two properties of streptavidin make it more suitable than avidin for use in DNA-affinity purification. The first is that streptavidin, unlike avidin, is not a glycoprotein, and the second is that streptavidin is slightly acidic whereas avidin is basic. Therefore, streptavidin is less likely to bind nonspecifically to cellular glycoproteins and to acidically charged cell components such as nucleic acids.

Several factors make this method simple, rapid, and effective. The same binding conditions and DNA fragment used in the mobility-shift DNA-binding assay to identify a protein (UNIT 12.2) can be used to effect its purification. In addition, the binding of the protein to its DNA recognition site in solution is more efficient than protein-DNA interactions that take place on a column matrix (discussed below). Most importantly, binding in solution allows each reaction parameter to be optimized on an analytical scale by using the gel binding assay.

As an analytical technique, biotin/streptavidin DNA-affinity purification permits the direct identification of a wide variety of sequence-specific DNA-binding proteins. It has already been successfully used to identify hormone receptors, components in mRNA splicing complexes, and RNA polymerase II and III transcription factors (Haeuptle et al., 1983; Grabowski and Sharp, 1986; Chodosh et al., 1986; Kasher et al., 1986).

Another method is commonly used for purifying DNA-binding proteins, whereby DNA-protein binding interactions occur on a column matrix. In this technique, catenated DNA-binding sites are covalently coupled with cyanogen bromide to Sepharose CL-2B (Kadonaga and Tjian, 1986; Rosenfeld and Kelly, 1986). A partially purified protein fraction is combined with competitor DNA and passed through a DNA-Sepharose resin, binding the protein to the surface of the matrix. Generally, multiple passes through the column are used to effect purification, with 25- to 50-fold purification achieved with each column passage. The biotin/streptavidin technique, on the other hand, typically yields 50- to 250-fold purification.

Critical Parameters

Only one end of the DNA fragment should be labeled with biotin. If both ends are labeled, the biotinylated fragment may bind to the resin in such a fashion as to sterically displace the protein bound to the DNA fragment. Thus, one

of the restriction enzymes used must be chosen to permit the incorporation of biotin-11-dUTP in place of TTP. Furthermore, since only one end of the fragment is biotin-labeled, the restriction enzyme generating the nonbiotinylated end should leave no overhang, a 3' overhang, or a 5' overhang that will not incorporate biotin-dUTP. For binding sites cloned into the pUC polylinker, an *EcoRI* and *HincII* fragment fulfills these requirements. Biotin-11-dUTP may be incorporated into the *EcoRI* overhang along with a low-specific-activity dATP radioactive label. The blunt *HincII* end of the fragment remains unlabeled.

Alternately, if both ends have 5' overhangs which permit incorporation of biotin-dUTP, the plasmid may first be digested with one of the enzymes and end-labeled with biotin-dUTP and a radioactive dNTP using the Klenow fragment. After heat-inactivating the Klenow fragment, the plasmid may then be digested with the second restriction endonuclease.

The low-specific-activity label incorporated into the biotinylated DNA fragment is used to help monitor both the binding of the protein to the biotinylated fragment and the binding of the biotinylated fragment to the biotin-cellulose resin via a streptavidin bridge. The amounts of the radioactive dNTP and the nonradioactive dNTP added to the Klenow reaction should be in a ratio such that 1% to 2% of the biotinylated fragments are labeled. For example, 100 μCi of 6000 Ci/mmol dATP (0.2 μM) may be added to a reaction containing 20 μM unlabeled dATP.

If the radioactive dNTP and the biotin-dUTP residue are incorporated on the same end of the DNA fragment, as in an *EcoRI* site, decay of the radioactive nuclide will result in formation of an unlabeled, nonbiotinylated probe that binds to the protein but is incapable of binding to streptavidin. This molecule is a competitive inhibitor during protein purification and can be kept to a minimum by labeling to a lower specific activity.

Over time, streptavidin tetramers dissociate into monomers. The integrity of the tetramer may be monitored by performing native (non-denaturing) gel electrophoresis. Since streptavidin monomers will bind to the biotinylated DNA fragment, but will be unable to bind to the biotin-cellulose resin, the monomeric form of streptavidin will inhibit purification.

Most proteins can be eluted from their binding site with 1 M KCl. Since the added elution buffer is diluted by the binding buffer in the biotin-cellulose pellet, the actual salt concentration in the resuspended pellet will be lower

than that of the elution buffer. As a result, it is useful to remove a small aliquot, dilute it, and measure the actual salt concentration with a conductivity meter. Otherwise, the time, temperature, and composition of the buffer used in the elution step should be chosen to maximize the protein's dissociation rate from its binding site. Thus, if a protein's dissociation rate is 15 sec in 1 M KCl at room temperature, and 3 hr in 1 M KCl at 4°C, a 5-min incubation in 1 M KCl at room temperature should be sufficient to elute the protein. Dissociation rates can easily be measured using the mobility shift DNA-binding assay described in this chapter (UNIT 12.2).

Troubleshooting

A major advantage of the biotin/streptavidin method is the ability to monitor the purification on an analytical scale using the mobility-shift assay (see UNIT 12.2). Because different parameters can be independently examined, it is possible to pinpoint the particular step that is not working. Several parameters can be examined routinely. Using the biotinylated radiolabeled fragment, the specific binding of the DNA fragment to its protein can be directly determined. In addition, the binding conditions can be optimized in a binding reaction containing the DNA probe and protein. The probe can be a biotinylated or a nonbiotinylated radiolabeled DNA fragment. The complex is then resolved by native (nondenaturing) gel electrophoresis.

Streptavidin binding to the probe can be monitored and titrated by varying the amount of streptavidin in a binding reaction. The resulting streptavidin-DNA complex is resolved from free DNA by native gel electrophoresis.

Binding of this complex to the biotin-cellulose matrix can be directly monitored. First, biotin-cellulose is incubated with the complex. Next the resin is spun and aliquots of the supernatant are assayed for the presence of the radiolabeled fragment on a polyacrylamide gel. This basic procedure allows several relevant parameters to be examined, including the amount of streptavidin required for complete binding of the fragment to the resin, the amount of biotin-cellulose required to bind a given amount of fragment, the binding time, and the optimal binding conditions. These three final steps can also be monitored for the specific adsorption of the protein to the column. By assaying the amount of binding activity in the supernatant before and after addition of biotin

cellulose, the adsorption efficiency can be determined.

Nonspecific resin binding can be examined by assaying the binding activity in a supernatant containing the protein, the DNA carrier poly(dI-dC)-poly(dI-dC), streptavidin, and biotin-cellulose, but lacking the biotinylated DNA fragment with the protein's binding site. Alternatively, a nonspecific biotinylated DNA fragment can be added. Interestingly, nonspecific protein binding to the resin is minimized with a lower poly(dI-dC)-poly(dI-dC) concentration than is required to generate a discrete band in the mobility shift assay.

The conditions for protein elution from the column can also be directly examined and optimized. After protein adsorption onto the matrix, elution parameters such as time, temperature, pH, carrier protein, and ionic strength can be varied. The amount of protein released into the supernatant is then assayed by the mobility shift assay. In optimizing this step, it is very helpful to know as much as possible about the variables affecting the dissociation rate of the protein from its DNA binding site. These can be studied quickly and rigorously with the mobility shift assay.

Anticipated Results

The strong interaction between biotin and avidin can result in 25 nmol of biotinylated DNA fragment binding to 1 ml of biotin-cellulose resin. This corresponds to 1.5 mg of a 60 kDa polypeptide. After parameter optimization, ~50- to 250-fold purification of the DNA-protein complex can be obtained. Once the protein has been adsorbed to the column >99% of the remaining protein can be removed with repeated column washing using the binding buffer. Moreover, ~30% to 80% of the binding activity can be recovered from the column. The recovery efficiency depends on how effectively nonspecific binding sites have been blocked. This purification scheme may be used either with crude extracts or with partially purified protein fractions.

Time Considerations

Starting with a biotinylated DNA fragment, the batch (basic) protocol can be performed in ~1.5 hr, and the microcolumn procedure in ~2.5 hr.

Detection, Purification, and Characterization of cDNA Clones Encoding DNA-Binding Proteins

In this unit, an appropriate recombinant clone is detected in an expression library with a DNA recognition-site probe, purified, and shown to encode a DNA-binding domain of defined sequence specificity. The strategy described below obviates purification of a sequence-specific DNA-binding protein for the purpose of isolating its gene; it simply requires a suitable cDNA library constructed in the expression vector λ gt11 and a DNA recognition-site probe. The basic protocol enables the detection and purification of clones encoding sequence-specific DNA-binding proteins. The alternate protocol describes a denaturation/renaturation procedure that can increase detection of certain clones. The support protocol provides a rapid means of characterizing the DNA-binding activities of the proteins encoded by the cloned cDNAs.

BASIC PROTOCOL

SCREENING A λ gt11 EXPRESSION LIBRARY WITH RECOGNITION-SITE DNA

A clone encoding a sequence-specific protein is detected in a λ gt11 library because its recombinant protein binds specifically to a radiolabeled recognition-site DNA. Bacteriophage from a cDNA library constructed in the vector λ gt11 are plated under lytic growth conditions. After plaques appear, expression of the β -galactosidase fusion proteins encoded by the recombinant phage is induced by placing nitrocellulose filters impregnated with IPTG onto the plates. Phage growth is continued and is accompanied by the immobilization of proteins, from lysed cells, onto the nitrocellulose filters. The filters are lifted after this incubation, blocked with protein, then reacted with a radiolabeled recognition-site DNA (containing one or more binding sites for the relevant sequence-specific protein) in the presence of an excess of nonspecific competitor DNA. After the binding reaction, the filters are washed to remove nonspecifically bound probe and processed for autoradiography. Potentially positive clones detected in the primary screen are rescreened after a round of plaque purification. Recombinants which screen positively after enrichment and whose detection specifically requires the recognition-site probe (not detected with control probes lacking the recognition site for the relevant protein) are then isolated by further rounds of plaque purification.

Materials

pUC recombinant plasmid DNA containing multiple tandem copies of recognition-site DNA and lacking the recognition site (or containing mutant versions; *UNITS 1.5 & 3.16*; see commentary)

*Eco*RI and *Hind*III restriction endonucleases (*UNIT 3.1*)

1 M Tris·Cl, pH 7.5 (*APPENDIX 2*)

5 mM each dCTP, dGTP, dTTP, and dATP (*UNIT 3.4*)

5000 Ci/mmol [α -³²P]dATP

Klenow fragment of *E. coli* DNA polymerase I (*UNIT 3.5*)

500 mM EDTA, pH 8.0

25:24:1 phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)

24:1 chloroform/isoamyl alcohol

3 M sodium acetate, pH 5.2 (*APPENDIX 2*)

100% ethanol

Elution buffer

E. coli Y1090 (Table 1.4.5)

λ gt11 cDNA library (*UNIT 5.8*; see commentary)

LB medium containing 0.2% maltose and 50 μ g/ml ampicillin (*UNIT 1.1* and Table 1.4.1)

0.7% top agarose, melted and equilibrated to 47°C (UNIT 1.1)
100- and 150-mm LB plates containing 50 µg/ml ampicillin, dry and prewarmed to 37°C (UNIT 1.1 and Table 1.4.1)
10 mM IPTG (prepare 1 M stock with sterile H₂O and store at -20°C; Table 1.4.2)

BLOTTO

Binding buffer

1 mg/ml sonicated (to ~1 Kb) calf thymus DNA

Chloroform

Elutip-d columns (Schleicher & Schuell)

37° and 42°C incubators

132- and 82-mm nitrocellulose membrane filters (Schleicher & Schuell)

Additional reagents and equipment for restriction digest (UNIT 3.1), mobility shift DNA-binding assay (UNIT 12.2), phenol extraction and ethanol precipitation (UNIT 2.1), nondenaturing polyacrylamide gel electrophoresis (UNIT 2.7), Elutip-d chromatography (UNIT 2.6), titrating and plating bacteriophage (UNITS 1.11 & 6.1), autoradiography (APPENDIX 3), and purifying and storing bacteriophage clones (UNITS 6.5 & 1.12)

Prepare and analyze radiolabeled recognition-site DNA

1. Digest 20 µg of an appropriate pUC recombinant plasmid DNA (containing multiple tandem copies of the recognition site in the polylinker) with *Eco*RI and *Hind*III in a final volume of 100 µl.

It is preferable to use a probe containing multiple (2 to 10) protein-binding sites with an overall length <200 bp. Longer probes yield higher nonspecific signals. A multisite probe is constructed by cloning tandem copies of a synthetic binding-site oligomer in a pUC vector. The synthetic probe should be tested for recognition by the desired protein before use in screens. This is most easily done using the mobility shift DNA-binding assay.

2. Add the following components to the restriction digest:

1 M Tris·Cl, pH 7.5, to a final concentration of 50 mM
5 mM each dCTP, dGTP, dTTP to 100 µM each final concentration
200 µCi [α -³²P]dATP (5000 Ci/mmol)
10 U Klenow fragment.

Incubate mixture 30 min at room temperature. Add cold 5 mM dATP to 100 µM. Continue the incubation for another 30 min.

This reaction labels the ends of the probe.

3. Stop the end-labeling reaction by adding 500 mM EDTA to 20 mM. Extract the DNA sequentially with 25:24:1 phenol/chloroform/isoamyl alcohol and 24:1 chloroform/isoamyl alcohol, adjust the salt concentration with 3 M sodium acetate, pH 5.2, to 0.3 M final, and precipitate with 100% ethanol.
4. Resuspend the pellet in 200 µl water, add 22 µl of 3 M sodium acetate, pH 5.2, and reprecipitate with 100% ethanol.
5. Separate the labeled fragments by nondenaturing polyacrylamide gel electrophoresis using a 0.75-mm-wide, 5% gel.
6. Visualize the labeled fragments by autoradiography. Cut out a gel slice containing the binding-site fragment. Elute the binding-site fragment by incubating the gel slice in 1.5 ml elution buffer with shaking at 4°C overnight.
7. Remove supernatant with a pipettor and purify the labeled fragment by Elutip-d chromatography. Determine the activity of the ³²P-labeled DNA binding-site probe

by scintillation counting (cpm) and store at 4°C.

These reaction conditions yield DNA probes with specific activities of $2-4 \times 10^7$ cpm/pmol. The probe yield should be 10^8 to 2×10^8 cpm. This amount of probe is sufficient to screen 20 large filters representing $\sim 10^6$ plaques (see screening conditions below). Multisite probes can also be prepared for screening simply by catenation of a binding-site oligonucleotide with DNA ligase followed by nick translation (Vinson et al., 1988).

Prepare nitrocellulose filter replicas

8. Grow *E. coli* Y1090 to saturation (usually overnight) in LB/maltose/ampicillin medium at 37°C.
9. For each plating, mix a 0.5-ml aliquot of the overnight Y1090 culture with λ gt11 library (containing $3-5 \times 10^4$ pfu) in a tube.
10. Incubate the tubes 15 min at 37°C to adsorb phage to cells.
11. Add 9 ml top agarose to each tube. Mix by inverting a few times and plate each suspension onto a 150-mm LB/ampicillin plate.
12. Incubate the plates ~ 3 hr at 42°C until tiny plaques are visible.
13. Move plates to a 37°C incubator. Do not allow plates to cool below 37°C.
14. Prepare 132-mm nitrocellulose filters for overlays (handle filters with blunt-ended forceps) by immersing in 10 mM IPTG for 30 min. Air dry filters at room temperature for 60 min.
15. Overlay each plate with a dry nitrocellulose filter impregnated with IPTG and continue incubation 6 hr at 37°C.
16. Cool plates 10 min at 4°C. Mark the position of each filter with needle holes. Lift filters sequentially and immerse in a deep dish containing BLOTTO. Incubate 60 min at room temperature with gentle swirling on an orbital platform shaker.

Plates are cooled so as to avoid lifting the top agar with the filter. Hybridization chambers (Altec Plastics) are very useful for processing multiple filters in this and subsequent steps. Avoid trapping air bubbles while immersing the filters. The master plates are sealed with Parafilm and stored at 4°C.

17. Transfer filters to a dish containing enough binding buffer to immerse all filters (500 ml/10 filters) and incubate 5 min at room temperature with shaking. Repeat this wash twice with fresh binding buffer.

Filters can be stored in binding buffer for up to 24 hr at 4°C prior to screening. The DNA-binding activities of various recombinant proteins are quite stable under these conditions.

Screen nitrocellulose filter replicas

18. Heat denature 1 mg/ml sonicated calf thymus DNA 10 min at 100°C, quench on ice, and add to binding buffer to 5 μ g/ml final (final volume should be 25 ml/10 filters). To this solution, add 32 P-labeled DNA binding-site probe (from step 7) to $1-2 \times 10^6$ cpm/ml ($\sim 10^{-10}$ M). Add filters into the probe solution one by one in a dish and shake gently 60 min at room temperature.

Filters should be sequentially immersed in probe solution without trapping air bubbles.

19. Wash filters in batches, 4 times (7.5 min per wash, 30 min total) at room temperature with 500 ml binding buffer/10 filters.

Filters should shake freely in large dish without sticking to one another.

20. Blot filters dry, cover with plastic wrap, and expose to X-ray film with an intensifying screen at -70°C .

Positive signals should be detectable after 12 to 24 hr of autoradiography. Longer exposures result in high background.

Identify and purify sequence-specific clones

21. Align phage plates with autoradiographs, isolate agarose plugs corresponding to positive signals, and generate secondary phage stocks.

To reduce the number of irrelevant clones (false positives), it is helpful to generate autoradiography exposures of varying times with the primary filters. Such exposures help to distinguish spots with intense centers (likely to be artifacts) from those with a diffuse halo-like appearance (likely to represent true positives). Multiple autoradiographs also eliminate from consideration positive spots that do not reproduce on each exposure.

22. Plate secondary phage stocks (~ 5000 pfu/100-mm plate) as described in steps 8 to 11. For each plating, use a 0.2-ml aliquot of a Y1090 culture and 3 ml top agarose.
23. Prepare and screen secondary nitrocellulose filter replicas as described in steps 12 to 20, using 82-mm filters.

Recombinants that screen positively after enrichment represent true positives but may encode non-sequence-specific DNA-binding proteins.

24. Label a pVC recombinant plasmid DNA lacking the recognition site (or containing mutant versions) as in steps 1 to 7. Use this labeled probe to screen secondary stocks of true positives.

Phage detected with both test and control probes likely encode non-sequence-specific DNA-binding proteins.

25. Plaque purify and store phage (whose detection specifically requires the wild-type recognition-site probe over) over a drop of chloroform at 4°C .

These phage are likely to encode a β -galactosidase fusion protein that specifically binds the recognition site (see support protocol).

DENATURATION/RENATURATION CYCLING OF DRIED REPLICA FILTERS USING GUANIDINE-HCl

**ALTERNATE
PROTOCOL**

Protein replica filters suitable for screening with DNA recognition-site probes are most easily prepared as described in steps 8 to 17 of the basic protocol. Recently, Vinson et al. (1988) have shown that processing dried nitrocellulose replica filters through a denaturation/renaturation cycle using 6M guanidine-HCl significantly enhances the signal from a λ gt11 recombinant encoding C/EBP. However, it is not possible from this report to directly compare the sensitivity of the two protocols in detecting the C/EBP phage since in the basic protocol the replica filters are not dried. In this alternate protocol, the filters are first washed in HEPES binding buffer with 6 M guanidine-HCl, followed by several buffer washes containing two-fold dilutions of guanidine-HCl. They are then processed as described in the basic protocol.

Additional Materials

HEPES binding buffers

1. Follow steps 1 to 15 of the basic protocol.
2. Cool plates 10 min at 4°C . Mark the position of each filter with needle holes. Lift filters carefully and air dry 15 min at room temperature.

**DNA-Protein
Interactions**

12.7.4

3. Immerse filters in HEPES binding buffer/6 M guanidine-HCl and incubate 10 min at 4°C with gentle shaking. Repeat this once with fresh HEPES binding buffer/6 M guanidine-HCl.
4. Prepare HEPES binding buffer/3 M guanidine-HCl and immerse filters (50 ml/10 filters) 5 min at 4°C. Repeat this wash four times, each time using HEPES binding buffer containing a two-fold dilution of guanidine-HCl from the previous wash.
5. Incubate filters in HEPES binding buffer (50 ml/10 filters) 5 min at 4°C. Repeat this once with fresh HEPES binding buffer.
6. Block filters by incubating in BLOTTO as described in step 16 of the basic protocol.
7. Process filters for screening as described in steps 17 to 25 of the basic protocol.

**SUPPORT
PROTOCOL**

**PREPARATION OF A CRUDE EXTRACT FROM λ gt11
RECOMBINANT LYSOGEN TO CHARACTERIZE DNA-BINDING
ACTIVITY OF THE FUSION PROTEIN**

The specific detection of a recombinant phage with a wild-type recognition-site probe suggests that the phage expresses a β -galactosidase fusion protein that binds specifically to the recognition site. Direct evidence is obtained by analyzing a crude extract from a lysogen harboring the recombinant phage for appropriate DNA-binding activity. *E. coli* Y1089 cells are infected with the recombinant phage and lysogenized clones are isolated. Lysogenized cells growing in liquid culture are induced for the expression of the β -galactosidase fusion protein, harvested, and then lysed. A crude extract is obtained and used to characterize the DNA-binding activity of the fusion protein (see accompanying units in this chapter). Such an analysis not only confirms the sequence specificity of the fusion protein but allows a better definition of its recognition properties.

Additional Materials

- E. coli* Y1089 *hflA*150 (Table 1.4.5)
- LB medium with and without 10 mM MgCl₂ (UNIT 1.1)
- 10¹⁰ pfu/ml λ gt11 recombinant phage stock (see basic protocol)
- 1 M IPTG (Table 1.4.2)
- Extract buffer
- 5 mg/ml lysozyme in extract buffer (store at -20°C)
- 4 M NaCl
- 32°C incubator
- Sterile toothpicks
- 0.025- μ m filter disks (Millipore VS)

Isolate recombinant phage lysogen

1. Grow *E. coli* Y1089 *hflA*150 to saturation in LB/maltose/ampicillin medium at 37°C.
2. Dilute saturated cell suspension 100-fold in LB/MgCl₂ medium. Infect 100 μ l of diluted cell suspension with 5 μ l of 10¹⁰ pfu/ml λ gt11 recombinant phage stock and incubate 20 min at 32°C.

The phage and host cell mixture represents a multiplicity of infection of 5 to 10.

3. Dilute infected cell suspension 1000-fold in LB medium. Spread 100- μ l aliquots on LB/ampicillin plates and incubate overnight at 32°C.

At 32°C the temperature-sensitive phage repressor is functional and thus permits lysogeny. Approximately 100 colonies should be obtained on each plate after an overnight incubation.

4. Test single colonies for temperature-sensitive growth. Spot single colonies using sterile toothpicks onto two LB/ampicillin plates. Incubate the first plate at 42°C and the second at 32°C.

Clones that grow at 32°C but not at 42°C represent lysogens. Lysogens should arise at a frequency of 10% to 80%.

Prepare a crude extract from a recombinant phage lysogen

5. Grow overnight cultures of recombinant phage lysogens in LB/ampicillin medium at 32°C.
6. Inoculate 2-ml aliquots of LB/ampicillin medium with 20- μ l aliquots of the overnight cultures. Incubate at 32°C with good aeration.

A small air-shaker incubator should be used for this purpose. It allows for rapid temperature equilibration required in subsequent steps.

7. Grow cultures to OD₆₀₀ = 0.5 (~3 hr). Shift the temperature of the incubator to 44°C. Incubate 20 min at the elevated temperature.

The temperature shift should be accomplished as rapidly as possible while the cells are in log phase. At the elevated temperature the cI repressor is inactivated, inducing replication of the recombinant phage.

8. Add 1 M IPTG to 10 mM final and reduce the temperature of the incubator to 37°C. Continue the incubation for 1 hr.

Expression of the β -galactosidase fusion protein is induced with IPTG.

9. Microcentrifuge 1-ml aliquots of induced cultures ~45 sec at room temperature.
10. Resuspend each pellet in 100 μ l extract buffer and quick freeze with dry ice/ethanol. If desired, store cell suspensions at -70°C.
11. Rapidly thaw frozen cell suspension. Add 5 mg/ml lysozyme to 0.5 mg/ml final. Incubate 15 min on ice.

At the end of this incubation, the cell suspension should be very viscous due to efficient lysis.

12. Add 4 M NaCl to 1 M final and mix thoroughly. Incubate on rotator for 15 min at 4°C.
13. Microcentrifuge lysates 30 min at 4°C and remove supernatants carefully.
14. Float 0.025- μ m filter disks on 100 ml extract buffer in a petri dish and apply samples on the filters. Dialyze 60 min at 4°C then quick freeze aliquots with dry ice/ethanol and store at -70°C.

Crude extracts are unstable at 4°C because they contain significant proteolytic activity. Frozen aliquots are used subsequently to characterize the DNA-binding activity of the fusion protein (see accompanying units in this chapter).

REAGENTS AND SOLUTIONS

Binding buffer

- 10 mM Tris-Cl, pH 7.5
- 50 mM NaCl
- 1 mM EDTA
- 1 mM dithiothreitol (DTT)

BLOTTO

5% Carnation nonfat milk powder
50 mM Tris-Cl, pH 7.5
50 mM NaCl
1 mM EDTA
1 mM DTT
Store 1 to 2 weeks at 4°C

The milk powder should be thoroughly dissolved in sterile water containing the other components.

Elution buffer

20 mM Tris-Cl, pH 7.5
200 mM NaCl
1 mM EDTA
Store at room temperature

Extract buffer

50 mM Tris-Cl, pH 7.5
1 mM EDTA
1 mM DTT
1 mM Phenylmethylsulfonyl fluoride (PMS)
Store at -20°C

HEPES binding buffers

25 mM HEPES, pH 7.9
25 mM NaCl
5 mM MgCl₂
0.5 mM DTT

Prepare separate solutions without guanidine-HCl and with 6 M guanidine-HCl. Prepare solutions fresh for each use and keep briefly at 4°C.

COMMENTARY

Background Information

Sequence-specific DNA-binding proteins function in diverse capacities including DNA replication, recombination, and transcription. In higher eukaryotic cells, biochemical approaches have been used to identify such proteins (see accompanying units in this chapter). Typically, these proteins bind specifically and with high affinity to distinct sequence motifs. Prior to the application of the cloning strategy described by Singh et al. (1988), genes encoding these proteins could only be isolated through purification of substantial amounts of the relevant activities (Weinberger et al., 1985; Kadonaga et al., 1987). The screening strategy discussed below obviates purification of a DNA-binding protein for the purpose of isolating its gene. Therefore, it is ideally suited for facilitating the analysis of rare regulatory molecules.

The strategy is designed to directly detect recombinant clones that encode sequence-specific DNA-binding proteins. It depends on the

functional expression of the DNA-binding domain of a sequence-specific protein in *E. coli* at high levels and a strong interaction between this domain and its recognition site. If these conditions are fulfilled, a recombinant clone encoding a sequence-specific DNA-binding protein can be detected by probing nitrocellulose filter replicas of a lambda expression library with the corresponding recognition-site DNA (Singh et al., 1988; Staudt et al., 1988). This strategy is quite similar to that previously developed for the isolation of genes by screening recombinant expression libraries with antibodies specific for given proteins (Young and Davis, 1983; see *UNIT 6.7*). In fact, the phage expression vector λ gt11—designed for immunological screening—is also employed in the detection of DNA-binding protein clones. The simple procedure described in the basic protocol has permitted the isolation of many clones encoding different transcription factors including MBP-1 (Singh et al., 1988), Oct-2 (Staudt et al., 1988), E12 (Murre

et al., 1989), XBP (Hsiou-Chi et al., 1988), IRF-1 (Miyamoto et al., 1988), and CREB (Hoeffler et al., 1988). The denaturation/re-naturation cycle described in the alternate protocol may in some cases increase the detection signal by facilitating the correct folding of a larger fraction of the *E. coli* expressed protein. Alternatively, it may help to dissociate insoluble aggregates that form as a consequence of overexpression. This modified procedure has been successfully used to isolate clones encoding Oct-1 (Sturm et al., 1988), Oct-2 (Müller et al., 1988), Pit-1 (Ingraham et al., 1988), and RF-X (Reith et al., 1989).

Prospects for the isolation of cDNAs encoding sequence-specific DNA-binding proteins by this strategy can be assessed by examining the three assumptions on which it is based: (1) functional expression of the DNA-binding domain of the sequence-specific protein in *E. coli*; (2) a strong and specific interaction of the binding domain with its recognition site; and (3) high-level expression of the DNA-binding domain. A number of eukaryotic sequence-specific DNA-binding proteins have been functionally expressed in *E. coli* including the proteins GAL4 (Keegan et al., 1986) and GCN4 (Arndt and Fink, 1986) of yeast, engrailed of *Drosophila* (Desplan et al., 1985), E2 of the bovine papillomavirus (Androphy et al., 1987), and EBNA-1 of the Epstein-Barr virus (Rawlins et al., 1985). Thus it is reasonable to expect the functional expression of the DNA-binding domains of many eukaryotic sequence-specific proteins in *E. coli*. Interestingly, in most cases the functional DNA-binding domain is contained within a small tract of 100 to 300 amino acids. Therefore, successful screening is not dependent on full-length cDNA clones. It simply requires that a given recombinant expression library contain partial cDNA clones spanning the DNA binding domain of the sequence-specific protein. However, if this DNA-binding domain is encoded in the 5' region of a long mRNA, the frequency of functional cDNA clones in a library made by oligo(dT) priming is expected to be low. It is therefore preferable for the purpose of this screening strategy to construct a library by randomly priming cDNA synthesis (Staudt et al., 1988). Finally, it should be noted that some eukaryotic sequence-specific proteins have been shown to recognize target DNA only as heterodimers (Chodosh et al., 1988). Obviously, genes encoding the subunits of these proteins cannot be cloned by this strategy.

Successful screening may be restricted to

proteins with relatively high binding constants since only these are likely to form complexes with half-lives long enough to withstand the wash protocol. For example, if the DNA-binding protein has an association constant of 10^{10} M^{-1} , then under the screening conditions (the DNA probe in excess at a concentration of $\sim 10^{-10} \text{ M}$), approximately half of the active molecules on the filter will have DNA bound. Since the filters are subsequently washed for 30 min, the fraction of protein-DNA complexes that remain will be determined by their dissociation rate constant. Assuming a diffusion-limited association rate constant of $10^7 \text{ M}^{-1} \text{ S}^{-1}$, the dissociation rate constant in solution will be 10^{-3} S^{-1} . This rate constant translates into a half-life of ~ 10 min. Thus one-eighth of the protein-DNA complexes should survive the 30-min wash. For a binding constant of 10^9 M^{-1} , about one-tenth of the active protein molecules will have DNA bound, but virtually all of this signal should be lost since the half-life of these complexes in solution is ~ 1 min.

However, it is unclear whether the equilibrium and kinetic constants of a protein-DNA interaction in solution accurately describe the reversible binding of a DNA probe to a matrix of protein immobilized on a filter. Thus, it may be possible to isolate recombinants encoding proteins with binding constants of $\leq 10^9 \text{ M}^{-1}$. These considerations nevertheless suggest that the sensitivity of this methodology for low-affinity proteins might be significantly enhanced by using DNA probes containing multiple binding sites that are spaced such that the probe can simultaneously bind two or more immobilized protein molecules. Enhanced sensitivity with a multisite probe has been impressively demonstrated in the molecular cloning of a mammalian regulatory protein (Staudt et al., 1988). Finally, since the binding constants of sequence-specific proteins are dependent on ionic strength, temperature, and pH, manipulation of these factors might also enhance detection.

The DNA-binding domains of sequence-specific proteins need to be overexpressed in *E. coli* to permit detection with radiolabeled recognition-site probes. These proteins, when expressed to a level of $\sim 1\%$ of the total cellular protein, can be readily detected (Singh et al., 1988; Staudt et al., 1988). This level of recombinant protein expression is typical of λ gt11.

Critical Parameters

The success of the screening strategy is critically dependent on the quality of the cDNA

library and the recognition-site probe used. Recombinant cDNA libraries made by random priming and multisite recognition probes are the preferred reagents. The synthetic probe should be tested for recognition by the desired protein before use in screens (UNIT 12.2). If possible, the highest affinity site among a set of related sites should be chosen for the construction of the multisite probe.

Plating mixtures for 100- and 150-mm plates should contain a maximum of 2×10^4 pfu and 5×10^4 pfu, respectively, of λ phage. Higher plating densities result in diminished signals. Plating mixtures in top agarose should be spread uniformly by swirling, avoiding air bubbles. This ensures efficient contact of the nitrocellulose filters with the agarose overlay. Plates should be cooled at 4°C before lifting the nitrocellulose filters. This step minimizes peeling off of the agarose overlay. Filters should be submerged in BLOTTO without trapping air bubbles to permit uniform blocking. Filters should be transferred from one solution to the next as rapidly as possible to avoid drying.

The DNA probe preparation used for screening ($\sim 10^8$ cpm/ μ g) should not contain significant levels of either radiolabeled nucleotide or radiolabeled single-stranded DNA because these greatly increase the background. The quality of a probe preparation can be checked by screening control λ gt11 plaques (there should be no signal). The protein-DNA complexes formed on the nitrocellulose filters appear to be labile. Therefore, filters should be shaken gently during the bind and wash steps.

Sonicated and denatured calf thymus DNA is a preferred nonspecific competitor. Earlier screens using poly(dI-dC)-poly(dI-dC) as the nonspecific competitor yielded recombinant phage encoding proteins that bound nonspecifically to either double-stranded or single-stranded DNA (Singh et al., 1988). The signal from these phage, but not phage encoding sequence-specific DNA-binding proteins, could be efficiently competed with denatured calf thymus DNA (R. Clerc, personal communication; Staudt et al., 1988).

A recombinant phage specifically detected with a given recognition-site probe may not necessarily encode a protein that binds to the desired site. It is therefore necessary to characterize the recognition properties of the phage-encoded fusion protein thoroughly with in vitro binding assays. The relation between a protein cloned by this strategy and a previously char-

acterized DNA-binding activity can be explored with antibodies generated against the cloned molecule.

Anticipated Results

If 10^6 recombinant clones are screened, 1 to 10 putative clones can be expected.

Time Considerations

The screening procedure is well suited for a 3-day cycle time. The phage are plated in the morning of the first day. Nitrocellulose filters are placed on plates 3 hr after the infection. After a further 6-hr incubation, the filters are lifted and blocked for 1 hr. Filters are rinsed and stored immersed in buffer overnight at 4°C. Filters are screened on the second day with a DNA recognition-site probe and processed for autoradiography. Positive signals are detected after 12 to 24 hr of autoradiography. If the filters are to be put through a denaturation/renaturation cycle, it is convenient to stop on the first day after they are dried.

Rapid Separation of Protein-Bound DNA from Free DNA Using Nitrocellulose Filters

BASIC PROTOCOL

This protocol relies on the ability of nitrocellulose to bind proteins but not double-stranded DNA. Use of radioactively labeled double-stranded DNA fragments allows quantitation of DNA bound to the protein at various times and under various conditions, permitting kinetic and equilibrium studies of DNA-binding interactions. Purified protein is mixed with double-stranded DNA in an appropriate buffer to allow interaction. After incubation, the mixture is suction filtered through nitrocellulose, allowing unbound DNA to pass through the filter while the protein (and any DNA interacting with it) is retained.

Materials

- 2× DNA-binding buffer
- Double-stranded, ³²P-labeled DNA
- Protein sample
- Bovine serum albumin (BSA; optional)
- 0.45- μ m nitrocellulose filter discs (13-, 24-, or 25-mm diameter to fit filtration apparatus being used)
- Flat, smooth-tip forceps for handling nitrocellulose
- Filtration apparatus and vacuum source

Prepare materials

1. Prepare 30 ml of fresh 2× DNA-binding buffer by adding DTT and PMSF (see reagents and solutions). Mix well and set aside 0.5 ml for use in step 3. Dilute remaining 29.5 ml to 1× with distilled water.

This will be enough 2× and 1× DNA-binding buffer to set up and filter ten reactions. This is a good general buffer but the optimal buffer conditions for binding a given protein must be individually determined. See critical parameters.

CAUTION: PMSF is toxic. Handle carefully!

2. Place the filters in a small tray containing ~30 ml of 1× DNA-binding buffer (diluted in step 1). Soak \geq 30 min. Retain at least 10 ml of 1× buffer for the filtration step.

Always handle the filters with forceps because direct handling can increase background. Any filters that do not wet uniformly should be discarded. If desired, the filters can be carefully labeled at the edge with a pen prior to wetting. Special pens are available, although ballpoint pens work well.

Bind DNA to protein

3. For each sample, set up a microcentrifuge tube as follows. Add \geq 10,000 cpm double-stranded, ³²P-labeled DNA (2 to 10 ng) to 25 μ l of 2× DNA-binding buffer. Add sufficient water to make a final volume of 50 μ l, accounting for the volume of protein solution added in step 4. Vortex and microcentrifuge 1 to 2 sec.

Typically DNA fragments of a few hundred base pairs or more—which are believed to contain a specific binding site—are used. DNA fragments can be labeled by filling in the ends with Klenow fragment (UNIT 3.5) or by kinasing (UNIT 3.10). Fragments are isolated by any of the standard techniques described in Chapter 2 or in UNIT 12.2.

4. Add protein solution to the reaction tubes. GENTLY invert or flick the tubes up to 4 times to mix in the protein solution. Microcentrifuge 1 to 2 sec to bring all the liquid to the bottom of the tubes. Incubate 25 min at 30°C.

Time and temperature parameters will vary for different proteins. In general, 20 min is sufficient to allow the protein-DNA interaction to reach equilibrium. Temperatures above 37°C may affect the stability of the protein.

The final concentration of protein needed to detect specific binding is best determined by titrating (see background information) and can range from 10^{-8} to 10^{-14} M. Low concentrations of protein may be stabilized by including in the reactions a non-DNA-binding carrier protein (e.g., BSA at ~100 mg/ml) with no detrimental effect on the binding assay.

Filter the DNA-protein complex and determine cpm

5. During the incubation, number and label scintillation vials. Attach a vacuum source to the apparatus as indicated in Figure 12.8.1 but do not apply vacuum.

The most common filtration apparatus holds a single filter and can be set up using supplies found in most labs (Fig. 12.8.1A). A multiwell apparatus is more convenient, allowing filtration of several samples simultaneously. We recommend the Hoefer 10-well apparatus, which has stopcocks to control suction for individual wells and allows filtrate to be collected from individual wells (Fig. 12.8.1B). Although a standard suction-filtration setup is described here, disposable units for filtration by centrifugation are available from Schleicher & Schuell (Centrex).

If the Hoefer 10-well apparatus is being used, number enough vials to count the filtrates and the filters and place the vials in the collection rack in the apparatus. The flowthrough and all washes can be collected into one vial for each reaction. The filter is counted separately.

6. Place filters in the apparatus with weights on top, as shown in Figure 12.8.1 (do this no more than 5 min prior to start of filtration to avoid drying out the filters). At the end of the incubation, turn on the vacuum source. Apply the contents of each tube gently but quickly to separate filters. Filtering should proceed at ~1 ml/min.
7. When the liquid is gone from each filter well, add 0.5 ml of 1× DNA-binding buffer (this comprises the first wash). Allow to filter through. Apply the second 0.5-ml 1× buffer wash. When washing is complete, increase the suction and observe the liquid dripping into the collection vessels. Turn off the vacuum when dripping has ceased.
8. Remove the weights and transfer filters to scintillation vials for Cerenkov counting. Total cpm is determined by adding the counts in the filtrate and those on the filters (where the filtrates were collected), or by estimating input cpm. Percent cpm retained = $\text{cpm on filter} / \text{total cpm} \times 100$; this reflects the percentage of input DNA bound by protein at the time of filtration (see background information).

For further characterization, see support protocol describing recovery of DNA from filters.

DETECTION OF SPECIFICITY IN DNA BINDING

When the binding site of a protein is unknown, the pure protein can be added to a mixture of fragments to select those fragments of DNA for which it has the greatest affinity. Specificity of binding can be influenced by the buffer conditions and filtering regimen. This alternate protocol creates conditions that disrupt weaker, presumably nonspecific binding interactions, while retaining the stronger binding interactions. Differences from the basic protocol include using more labeled DNA and more extensive washing. The goal is to recover enough of a single input fragment to visualize by subsequent autoradiography. This protocol uses the same binding buffer as the basic protocol, however increasing the KCl to 150 mM (final concentration in the 1× binding buffer) could further improve detection of specific binding in some cases.

ALTERNATE PROTOCOL

DNA-Protein Interactions

12.8.2

Figure 12.8.1 (A) A single filtration apparatus can be set up with a sidearm flask connected to a vacuum source. The tubing arrangement need not be precisely as depicted but should include an adjustable clamp on a vent to allow precise control of the vacuum. (B) The 10-well filtration apparatus from Hoefer contains a removable rack for collection vessels. Many types of tubes or vials can be held in place by a rubber band as shown. Stopcocks allow vacuum to be shut off to any subset of the 10 wells, so that any number of samples from 1 to 10 can be filtered at one time. The lower tubing connector can be set up with tubing and a clamp to regulate the vacuum as with the vent on the sidearm flask unit. In both setups the interlocking design and weight of the steel are sufficient to create a seal around the filter.

1. Prepare 40 ml of fresh 2× DNA-binding buffer (see step 1 of basic protocol). Set aside 3 ml and dilute remaining 37 ml to 1× with distilled water.
2. Soak filters in ~10 ml of 1× binding buffer. Retain 60 ml of 1× binding buffer for the filtration step.
3. Add ~100,000 cpm of double-stranded, ³²P-labeled DNA (20 to 100 ng of a mixture of labeled fragments) to 250 μl of 2× DNA binding buffer. Add sufficient water to make a final volume of 500 μl, accounting for the volume of protein solution added in step 4. Vortex and microcentrifuge 1 to 2 sec.

As in the basic protocol, the method of labeling is not critical. However, there may be some differences in retention of fragments based on size alone.

4. Add the protein solution to the reaction tubes, mix, microcentrifuge, and incubate, as described in step 4 of the basic protocol.

As in the basic protocol, time and temperature parameters will vary for different proteins. The amount of protein should be titrated to determine the ratio of protein to DNA that gives the optimal specific signal. High concentrations of protein result in all DNA fragments in the mixture being retained on the filter.

5. During the incubation, number and label scintillation vials for counting of filters, and of flowthrough and washes if using Hoefer apparatus. Set up filtration apparatus as described in step 6 of the basic protocol.

If using the Hoefer apparatus, the flowthrough and all washes can be collected into one vial for each reaction. However, it is often reassuring to collect the last wash separately for comparison to filter-bound cpm. It is expected that effective washing will leave fewer cpm in the last wash than retained on the filter. The importance of washing is further discussed in critical parameters.

6. Place filters in the apparatus with weights on top (Fig. 12.8.1)—again, ≤5 min prior to the start of filtration to avoid drying the filters. At the end of the incubation, apply each sample to a separate filter with the vacuum off. Apply vacuum to filter at ~1 ml/min.
7. When all liquid is gone from the filter, increase the vacuum until dripping into the collection vessel slows. Release the vacuum. Add 2 ml of 1× buffer for the first wash to the wells. If the next wash is to be collected in separate vials, the vials can be changed quickly at this time while the 2 ml of buffer keeps the filter from drying. Apply vacuum and filter the first wash as above.

Repeat this washing procedure a total of three times. On the third wash increased suction is used until dripping ceases.

ELUTION OF BOUND DNA

In some cases the quantitation (by scintillation counting) of DNA retained is not sufficient information. This support protocol describes how the DNA can be recovered from the filters for further analysis by gel electrophoresis or amplification and cloning.

Additional Materials

Filter elution buffer
Carrier nucleic acid
Ethanol

1. Remove filters and place face down in scintillation vials containing 450 μl filter elution buffer.

SUPPORT PROTOCOL

DNA-Protein Interactions

12.8.4

2. Place vials in 30°C water bath, weighted down, for 2 hr. Periodically tilt vials gently to swirl the buffer.

Use lead pig lids or plate glass to weigh down the vials. It is most efficient to keep as much of the filter as possible in contact with the buffer. Any other arrangement that combines this temperature and gentle agitation should serve just as well. Yield with this method is usually 50% to 85% of the cpm originally on the filter.

3. Remove the liquid and transfer it to microcentrifuge tubes. Add carrier nucleic acid and mix. Add 1 ml ethanol, mix, and allow to precipitate overnight at -20°C. Run on a gel (Chapter 2) to determine which subset of the input fragments was retained.

Precipitation should go overnight because of the small amount of DNA in the large volume. However, sufficient carrier (~1 µg per tube) can decrease the time needed for precipitation. Conventional carriers such as tRNA will do; however, for analysis by agarose gel electrophoresis, it is helpful to use as carrier cold DNA fragments that are identical to the labeled ones. Directly after running the gel, a picture can be taken of the gel stained with ethidium bromide. After drying and autoradiography, the radioactive band(s) can be identified by comparing the autoradiogram to the picture.

REAGENTS AND SOLUTIONS

2× DNA-binding buffer

40 mM Tris-Cl, pH 7.5
20% glycerol
100 mM KCl
0.2 mM dithiothreitol (DTT)
0.2 mM PMSF (phenylmethylsulfonyl fluoride) in isopropanol

DTT and PMSF should be added to binding buffer immediately before use, as described in step 1 of basic protocol.

CAUTION: PMSF is extremely toxic. Handle carefully!

Filter elution buffer

20 mM Tris-Cl, pH 7.8
0.2% sodium dodecyl sulfate
0.3 M sodium acetate

COMMENTARY

Background Information

Filter binding is used predominantly to characterize interactions between purified DNA-binding proteins and their specific sites as well as various nonspecific DNAs. This assay is ideal for kinetic and equilibrium studies because bound DNA can be rapidly separated from free DNA. However, slower methods such as the mobility shift (UNIT 12.2) or immunoprecipitation (UNIT 10.16) assays, have the advantage that they can be used with cruder protein preparations.

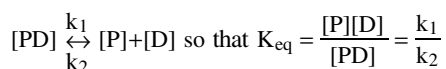

DNA retained on the filters can be recovered for gel electrophoresis. This has allowed selection of fragments containing a specific binding

site from a pool of several fragments in the initial reaction mix (Strauss et al., 1981). Filter binding has also been used to separate bound DNA from free DNA for methylation interference experiments (UNIT 12.3), although the mobility shift assay is more popular for this purpose.

The use of the filter-binding technique for kinetic and equilibrium analyses is described briefly below. For more detailed discussion of the validity of these approaches, as well as alternative approaches, consult Riggs et al. (1970) and Hinkle and Chamberlin (1972b).

The protein-DNA binding interaction can be looked at as an equilibrium represented

by the equation:

where [P] = concentration of free protein

[D] = concentration of free DNA

[PD] = concentration of protein-DNA complex

k_1 = dissociation rate constant

k_2 = association rate constant

K_{eq} = equilibrium dissociation constant (often refer to as the dissociation constant, K_D)

Equilibrium studies. The K_{eq} of a given protein-DNA interaction is a measure of the affinity of the protein for that particular piece of DNA. The apparent K_{eq} can be determined by an experiment in which protein is titrated against a known amount of DNA containing the binding site being tested. The half-maximal point on the resulting curve (see Fig. 12.8.2) is equal to the K_{eq} , since at 50% saturation of the DNA, $[PD] = [D]$. Therefore, the equation

$$K_{eq} = \frac{[P][D]}{[PD]}$$

is reduced to $K_{eq} = [P]$. This simplification is true only if $[D] \ll K_{eq}$. Therefore, the amount of DNA used in these experiments is usually very small.

This experimental method of determining K_{eq} also relies on the assumption that [P] equals

the concentration of active protein molecules with respect to DNA binding. If this is not the case (for example, if the protein is only 30% active after purification), kinetic experiments can give an estimate of the K_{eq} .

Kinetic studies. This kind of estimate of the K_{eq} is based on the relation $K_{eq} = k_1/k_2$. For many DNA binding proteins the “on rate” (rate of association) is diffusion limited. By making this assumption, and experimentally determining the “off rate” (rate of dissociation of formed complexes), an estimate for the K_{eq} can be obtained. The off rate is experimentally measured as follows: (1) protein and labeled DNA (containing the specific binding site) are mixed and allowed to reach equilibrium; (2) the reaction volume is diluted 10-fold in the presence of an excess of cold competitor DNA—e.g., 50-fold excess of unlabeled DNA containing the specific binding site; and (3) aliquots are filtered at various time points. As proteins dissociate they have little chance of reassociating with labeled DNA due to dilution and competitor DNA factors.

A dissociation curve is generated where the filter-bound cpm at $t = 0$ are defined as 100% binding (see Fig. 12.8.3). This data can be applied to the following rearranged form of the equation for first-order rates of decay:

$$\ln(\% \text{ bound}) = \ln(\% \text{ bound at start} = 100) - k_1 t.$$

From the experimentally determined half-time of dissociation (t at which % bound = 50), this equation can be solved for k_1 , the apparent dissociation rate constant. An estimate for the

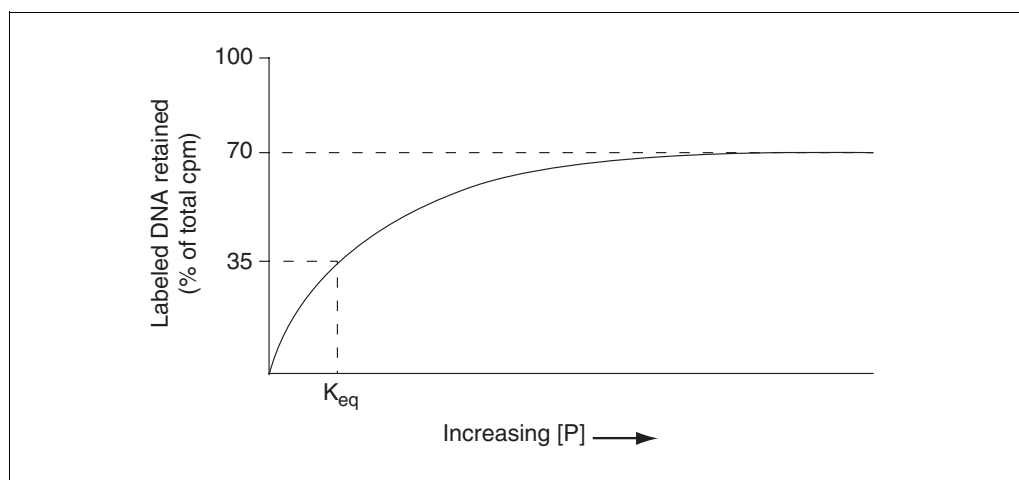

Figure 12.8.2 Plot of increasing concentration of protein vs. amount of DNA retained (expressed as % of total input labeled DNA in cpm). In this example, plateau occurs when 70% of labeled DNA is bound. Therefore, the half-saturation point is when half of this possible maximum is reached—i.e., when 35% of labeled DNA is bound. The concentration of protein necessary to achieve this half point is an experimental estimate of the K_{eq} (see discussion in background information).

K_{eq} is readily made using this value for k_1 and a diffusion limited value for k_2 (Hinkle and Chamberlin, 1972b).

The K_{eq} of a protein for DNAs other than those containing its specific site can be calculated from filter-binding data obtained by equilibrium or rate competition experiments as described by Lin and Riggs (1972). Equilibrium competition experiments involve the mixing of various amounts of cold competitor with a fixed amount of labeled specific DNA during the binding incubation. The amount of competitor needed to reduce labeled DNA retained measures the affinity of the protein for that competitor. Such experiments are particularly useful when the competitor is a single-stranded nucleic acid that could bind directly to the filter, precluding a direct measurement, or when the competitor is difficult to label (Riggs et al., 1970).

Literature Review

Filter binding was first used to study ribosome-RNA interactions (Nirenberg and Leder, 1964) and was applied to DNA-protein interactions by Jones and Berg (1966) to study RNA polymerase. Earlier studies of protein-nucleic acid interactions had relied on glycerol or sucrose gradients for separation of molecules and molecule complexes.

The first detailed discussion of the filter binding method and its general applicability was by Riggs et al. (1970). Beginning in the early 1970s this technique was used exten-

sively—e.g., by Lin and Riggs (1972, 1975) to characterize *lac* repressor binding, and by Hinkle and Chamberlin (1972a,b,c) and later Strauss et al. (1980a,b; 1981) to characterize *E. coli* RNA polymerase binding. Since then, the general applicability of this technique has been borne out as it has been used to analyze many other DNA-binding proteins.

Critical Parameters

The optimal filter-binding conditions are usually different for every protein. In addition, those conditions which permit the strongest binding to a known specific site are often not the conditions desired when one is looking for such a site (as in the alternate protocol). This is because maximizing specific binding usually increases nonspecific binding.

The following is a brief discussion of some parameters to consider when designing an experiment. It is best to titrate individual components initially to establish the optima for the protein of interest.

Incubation conditions

Monovalent salt (e.g., NaCl or KCl). Lower salt favors tighter binding (slower dissociation) whereas higher salt favors quicker dissociation. Most kinetic and equilibrium experiments are done at 50 mM salt. When attempting to detect specific binding over nonspecific binding, 150 mM or higher salt may be appropriate. At high salt concentrations all binding is lost.

Figure 12.8.3 Two alternative ways to plot the results of a dissociation curve. Here the initial value of 100% equals the maximum amount of labeled DNA (measured in cpm) retained at the start of the experiment. Even though the maximum possible may only be 70% of the input labeled DNA (as shown in Fig. 12.6.2), if an amount of protein is used close to this plateau then this 70% value is the starting point for any dissociation and is therefore defined as 100%. The semi-log plot uses a log scale for the cpm bound to represent the data as a straight line whose slope is $-k_1$, the dissociation constant (see background information and Barkley et al., 1975).

pH. Lower pH favors tighter binding whereas higher pH favors dissociation. Most binding studies are done in the physiological range of 7.2 to 7.5. To accentuate specificity, it may be helpful to use a slightly higher pH. However, as this tends to weaken all binding, increasing either salt concentration or the number of wash steps may be preferable.

Divalent cations (e.g., Mg²⁺). The effect of divalent cations varies with each protein. For some proteins they increase binding but for others they decrease binding (thus, none were included in the basic protocol). It is best to titrate each protein against this parameter; however, binding can frequently be detected in the absence of divalent cations.

Temperature. Temperature effects in this assay are minimal. Most binding protocols consistently use one temperature in the range of 25° to 30°C. Some protocols call for dilution into ice-cold buffer prior to filtering or transfer of tubes to ice. This does not appear to be critical in most cases.

Time. Incubation time is usually between 10 min and 1 hr. Longer times favor equilibrium, but stability of the protein must be considered. Once the reaction has been filtered, complexes continue to dissociate during wash steps but presumably at a slower rate. Nonetheless, it is desirable to conclude the washing as quickly as possible.

Volume. Volumes smaller than 50 µl are not usually used due to the surface area of the filters. Larger volumes may provide more even filtering but necessitate using more protein to attain the desired concentrations. For rate experiments, it is reasonable to make up one large reaction and filter aliquots at various time points.

Manipulations

Mixing. Physical mixing has been reported to disrupt DNA-protein interactions permanently in some cases (Fried and Crothers, 1981). The minimum force possible should be used to mix the protein into the reaction. Avoid vortexing.

Filtration. Successful rates of filtration vary from less than 1 ml/min to 15 ml/min. The more rapid filtration rates have been reported to affect results adversely in some cases by allowing insufficient time for binding to nitrocellulose or by drying out the filter itself, leading to less reproducible results (Riggs et al., 1970).

Washing. The number and volume of washes depends on the application. For kinetic and equilibrium experiments it is not necessary to

wash extensively. One or two small washes (0.5 ml) can improve the reproducibility of the results by decreasing the trapping of reaction volume in the apparatus and within the filter itself. This is particularly helpful if the reaction volume is small. For detection of specificity in binding, more extensive washing is recommended to decrease the background (protein binding to nonspecific DNA). Three large (2-ml) washes as described in the alternate protocol should be sufficient for this purpose, and more may decrease the specific signal.

Troubleshooting

Background retention of labeled DNA on filters in the absence of protein can frequently be as high as 15% of input counts. Pretreating the filters in the following manner (Lin and Riggs, 1972) can reduce the background to between 0.1% and 1.5% of input counts. (Note: Because the treated filters become somewhat yellowed and more fragile, care must be taken in manipulating them.) Filters are wet and soaked in 0.4 M KOH for 40 min at room temperature (~25°C). Next, they are rinsed thoroughly with water and soaked as usual for a minimum of 30 min in 1× binding buffer. Batches of filters can be prepared this way and stored in binding buffer for days.

Anticipated Results

Graphs of some expected results are presented in Figures 12.8.2 and 12.8.3. When precise numbers are to be derived it is best to run triplicate samples. In general, 100% binding is not achieved when titrating protein against a constant amount of DNA. Plateau can be as low as 30% or as high as 70% (the higher value is depicted in Fig. 12.8.3). However, it is the shape of the curve that is most informative. In some cases, one protein molecule is sufficient for DNA binding and retention on nitrocellulose. Any indication of sigmoidicity at low concentrations of protein may be an indication that cooperativity exists in binding or that multiple protein molecules must bind to achieve retention of a given fragment (see Ptashne, 1987).

Time Considerations

Filter-binding experiments are quick. In one day, it is easily possible to set up and filter two experiments of 10 samples each, elute the bound DNA, and load the gel to run overnight. If only scintillation counts are required, approximately four or more experiments can be run in one day.

Analysis of DNA-Protein Interactions Using Proteins Synthesized In Vitro from Cloned Genes

UNIT 12.9

BASIC
PROTOCOL

The availability of a cloned gene makes it possible to synthesize the encoded protein by in vitro transcription and translation. As described in UNIT 10.17, protein-coding sequences are cloned into a vector containing a promoter for SP6 or T7 RNA polymerase (UNIT 1.5), messenger RNA is produced by transcribing the DNA template (UNIT 3.8), and the desired protein is synthesized as a ³⁵S-labeled species by in vitro translation. Such in vitro synthesized proteins are extremely useful for determining whether a cloned gene encodes a specific DNA-binding protein and for analyzing DNA-protein interactions. To detect DNA binding activity, the labeled protein is incubated with specific DNA fragments, and protein-DNA complexes are separated from free protein by electrophoresis in native acrylamide gels (UNIT 12.2). Unlike the more conventional mobility shift assay which utilizes ³²P-labeled DNA and unlabeled protein, the assay described here generally utilizes ³⁵S-labeled protein and unlabeled DNA. Major advantages of this method are that any desired mutant protein can be tested for its DNA-binding properties simply by altering the DNA template, and the subunit structure (e.g., dimer, tetramer) can be determined.

Materials

Plasmid DNA containing desired binding sites (UNIT 1.6)
³⁵S-labeled protein (UNITS 10.17 & 10.18)
5× binding buffer
10 mg/ml poly(dI-dC)·poly(dI-dC) or other bulk carrier DNA
Loading buffer
45% methanol/10% acetic acid
EN³HANCE (Du Pont NEN)

Additional materials for digesting DNA with restriction endonucleases (UNIT 3.1), phenol extraction and ethanol precipitation (UNIT 2.1), agarose and nondenaturing polyacrylamide gel electrophoresis (UNITS 2.5, 2.7, & 12.2), and autoradiography (APPENDIX 3). For some applications, materials for end-labeling DNA with T4 polynucleotide kinase (UNIT 3.9) or Klenow fragment (UNIT 3.5) will be necessary.

1. Cleave plasmid DNA containing the binding site with appropriate restriction endonucleases, generating a fragment whose length is between 150 and 700 bp and whose molecular weight differs from other fragments generated by restriction cleavage. Purify by phenol extraction and ethanol precipitation. If desired, purify the fragment with the binding site as well as control DNA fragments followed by agarose or acrylamide gel electrophoresis.

In considering how much plasmid DNA to cleave, each DNA-binding reaction requires the equivalent of ~0.5 μg DNA assuming a plasmid of 5 kb. ³²P-labeled DNA containing the binding site can also be prepared as described in the more conventional mobility shift assay (UNIT 12.2).

2. Set up the following 15-μl binding reaction:

5 μl H₂O
3 μl 5× binding buffer
5 μl DNA (DNA fragments each at 9 nM)
1 μl 10 mg/ml poly(dI-dC)·poly(dI-dC)
1 μl [³⁵S]protein (UNIT 10.17).

Incubate 20 min at room temperature.

DNA-Protein
Interactions

Supplement 24

It is essential to perform control reactions that contain no DNA and that contain nonspecific DNA (i.e., lacking a binding site). The binding conditions—especially the amount of carrier DNA, ionic strength, divalent cations, and temperature—can be varied if necessary. It is also possible to perform binding reactions with unlabeled protein and ³²P-labeled DNA fragments as described for more conventional mobility shift assays (UNIT 12.2).

3. Add 5 µl loading buffer and immediately load on a 5% nondenaturing polyacrylamide gel. Carry out electrophoresis until the bromphenol blue is near the bottom of the gel (1 to 4 hr depending on the buffer conditions); do not heat the gel above room temperature.

The polyacrylamide gel can either be standard (30:0.8 acrylamide/bisacrylamide in 90 mM TBE buffer, pH 8.3; UNIT 2.7) or low-percentage and low-ionic-strength (UNIT 12.2). The composition of the gel and the ionic strength of the buffer can be varied and may be important for detecting a given protein-DNA interaction.

4. After electrophoresis, fix the gel in 45% methanol/10% acetic acid for 1 hr at room temperature. Treat the gel with EN³HANCE for 1 hr, dry, and analyze by autoradiography.

If the DNA-binding reaction was performed with unlabeled protein and ³²P-labeled DNA, simply dry the gel and autoradiograph as described for the conventional mobility shift assay (UNIT 12.2).

REAGENTS AND SOLUTIONS

5× binding buffer

100 mM Tris·Cl, pH 7.4
250 mM KCl
15 mM MgCl₂
5 mM EDTA
500 µg/ml gelatin

Loading buffer

1× binding buffer (see above)
20% glycerol
1 mg/ml bromphenol blue
1 mg/ml Xylene Cyanol

COMMENTARY

Background Information

The procedure described here for analyzing DNA-protein interactions was first utilized in studies on the yeast GCN4 transcriptional activator protein (Hope and Struhl, 1985). It differs from conventional biochemical approaches in that the protein of interest is not obtained from cells, but rather is synthesized by in vitro transcription and translation of a cloned gene. However, once the protein is synthesized, many standard procedures for studying specific DNA-protein interactions (e.g., UNITS 12.2, 12.3, & 12.4) can be performed with only minor modifications. In addition, the method is extremely useful for analyzing the properties of mutant proteins and for determining subunit structure, issues that are much more difficult to investi-

gate by more classical biochemical techniques.

The protocol for synthesizing [³⁵S]protein by in vitro transcription and translation is detailed in UNIT 10.17. DNA-binding activity is detected by incubating the labeled protein with appropriate DNA fragments, and separating the protein-DNA complexes from free protein by electrophoresis in native acrylamide gels. This DNA-binding assay is essentially the reverse of the standard mobility shift assay (UNIT 12.2) in which unlabeled proteins are examined for their ability to retard the mobility of a ³²P-labeled DNA fragment. By incubating the protein with a variety of DNA fragments, it is possible to examine its specific and nonspecific DNA binding properties

and to precisely localize the DNA-binding sequences. This “reverse mobility shift assay” is very convenient, and it has the advantage that the fate of the ^{35}S -labeled protein is followed directly. However, *in vitro* synthesized proteins can be tested for their DNA-binding properties by the conventional mobility shift assay using ^{32}P -labeled DNA (in which case the protein does not have to be radiolabeled) or by immunoprecipitation of protein-DNA complexes (Johnson and Herskowitz, 1985).

In interpreting the results of such reverse mobility shift assays it is necessary to consider the parameters governing gel mobilities. The mobility of a given free protein in nondenaturing gels depends upon its charge:mass ratio, a property that varies greatly among proteins and is strongly affected by pH. This means that the band corresponding to free protein can appear anywhere on the gel and its location can be strongly affected by the precise gel conditions. Thus, in order to distinguish between bands corresponding to free protein and those corresponding to protein-DNA complexes, it is crucial to perform parallel control reactions that lack DNA (since the DNA is unlabeled, its mobility in the absence of protein is irrelevant). With respect to the specific protein-DNA complex, the mobility is affected by the amount of nonspecific bulk DNA in the reaction. In the absence of carrier DNA, the complex migrates very slowly because it contains nonspecific DNA-binding proteins from the translation extract in addition to the ^{35}S -labeled protein. As the amount of bulk DNA is increased, these nonspecific DNA-binding proteins are competed off the target DNA; hence the protein-DNA complex migrates further in the gel. In addition, it is important to note that because the protein is radiolabeled, nonspecific DNA-binding complexes can be observed; for this reason, it is inadvisable to use very high concentrations of bulk carrier DNA. Finally, the mobility of a protein-DNA complex is strongly influenced by the molecular weight of the protein component; complexes with larger proteins migrate more slowly.

Perhaps the most significant advantage of this approach is that any desired mutant protein can be created simply by altering the DNA template, and then tested for its DNA-binding properties. For example, by creating a set of N- or C-terminal deletions of the protein, the DNA-binding domain can be localized (Hope and Struhl, 1986). The availability of truncated but functional proteins can be useful for determining the subunit structure of a protein (Hope

and Struhl, 1987). Specifically, the target DNA is incubated with a cosynthesized mixture of two proteins of different size obtained by carrying out the protocol on an equimolar mixture of DNA templates. As mentioned above, protein-DNA complexes involving each of the individual proteins will have a different electrophoretic mobility. If, for example, the protein binds as a dimer, the cosynthesized mixture will generate three protein-DNA complexes in a 1:2:1 molar ratio, with the complex of intermediate mobility representing a heterodimer containing the two different protein species. Proteins binding as monomers will yield two equimolar complexes, whereas proteins binding as tetramers will yield five complexes in a 1:4:6:4:1 molar ratio. The principle of using different sized proteins to determine stoichiometry is not constrained to the specific DNA-binding assay. Other methods, such as glutaraldehyde crosslinking followed by SDS-PAGE can be used to examine the protein species.

Critical Parameters

The ability to demonstrate specific DNA-binding activity using the “reverse mobility shift assay” depends on a number of factors. Of course, it is crucial that a reasonable amount of the ^{35}S -labeled protein is synthesized by *in vitro* transcription and translation (see *UNIT 10.17* for a detailed discussion). In general, it is not necessary to purify the radiolabeled protein away from the unlabeled proteins in the translation extract. As is the case with the more conventional mobility shift assay, the conditions for carrying out the binding reaction and electrophoresis can have an enormous impact (for a detailed discussion, see *UNIT 12.2*). The relative amounts of radiolabeled protein, specific DNA fragment, nonspecific DNA fragments, and bulk carrier DNA are particularly important because the presence of labeled protein means that all protein-DNA complexes are observable. If multiple DNA fragments are included in the binding reaction, their molecular weights should be sufficiently different such that the individual complexes can be distinguished. It is also important to perform electrophoresis under conditions that clearly separate the protein from the protein-DNA complex; this is generally very easy. Finally, a general consideration is that the protein synthesized *in vitro* may not be active either because its structure is different from the native protein or because a critical cofactor is missing. For such reasons, it is possible that proteins synthesized in wheat

germ extracts or reticulocyte lysates might have different properties.

Anticipated Results

The ideal protein-DNA complex gel should appear as follows. In the absence of DNA, many radiolabeled proteins will not yield a band because they migrate in the wrong direction due to their positive charge at the gel pH; other "free proteins" will generate a band. In the presence of DNA containing a high-affinity binding site, a new band indicative of a protein-DNA complex will be observed. In the presence of DNA fragments containing mutant binding sites or unrelated DNA sequences, protein-DNA complex bands may be observed, but their intensities should be significantly lower than observed for the specific binding site. Such low-intensity bands reflect nonspecific, low-affinity interactions with DNA that are characteristic of specific DNA-binding proteins. The distinction between specific and nonspecific interactions can often be enhanced by competition binding experiments in which the radiolabeled protein is incubated with a collection of DNA fragments, only one of which contains the correct target sequence. In this case, there should be one intense band corresponding to the nonspecific complexes. For experiments involving different sized derivatives of a given protein, complexes formed with truncated proteins will migrate more quickly than those with full-length proteins.

Time Considerations

It is useful to prepare the DNA fragments to

be tested for binding concurrently with the preparation of protein. Once radiolabeled protein has been synthesized and the target DNA fragments prepared, it takes about an hour to set up and perform the DNA-binding reactions, a few hours to run the non-denaturing gel, and a few more hours to carry out the steps for autoradiography. An overnight exposure is usually sufficient to visualize the results.

A typical preparation of protein can be used for 20 to 50 DNA-binding reactions (including control reactions). If a given protein is to be synthesized on multiple occasions, it is useful to prepare excess amounts of cleaved DNA template and/or mRNA.

Purification of Sequence-Specific DNA-Binding Proteins by Affinity Chromatography

UNIT 12.10

Many biological processes, such as recombination, replication, and transcription, involve the action of sequence-specific DNA-binding proteins. Analysis and purification of these proteins by conventional chromatographic methods is often difficult because DNA-binding proteins typically make up <0.01% of the total cellular protein. Various methods have been developed for purifying such proteins. Affinity chromatography is a very effective means of purifying a protein based on its sequence-specific DNA-binding properties and is relatively straightforward if proper care is taken. The affinity chromatography procedure described in this unit uses DNA containing specific recognition sites for the desired protein that has been covalently linked to a solid support. Researchers in the past have purified proteins based on the proteins' ability to bind DNA, only to be disappointed to find that the DNA-binding activity of their highly purified products was not sequence-specific. This situation can be avoided by carefully performing all of the preliminary steps and experimental controls.

The first basic protocol describes preparation of a DNA affinity resin, including cyanogen bromide (CNBr) activation of the agarose support. The alternate protocol provides a method to couple DNA to commercially available CNBr-activated Sepharose. The first support protocol describes how to purify crude synthetic oligonucleotides by gel electrophoresis prior to preparation of the affinity resin. The second basic protocol outlines the affinity chromatography procedure. The second support protocol describes determination of the appropriate type and quantity of nonspecific competitor DNA that should be used in the procedure and its preparation. Parameters essential to the success of an affinity chromatography experiment are discussed in detail in the Commentary. Figure 12.10.1 provides a summary diagram of the entire chromatography procedure.

PREPARATION OF DNA AFFINITY RESIN

Correct choice of oligonucleotide sequence (discussed in detail in the Commentary) and preparation of the affinity resin are probably the most important parts of the affinity chromatography procedure. Preparation of affinity resin can be broken down into four steps: (1) preparing oligonucleotides; (2) activating Sepharose; (3) coupling DNA to resin; and (4) blocking unreacted CNBr. The first step requires highly purified oligonucleotides that contain the recognition sequence for the desired protein. Once purified, the complementary oligonucleotides are annealed, phosphorylated with T4 polynucleotide kinase, and ligated into long, multimeric chains (averaging ≥ 10 -mers) with T4 DNA ligase. Sepharose CL-2B is activated with CNBr, the ligated DNA added, and the coupling reaction carried out overnight. Because CNBr is very toxic, researchers may prefer to employ the alternate protocol, which uses commercially available CNBr-activated Sepharose and therefore avoids direct handling of CNBr. After the coupling reaction, the remaining reactive groups are blocked with ethanolamine. This protocol is designed to prepare 10 ml of affinity resin.

NOTE: Glass-distilled or other high-quality water should be used throughout these procedures.

Interactions**

12.10.1

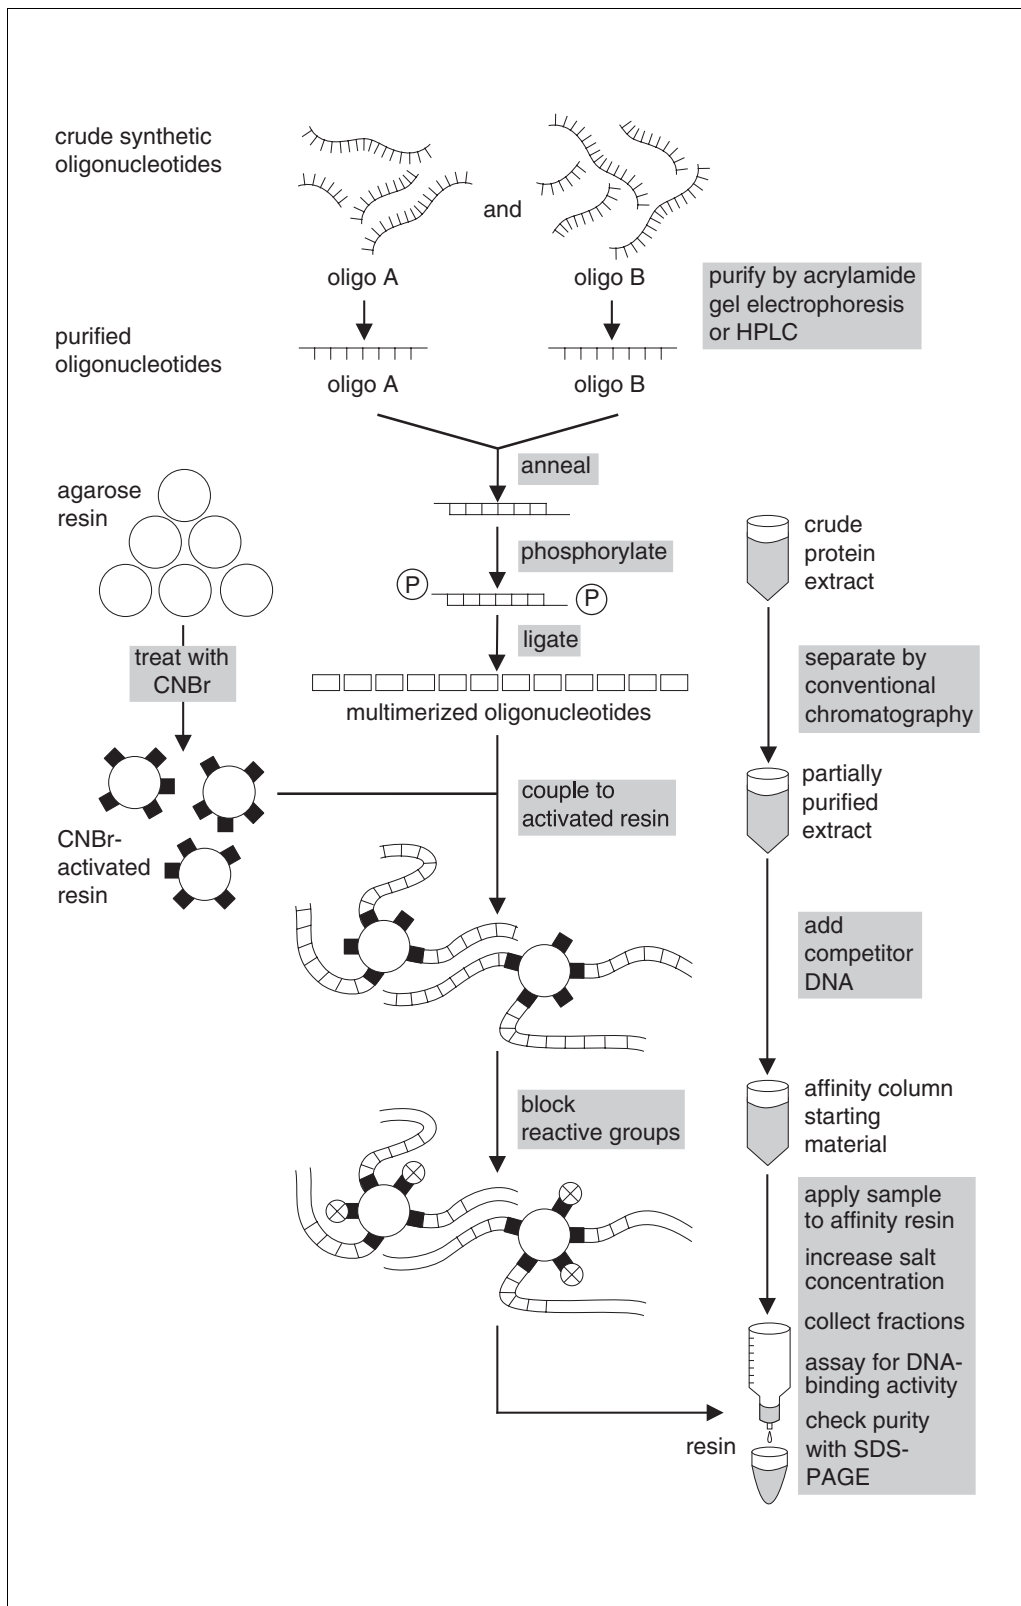

Figure 12.10.1 Purification of sequence-specific DNA-binding proteins with DNA affinity chromatography. Shown are the steps required to perform an affinity chromatography experiment using the methods described in this unit.

Materials

440 µg each of two synthetic oligonucleotides with desired binding site
(support protocol or commercial HPLC-purified)
TE buffer, pH 7.8 (*APPENDIX 2*)
10× T4 polynucleotide kinase buffer
20 mM ATP (Na⁺ salt), pH 7.0
150 mCi/ml [γ -³²P]ATP (6000 Ci/mmol)
10 U/µl T4 polynucleotide kinase (New England Biolabs; *UNIT 3.10*)
10 M ammonium acetate (*APPENDIX 2*)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (*UNIT 2.1*)
24:1 (v/v) chloroform/isoamyl alcohol
3 M sodium acetate (*APPENDIX 2*)
100% and 75% ethanol
10× linker/kinase buffer
6000 U/ml T4 DNA ligase (measured in Weiss units;
New England Biolabs; *UNIT 3.14*)
Buffered phenol (*UNIT 2.1*)
Isopropanol (2-propanol)
Sephacryl CL-2B (Pharmacia Biotech)
Cyanogen bromide (CNBr; Aldrich)
N,N-dimethylformamide
5 N NaOH (*APPENDIX 2*)
10 mM and 1 M potassium phosphate buffer, pH 8.0
1 M ethanolamine hydrochloride, pH 8.0
NaOH, solid
Glycine
1 M KCl (*APPENDIX 2*)
Column storage buffer

15-ml screw-cap polypropylene tubes
Heating blocks or water baths, 15°C, 37°C, 65°C, and 88°C
60-ml coarse-sintered glass funnel
Rotating wheel

Additional reagents and equipment for agarose gel electrophoresis of
DNA (*UNIT 2.5A*) and DNA purification (*UNIT 2.1*)

5'-phosphorylate the oligonucleotides

1. In a 1.5-ml microcentrifuge tube, prepare a mixture containing 440 µg of each oligonucleotide in TE buffer in a total volume of 130 µl. Add 20 µl of 10× T4 polynucleotide kinase buffer. Incubate 2 min at 88°C, 10 min at 65°C, 10 min at 37°C, and 5 min at room temperature.

A 1-µmol synthesis of oligonucleotide should yield enough purified DNA for ~20 ml of affinity resin.

2. Divide mixture in half in separate microcentrifuge tubes. To each 75-µl aliquot, add 15 µl of 20 mM ATP (pH 7.0), ~5 µCi [γ -³²P]ATP, and 10 µl of 10 U/µl T4 polynucleotide kinase (100 U total). Incubate 2 hr at 37°C.

Dividing the reaction in half at this point facilitates the steps that follow. To add the labeled ATP, do not thaw, but simply touch (do not jab) the top of the frozen [γ -³²P]ATP with a yellow pipet tip and transfer the resulting tiny amount to the reaction tube.

3. Inactivate the kinase by adding 50 µl of 10 M ammonium acetate and 100 µl water to each tube and heating 15 min at 65°C. Allow to cool to room temperature.

Purify phosphorylated oligonucleotides

4. Add 750 μ l of 100% ethanol and mix by inversion. Microcentrifuge at high speed 15 min at room temperature to pellet DNA. Discard supernatant.
5. Resuspend each pellet in 225 μ l TE buffer.
6. Add 250 μ l of 25:24:1 phenol/chloroform/isoamyl alcohol to each tube. Vortex 1 min. Microcentrifuge at high speed 5 min to separate phases. Transfer the aqueous phase (upper layer) to a new tube.
7. Add 250 μ l of 24:1 chloroform/isoamyl alcohol to aqueous phase. Vortex 1 min. Microcentrifuge at high speed 5 min to separate phases. Transfer the aqueous phase (upper layer) to a new tube.
8. Add 25 μ l of 3 M sodium acetate to aqueous phase and mix by vortexing. Then add 750 μ l of 100% ethanol and mix by inversion. Microcentrifuge at high speed 15 min to pellet DNA. Discard supernatant.
9. Wash pellet with 800 μ l of 75% ethanol. Mix by vortexing. Microcentrifuge at high speed 5 min. Discard supernatant.
10. Dry pellet in vacuum evaporator (e.g., Speedvac).

Ligate oligonucleotides

11. Add 65 μ l water and 10 μ l of 10 \times linker/kinase buffer to each pellet. Dissolve DNA by vortexing. Add 20 μ l of 20 mM ATP (pH 7.0) and 5 μ l of 6000 U/ml T4 DNA ligase (30 Weiss units). Incubate \geq 2 hr at room temperature or overnight at 15°C.

Depending upon the oligonucleotides used, the optimal temperature for ligation will vary from 4° to 30°C. Short oligonucleotides (\leq 15-mers) tend to ligate better at lower temperatures (4° to 15°C), whereas oligonucleotides that have a moderate degree of palindromic symmetry tend to self-anneal and therefore ligate better at higher temperatures (15° to 30°C).

12. Monitor the ligation reaction by agarose gel electrophoresis, using 0.5 μ l of ligation reaction per gel lane and including lanes containing size markers. Visualize DNA by ethidium bromide staining and UV photography.

5'-phosphorylated oligonucleotides often do not ligate on the first attempt. If ligation has not occurred, extract the DNA once with 25:24:1 phenol/chloroform/isoamyl alcohol and once with 24:1 chloroform/isoamyl alcohol, then ethanol precipitate using sodium acetate as the precipitating salt. Dissolve the DNA in 225 μ l TE, add 25 μ l of 3 M sodium acetate, and reprecipitate with 750 μ l of 100% ethanol. Wash with 75% ethanol, dry in Speedvac, and repeat ligation.

The average length of the ligated oligonucleotides should be \geq 10-mers. Ligating the oligonucleotides increases the binding capacity of the affinity resin and helps avoid potential problems due to steric hindrance between the factor and the Sepharose support. However, oligonucleotide multimers $<$ 10-mers will probably also work.

Purify oligonucleotide multimers

13. Add 100 μ l buffered phenol to the 100- μ l ligation reactions. Vortex 1 min. Microcentrifuge at high speed 5 min at room temperature. Transfer aqueous phase (upper layer) to a new tube.
14. Add 100 μ l of 24:1 chloroform/isoamyl alcohol to aqueous phase. Vortex 1 min. Microcentrifuge at high speed 5 min, room temperature. Transfer aqueous phase (upper layer) to a new tube.
15. Add 33 μ l of 10 M ammonium acetate to the aqueous phase. Mix by vortexing.

16. Add 133 μ l isopropanol. Mix by inversion. Incubate 20 min at -20°C . Microcentrifuge at high speed 15 min to pellet DNA. Discard supernatant.

The ammonium acetate/isopropanol precipitation removes residual ATP, which would otherwise interfere with coupling of the ligated DNA to the CNBr-activated Sepharose.

17. Add 225 μ l TE buffer. Vortex to dissolve pellet. Add 25 μ l of 3 M sodium acetate. Mix by vortexing. Add 750 μ l of 100% ethanol. Mix by inversion. Microcentrifuge at high speed 15 min to pellet DNA. Discard supernatant.
18. Wash DNA twice with 75% ethanol. Dry pellet in vacuum evaporator.
19. Dissolve DNA in 50 μ l water. Store at -20°C .

Do not dissolve the DNA in TE buffer, as the Tris buffer in TE will interfere with the coupling reaction.

Prepare CNBr-activated Sepharose

It is best to assemble all equipment and reagents required for the activation and coupling reactions *before* proceeding with the following steps.

20. Place 10 to 15 ml (settled bed volume) of Sepharose CL-2B in a 60-ml coarse-sintered glass funnel and wash extensively with 500 ml water.

To wash, add water to resin in funnel, stir gently with a glass rod, and remove water by vacuum suction, making sure to release vacuum before the resin is suctioned into a dry cake. Repeat until all 500 ml water is used.

21. Transfer moist Sepharose resin to a 25-ml graduated cylinder, estimating 10 ml of resin. Add water to 20 ml final volume. Transfer the resulting slurry to a 150-ml glass beaker containing a magnetic stir bar. Place beaker in a water bath equilibrated to 15°C and set up over a magnetic stirrer in a fume hood. Turn on stirrer to slow medium speed.

Keep the water bath at 15°C by periodically adding small chunks of ice as needed. Occasional variation of a degree or two is not critical.

22. In the fume hood, measure 1.1 g CNBr into a 25-ml Erlenmeyer flask, keeping the mouth of the flask covered with Parafilm or a ground glass stopper as much as possible (it is better to have slightly more than 1.1 g than slightly less). Add 2 ml *N,N*-dimethylformamide (the CNBr will dissolve instantly). Over the course of 1 min, add the resulting CNBr solution dropwise to the stirring Sepharose slurry.

CAUTION: *CNBr is highly toxic and volatile. Use only in a fume hood with extreme caution. Observe appropriate decontamination and disposal procedures.*

23. Immediately add 5 N NaOH as follows: add 30 μ l to the stirring mixture every 10 sec for 10 min until 1.8 ml NaOH has been added.

It is convenient to measure 1.8 ml NaOH into a small tube before addition to the reaction to avoid having to change pipet tips during the 10-sec additions.

24. Immediately add 100 ml ice-cold water to the beaker and pour the mixture into a 60-ml coarse-sintered glass funnel.

IMPORTANT: *At this point, it is very important to avoid suction-filtering the resin into a dry cake. If the resin is accidentally dried into a cake, do not use; instead, repeat steps 20 to 24 with fresh resin.*

25. Still working in the fume hood, wash the resin in the funnel with four 100-ml washes of ice-cold ($\leq 4^{\circ}\text{C}$) water followed by two 100-ml washes of ice-cold 10 mM potassium phosphate, pH 8.0.
26. Immediately transfer the resin to a 15-ml polypropylene screw-cap tube and add ~4 ml of 10 mM potassium phosphate (pH 8.0) until the resin has the consistency of a thick slurry.

Couple oligonucleotide multimers to CNBr-Sepharose

27. Immediately add the two 50- μl aliquots of DNA from step 19. Incubate on a rotating wheel overnight (≥ 8 hr) at room temperature.
28. In the fume hood, transfer the resin to a 60-ml coarse-sintered glass funnel and wash with two 100-ml washes of water and one 100-ml wash of 1 M ethanolamine hydrochloride, pH 8.0.

Using a Geiger counter, compare the level of radioactivity in the first few milliliters of filtrate with the level of radioactivity in the washed resin to estimate the efficiency of incorporation of DNA to the resin. Usually, all detectable radioactivity is present in the resin.

29. In the fume hood, transfer the resin to a 15-ml polypropylene screw-cap tube and add 1 M ethanolamine hydrochloride (pH 8.0) until the mixture is a smooth slurry. Incubate the tube on a rotating wheel 2 to 4 hr at room temperature.

This step inactivates unreacted CNBr-activated Sepharose.

It is important to clean up all CNBr waste carefully. In the fume hood, add solid NaOH and glycine (~10 to 20 mg/ml) to inactivate the CNBr. Soak contaminated instruments in a similar solution. Let sit overnight in the fume hood, then discard.

30. Wash the resin in a 60-ml coarse-sintered glass funnel with 100 ml of 10 mM potassium phosphate (pH 8.0), 100 ml of 1 M potassium phosphate (pH 8.0), 100 ml of 1 M KCl, 100 ml water, and 100 ml column storage buffer.
31. Store the resin at 4°C (stable at least one year; do not freeze).

**ALTERNATE
PROTOCOL**

**COUPLING THE DNA TO COMMERCIALY AVAILABLE
CNBr-ACTIVATED SEPHAROSE**

The major advantage of this alternate procedure is that it begins with commercially available CNBr-activated chromatography resin, avoiding the need for preparation of CNBr-activated resin (first basic protocol). However, commercial CNBr-Sepharose is considerably more expensive than the homemade variety; moreover, the resulting column tends to run more slowly than one prepared as described above. Both resins are effective, leaving it up to the researcher's discretion which to use.

Additional Materials

1 mM HCl (*APPENDIX 2*), prepared fresh before use
CNBr-activated Sepharose 4B (Pharmacia Biotech)

1. Carry out steps 1 to 19 of the first basic protocol.
2. Weigh out 3 g CNBr-activated Sepharose 4B (1 g freeze-dried resin gives ~3.5 ml final gel volume).
3. Place the dry resin in a 15-ml conical polypropylene tube. Hydrate resin with 10 ml of 1 mM HCl and mix gently by flicking and inverting the tube. After 1 min, transfer

slurry to a 60-ml coarse-sintered glass funnel. Wash and swell the beads by gradually pouring 500 ml of 1 mM HCl through the funnel (this will take ~15 min).

4. Wash the resin with 100 ml water and then with 100 ml of 10 mM potassium phosphate, pH 8.0.
5. Proceed with steps 26 through 31 of the first basic protocol.

PURIFICATION OF OLIGONUCLEOTIDES BY PREPARATIVE GEL ELECTROPHORESIS

**SUPPORT
PROTOCOL**

Preparation of affinity resin requires a large amount (1- μ mol synthesis) of purified synthetic oligonucleotides. The oligonucleotides used to prepare the affinity resin must be of high purity because contaminating, incompletely synthesized oligonucleotides can interfere with the ligation reaction. HPLC-purified oligonucleotides are of sufficient purity for preparation of DNA affinity resins; however, it is normally expensive to obtain such oligonucleotides. An alternative is to purify crude oligonucleotides by the following method (a variation of the approach described in *UNIT 2.12*).

Additional Materials

40% (w/v) 19:1 acrylamide/bisacrylamide

10 \times TBE buffer (*APPENDIX 2*)

Urea

10% (w/v) ammonium persulfate (*UNIT 10.3*)

TEMED

Formamide loading buffer

sec-butanol (2-butanol)

Diethyl ether

1 M MgCl₂ (*APPENDIX 2*)

Saran wrap or other UV-transparent plastic wrap

Intensifying screen (e.g., Lightning Plus, DuPont NEN)

Hand-held short-wavelength UV light source

Silanized glass wool (*APPENDIX 3*)

Dry ice/ethanol bath (-78°C)

Additional reagents and equipment for purification of oligonucleotides by denaturing polyacrylamide gel electrophoresis (*UNIT 2.12*), agarose gel electrophoresis of DNA and gel photography (*UNIT 2.5A*), and butanol concentration and ether extraction of DNA (*UNIT 2.1*)

Purify oligonucleotides by gel electrophoresis

1. Prepare a 20 cm \times 40 cm \times 1.5 mm denaturing gel with four wells 3 cm in width, using 16% polyacrylamide/urea for separating oligonucleotides ~10 to ~45 bases long (or 8% or 6% polyacrylamide/urea for longer oligonucleotides). Let gel polymerize for \geq 30 min, then prerun at 30 W for \geq 1 hr.
2. Dissolve each oligonucleotide in formamide loading buffer to 200 μ l final. Heat 15 min at 65°C to remove any secondary structure in the DNA. Load 50 μ l of samples into separate wells, and run the gel at 30 W for ~4 hr.

The amount of oligonucleotide that is prepared in a 1- μ mol synthesis (~1 to 2 mg) can be loaded on one gel (0.25 μ mol per 3-cm well). This is the maximum amount that can be applied to the gel without overloading it.

It takes ~4 hr for the bromphenol blue to migrate three-quarters of the way down the gel, which is far enough to purify oligonucleotides of 15 to 30 bases. In a 16% gel, bromphenol blue comigrates with ~10-base oligonucleotides and xylene cyanol com-

**DNA-Protein
Interactions**

12.10.7

igrates with ~30-base oligonucleotides. If the oligonucleotide is 25 to 35 bases long, it is recommended that the formamide loading buffer be made without xylene cyanol.

Visualize gel by UV shadowing

3. Remove one of the glass gel plates and cover the gel with Saran wrap. Flip gel over and remove the other plate so that the gel is lying on the Saran wrap. Cover the other side of the gel with Saran wrap.
4. In a darkroom, lay the gel on an intensifying screen and hold a hand-held short-wavelength UV light source directly over it to visualize the DNA. Identify the major oligonucleotide band and mark its position directly on the Saran wrap using a marker, making sure that the light is directly over the band.

The major band (usually the largest oligonucleotide but sometimes the next-to-largest) should be visible as a thick, dark band in the gel.

Purify oligonucleotides from gel

5. Carefully cut out the band with a razor blade, trying to avoid shredding the gel material or pulverizing the gel slice into small pieces.
6. Soak the gel piece in 5 ml TE buffer in a 15-ml polypropylene tube overnight at 37°C with shaking.
7. Place a silanized glass wool plug in a Pasteur pipet and prerinse with ~5 ml water. Filter the supernatant containing the DNA through the glass wool.
8. Concentrate the DNA to $\leq 180 \mu\text{l}$ by repeated extractions with *sec*-butanol.
9. Extract the DNA once with diethyl ether and place in a vacuum evaporator (e.g., Speedvac) until all traces of ether are removed.
10. Adjust the volume of the liquid to 180 μl with TE buffer. Add 20 μl of 3 M sodium acetate and 2 μl of 1 M MgCl_2 . Mix by vortexing.
11. Add 600 μl of 100% ethanol. Mix by inversion. Chill 10 min in dry ice/ethanol. Let stand 5 min at room temperature. Microcentrifuge at high speed 15 min, room temperature, to pellet DNA. Discard supernatant.
12. Add 180 μl TE buffer. Dissolve pellet by vortexing. Add 20 μl of 3 M sodium acetate and 2 μl of 1 M MgCl_2 . Mix by vortexing.
13. Add 600 μl of 100% ethanol. Mix by inversion. Chill 10 min in dry ice/ethanol. Let stand 5 min, room temperature. Microcentrifuge at high speed 15 min, room temperature. Discard supernatant.
14. Add 800 μl of 75% ethanol. Mix by vortexing. Microcentrifuge at high speed 5 min, room temperature. Discard supernatant.
15. Carefully dry pellet in vacuum evaporator (sometimes static electricity will cause the pellet to jump out of the tube).
16. Dissolve DNA in 200 μl TE buffer and measure A_{260} and A_{280} . Store at -20°C indefinitely.

For sequence-specific DNA affinity resins, assume that 1 A_{260} unit = 40 $\mu\text{g/ml}$ DNA.

DNA AFFINITY CHROMATOGRAPHY

Affinity chromatography is performed by combining a partially purified protein sample with appropriate competitor DNA, pelleting the insoluble protein-DNA complexes by centrifugation, and loading the resulting soluble material by gravity flow onto the affinity resin. Nonspecific DNA-binding proteins flow through the column while the specific protein is retained by the column. The protein is then eluted by gradually increasing the salt concentration of the buffer and individual fractions are tested for DNA-binding activity and purity. Fractions containing appropriate DNA-binding activity can be reapplied to the affinity resin if further purification is desired. By using two sequential affinity chromatography steps, a typical protein can be purified 500- to 1000-fold with ~30% yield. The method described below is performed with buffer Z, but many other buffers will work as well. Buffer choice is addressed in the Commentary.

Materials

- Prepared DNA affinity resin (first basic or alternate protocol)
- Buffer Z or other column buffer (e.g., buffers Z^c or TM) made with varying KCl concentrations (buffers Z/0.1 M KCl through Z/1 M KCl)
- Partially purified protein fraction dialyzed against buffer Z/0.1 M KCl
- Nonspecific competitor DNA (support protocol)
- Column regeneration buffer
- Column storage buffer
- Disposable chromatography column (Poly-Prep, Bio-Rad)
- Sorvall SS-34 rotor or equivalent
- Liquid nitrogen
- Narrow glass rod, silanized (*APPENDIX 3*)
- Additional reagents and equipment for DNA-binding assays (*UNITS 12.2-12.4*), SDS-PAGE (*UNIT 10.2*), and silver staining (*UNIT 10.6*)

1. Equilibrate 1 ml settled bed volume of the DNA affinity resin in a disposable chromatography column with two 10-ml washes of buffer Z/0.1 M KCl.
2. Combine the partially purified protein fraction in buffer Z/0.1 M KCl with nonspecific competitor DNA as determined by DNA-binding studies (see Commentary and support protocols).
3. Incubate mixture 10 min on ice.
4. Centrifuge mixture 10 min at 12,000 × g (10,000 rpm in Sorvall SS-34 rotor), 4°C, to pellet insoluble protein-DNA complexes.
5. Load the supernatant onto the column at gravity flow (e.g., 15 ml/hr per column for Sepharose CL-2B).

A single 1-ml column is sufficient for a standard nuclear extract (e.g., 12 liters of HeLa cells or 150 g of Drosophila embryos). When purifying a larger quantity of material, it is preferable to use multiple 1-ml columns. It is common practice to apply as much as 50 ml of protein sample onto a single 1-ml column.

Typically, 1 ml of affinity resin contains ~80 to 90 μg DNA, which corresponds to a protein-binding capacity of 7 nmol/ml of resin, assuming one recognition site per 20 bp.

6. After loading the starting material, wash the column four times with 2-ml aliquots of buffer Z/0.1 M KCl, rinsing the sides of the column each time.

It is very important to wash the affinity column thoroughly at this step by rinsing down the sides of the column with the 2-ml wash buffer aliquots; a single 8-ml wash is not effective.

DNA affinity columns will often yield >100-fold purification of the desired factor. When a protein is purified 100-fold, however, a 1% contamination of the starting material due to inefficient washing of the column will lead to major contamination of the affinity-purified factor.

7. Elute the protein from the column by successive addition of 1-ml portions of buffer Z/0.2 M KCl, buffer Z/0.3 M KCl, buffer Z/0.4 M KCl, buffer Z/0.5 M KCl, buffer Z/0.6 M KCl, buffer Z/0.7 M KCl, buffer Z/0.8 M KCl, and buffer Z/0.9 M KCl, followed by three 1-ml aliquots of buffer Z/1 M KCl. Collect 1-ml fractions that correspond to the addition of the 1-ml portions of buffer. Quick-freeze the protein samples in liquid nitrogen and store at -80°C . Samples can generally be stored for at least 2 years.

It is convenient to save separate aliquots of each fraction for DNA-binding assays (20 μl each) and SDS-PAGE analysis (50 μl each).

8. Assay the protein fractions for the sequence-specific DNA-binding activity using a DNA-binding assay. Estimate the purity of the protein fractions by SDS-PAGE followed by silver staining to visualize the protein.

If further purification is desired, combine the fractions that contain the activity and, depending on the KCl concentration, either dilute (using buffer Z without KCl) or dialyze (against buffer Z/0.1 M KCl) to 0.1 M KCl. Then combine the protein fraction with nonspecific competitor DNA (the amount and type of which must be determined experimentally as described in the support protocol) and reapply to either fresh or regenerated DNA affinity resin.

In some instances, proteins might still be bound to the affinity resin after the 1 M salt elution step (step 7). Thus, if the desired protein is not detected in either the column fractions or flowthrough, it is possible that the protein is still on the column, and a wash at a higher salt concentration (e.g., 2 M KCl) may be needed to elute the protein from the resin.

9. Regenerate the affinity resin as follows: At room temperature, stop the column flow and add 5 ml column regeneration buffer to the column. Stir the resin with a silanized narrow glass rod to mix the resin with the regeneration buffer. Let the buffer flow out of the column. Repeat step.
10. To store column, add 10 ml column storage buffer and allow to flow through. Repeat this wash, then close the bottom of the column and add another 5 ml buffer. Cover top of column and store at 4°C .

The column may be stored for ≤ 1 year. Alternatively, the affinity resin may be removed from the column after the two washes and stored in a clean polypropylene tube with the 5 ml buffer.

SELECTION AND PREPARATION OF NONSPECIFIC COMPETITOR DNA

Proper use of competitor DNA is essential for successful purification of DNA-binding proteins by affinity chromatography. Common competitor DNAs include poly(dI-dC), poly(dA-dT), poly(dG-dC), and calf thymus DNA. The amount and type of competitor to use in a given experiment must be determined experimentally. A typical method is to mix a protein sample (the exact fraction that will be applied to the affinity resin) with varying amounts of different competitor DNAs and evaluate DNA binding using assays such as DNase I footprinting (*UNIT 12.4*) or gel mobility shifts (*UNIT 12.2*; see Commentary). The competitor DNA that inhibits DNA binding the least should be used for DNA affinity chromatography. It is perhaps easiest to think of these binding experiments as scaled-down affinity columns. First, determine the highest amount of competitor DNA that can be added to a DNA-binding reaction that does not interfere with the binding of the sequence-specific factor. To move up to a full-scale experiment, use one-fifth of the amount that would be required if the binding reaction were directly scaled up.

The following example with a hypothetical factor M illustrates how to determine the amount of competitor to use in an affinity chromatography experiment. Using DNase I footprinting, a strong footprint was observed with 5 μ l of a 0.4 M heparin fraction. Testing various competitors reveals that calf thymus DNA, poly(dI-dC), and poly(dG-dC) all strongly inhibit binding of factor M. However, no detectable inhibition of factor M binding is observed with 2 μ g poly(dA-dT), weak but detectable inhibition is observed with 3 μ g poly(dA-dT), and strong inhibition is observed with 4 μ g poly(dA-dT). In this example, with 5 μ l of the 0.4 M heparin fraction, the highest amount of poly(dA-dT) that does not inhibit factor M binding is 2 μ g. If 5 ml of the 0.4 M heparin fraction is available, the direct scale-up would be 1000-fold, so $1000 \times 2 \mu\text{g} = 2000 \mu\text{g}$ poly(dA-dT) would be needed. Because in an affinity chromatography experiment one-fifth of the direct scale-up amount is used, the appropriate amount of poly(dA-dT) to add to 5 ml of the 0.4 M heparin fraction is $2000 \mu\text{g} \times 1/5 = 400 \mu\text{g}$.

The optimal amount of competitor DNA will vary with the purity of the partially purified protein sample. Fractions that contain more nonspecific DNA-binding proteins will normally require more competitor DNA and thus it is necessary to determine experimentally the optimal amount of DNA to use with each protein fraction. In addition, the amount of competitor DNA is estimated as the mass of DNA (in micrograms) to add per volume (in milliliters) of protein fraction; this is because it is likely that competitor DNA acts by forming a complex with high-affinity, nonspecific DNA-binding proteins in the crude extract. Different competitor DNAs can be used in a single experiment.

To prepare poly(dI-dC), poly(dG-dC), and poly(dA-dT), dissolve the desired amount of competitor DNA to a final concentration of 10 A_{260} units in TE buffer per 100 mM NaCl. Heat the sample to 90°C and slowly cool to room temperature over 30 to 60 min. If the average length of the DNA is >1 kb, degrade it by sonication. Estimate the length of the DNA by agarose gel electrophoresis (*UNIT 2.5*).

REAGENTS AND SOLUTIONS

Buffer TM

50 mM Tris-Cl, pH 7.9
0 M *or* 1 M KCl
12.5 mM MgCl₂
1 mM dithiothreitol (DTT; add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) Nonidet P-40 (NP-40)

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

Buffer Z

25 mM HEPES (K⁺ salt), pH 7.6
0 M *or* 1 M KCl
12.5 mM MgCl₂
1 mM DTT (add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) NP-40
Adjust pH to 7.6 with KOH

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

Buffer Z^e

25 mM HEPES (K⁺ salt), pH 7.6
0 M *or* 1 M KCl
1 mM DTT (add fresh just before use)
20% (v/v) glycerol
0.1% (v/v) NP-40
Adjust the pH to 7.6 with KOH

Do not make a 10× buffer. To generate aliquots of buffer with the range of KCl concentrations described in the protocol, make two 500-ml batches of 1× buffer containing no KCl and 1 M KCl respectively and mix together appropriate quantities. Store at 4°C. Just prior to use, place 1.5-ml aliquots of each concentration in separate 1.5-ml microcentrifuge tubes, and add DTT.

Column regeneration buffer

10 mM Tris-Cl, pH 7.8
1 mM EDTA, pH 8.0
2.5 M NaCl
1% (v/v) NP-40
Store at room temperature

The solution will be cloudy and separate into two phases (NP-40 and aqueous) upon storage. Mix by swirling and shaking just before use.

Column storage buffer

10 mM Tris·Cl, pH 7.8

1 mM EDTA, pH 8.0

0.3 M NaCl

0.04% (w/v) sodium azide

Store at room temperature without sodium azide. Make a 4% (w/v) sodium azide stock solution and add just before use.

1 M ethanolamine hydrochloride, pH 8.0

1 M ethanolamine

Adjust pH to 8.0 with HCl

Filter sterilize

Store at room temperature

Formamide loading buffer

90 ml deionized formamide (*UNIT 14.3*)

10 ml 10× TBE (*APPENDIX 2*)

40 mg xylene cyanol

40 mg bromphenol blue

Store at -20°C

Linker-kinase buffer, 10×

660 mM Tris·Cl, pH 7.6

100 mM MgCl_2

100 mM DTT

10 mM spermidine

Store at -20°C

Add an extra 10 mM DTT just before use

16% polyacrylamide-urea gel

50 ml 40% (w/v) 19:1 acrylamide/bisacrylamide

12.5 ml 10× TBE (*APPENDIX 2*)

62.5 g urea

17 ml H_2O

Mix, filter, briefly degas, and then add:

750 μl 10% (w/v) ammonium persulfate

20 μl TEMED

Pour immediately into prepared gel plates.

1 M potassium phosphate buffer, pH 8.0

A: 1 M K_2HPO_4

B: 1 M KH_2PO_4

Add A to B until pH = 8.0

T4 polynucleotide kinase buffer, 10×

500 mM Tris·Cl, pH 7.6

100 mM MgCl_2

50 mM DTT

1 mM spermidine

1 mM EDTA, pH 8.0

Store at -20°C

Add an extra 50 mM DTT just before use

COMMENTARY

Background Information

Purification of sequence-specific DNA-binding proteins has historically been a difficult task, mainly because such proteins are a small fraction of the total cellular protein. However, it is now possible to purify these factors quickly, simply, and effectively by using multimerized synthetic oligonucleotides that contain the recognition sequence for a particular DNA-binding protein. Early efforts with DNA-affinity-chromatography involved adsorption or coupling of nonspecific DNA (such as calf thymus DNA) to either cellulose (Alberts and Herrick, 1971) or agarose (Arndt-Jovin et al., 1975) supports. These methods paved the way for the development of a variety of sequence-specific DNA affinity chromatography techniques, including the procedures described in this unit.

Other methods have been described to purify sequence-specific DNA-binding proteins, including chromatography using biotinylated DNA fragments attached to various supports by biotin-avidin or biotin-streptavidin coupling (UNIT 10.6; Chodosh et al., 1986; Kasher et al., 1986; Leblond-Francillard et al., 1987), oligonucleotides synthesized onto Teflon-based beads (Duncan and Cavalier, 1988), or synthetic oligonucleotide monomers attached to agarose supports (Wu et al., 1987; Blanks and McLaughlin, 1988; Hoey et al., 1993); and preparative gel mobility shifts (Gander et al., 1988). Although more than 50 sequence-specific DNA-binding proteins have been purified by the method described in this unit (Kadonaga, 1991, and references therein), it is likely that many of the techniques listed above are also effective for purifying sequence-specific DNA-binding proteins.

There are a variety of reasons that CNBr activation is commonly used in the preparation of affinity resins: it is simple, works well with agarose matrices, and is mild enough to bind ligands such as DNA. Briefly, the chemistry of the CNBr activation reaction is as follows. At high pH, the hydroxyl groups on the agarose resin react with CNBr. The majority of the CNBr added to the reaction reacts with water to yield inert cyanate ions, which is part of the reason such a large amount of CNBr is required. Additionally, the majority of the cyanate esters that are formed on the agarose either are hydrolyzed to form inert carbamate or react with the matrix hydroxyls to form imidocarbonates. The imidocarbonates that form can act effectively as chemical cross-links, thus stabilizing the

matrix (which is in most cases beneficial, particularly if the agarose resin chosen is not covalently cross-linked). The remaining active cyanate esters are coupled to the amino-containing ligands (in this case, oligonucleotides) at physiological pH. Finally, the unreacted cyanate esters are blocked with an excess of a suitable reagent, such as ethanolamine, to prevent coupling of the protein sample to the matrix (Janson and Rydén, 1989).

Critical Parameters and Troubleshooting

Basic strategy

The general approach to affinity purification of DNA-binding proteins is as follows. First, estimate the binding site of the desired protein by a technique such as DNase I footprinting (UNIT 12.4). If possible, it is best to survey a variety of promoters and enhancers. Next, determine the optimal conditions for protein binding to the DNA, considering factors such as temperature, ionic strength, pH, and Mg^{2+} concentration. Using conventional chromatography, partially purify the protein to remove contaminants such as nucleases that may degrade the affinity resin. Test a variety of nonspecific competitor DNAs, including poly(dI-dC), poly(dG-dC), poly(dA-dT), and calf thymus DNA to determine their effect on protein-DNA interactions. For best results, prepare two or more different DNA affinity resins with naturally occurring, high-affinity binding sites, preferably containing different flanking DNA sequences. The desired protein should bind with high affinity to both resins; if it does not, then it is likely that the protein that has been purified is not specific to the desired binding site. Finally, it is important to prepare a control resin that does not contain the recognition sequence for the desired protein. A control resin will make it possible to identify proteins that bind nonspecifically to DNA-Sepharose. Using this approach, it is possible to obtain a preparation containing a highly purified, sequence-specific DNA-binding protein.

Starting material and conventional chromatography

Extensive purification of the DNA-binding protein is not required for effective affinity chromatography. However, partial purification of the protein by conventional chromatography

is recommended prior to affinity chromatography to remove proteases and nucleases that might degrade either the protein or the affinity resin. Keep in mind that sequence-specific and nonspecific DNA-binding proteins will often co-purify in conventional chromatography, possibly because they may both interact with negatively charged polymers that resemble DNA. It is important to note that the most persistent contaminants in sequence-specific DNA-binding protein preparations are nonspecific, high-affinity DNA-binding proteins. Various conventional chromatographic methods may be employed prior to affinity purification of a DNA-binding protein; methods that have been used successfully in the past are discussed below.

Ion-exchange chromatography. One obvious first step might be cation-exchange chromatography with resins such as S-Sepharose Fast Flow/Mono S (Pharmacia Biotech), CM-52 (Whatman), CM Sepharose Fast Flow (Pharmacia Biotech), P11 phosphocellulose (Whatman), or Bio-Rex 70 (Bio-Rad). DNA-binding proteins (both specific and nonspecific) will normally bind to cation-exchange resins in buffers containing from 50 mM to 100 mM NaCl and can be eluted with higher salt concentrations.

Affinity chromatography. Nonspecific DNA-cellulose (Alberts and Herrick, 1971) or DNA-agarose (Arndt-Jovin et al., 1975) resins can be used for a preliminary purification step. These resins are typically prepared with salmon sperm or calf thymus DNA. Also, sequence-specific DNA affinity resins can be prepared with oligonucleotides that do not contain binding sites for the desired factor. A strategy for chromatography with either nonspecific DNA affinity resin (e.g., see Rosenfeld and Kelly, 1986) or sequence-specific DNA affinity resins that lack the binding site for the desired factor (e.g., see Kaufman et al., 1989) is as follows. Once the protein sample is applied to a nonspecific DNA affinity resin, the desired factor will either (1) flow through the resin or (2) elute from the resin at a low-salt concentration. High-affinity, nonspecific DNA-binding proteins should remain bound to the resin and will thus be separated from the desired protein. If this strategy is successful, it will not be necessary to add the competitor DNA prior to the subsequent sequence-specific affinity chromatography step because the high-affinity nonspecific DNA-binding proteins will already have been separated from the sample.

A resin that works well if the desired protein contains O-linked *N*-acetylglucosamine monosaccharide residues is wheat germ agglutinin-agarose. This method has been used successfully in the past with transcription factors such as Sp1 (Jackson and Tjian, 1989) and HNF1 (Lichtsteiner and Schibler, 1989).

Heparin-agarose chromatography. Heparin-agarose resins are also excellent for the purification of DNA-binding proteins because they possess properties similar to those of both ion-exchange and affinity resins. It is important to be aware that variability exists between different heparin-agarose preparations. This variability may be due to differences in the methods of coupling heparin to agarose, because alternate methods for coupling and blocking the agarose may produce different functional groups on the resin. If a particular batch of heparin-agarose is used successfully, it is wise to continue to use that batch to ensure reproducibility.

Gel-filtration chromatography. Finally, gel-filtration chromatography may be used effectively for partial purification of a DNA-binding protein because separation is based on size and shape, not DNA-binding properties. For example, gel filtration may be useful for separating a desired protein from contaminating nucleases and other nonspecific DNA-binding proteins, in contrast to chromatography using ion-exchange, heparin-agarose, and nonspecific DNA affinity resins that may actually enrich for DNA-binding proteins. In some cases gel filtration may be undesirable because significant sample dilution occurs; however, further concentration can be obtained by subsequent affinity chromatography.

DNA binding studies

Binding conditions. In order to use affinity chromatography to purify a DNA-binding protein, it is necessary to optimize binding conditions. It is important to determine these conditions experimentally, as ionic strength, temperature, pH, and presence or absence of Mg²⁺ can affect protein-DNA interactions. In addition, although HEPES and PIPES are often considered to be superior to Tris buffers, some commercially available preparations of HEPES and PIPES buffers contain contaminants that inhibit binding of proteins to DNA. Therefore, in some respects, it may be safer to use Tris buffer. It is also important to note that some factors, such as Sp1, bind with higher affinity to DNA in the absence of Mg²⁺ than in its

presence. Thus, in some cases it may be useful to omit Mg^{2+} in the chromatography buffer. In addition, although the procedures in this unit use buffers containing KCl, NaCl could probably be substituted. Although it is usually preferable to handle proteins at $4^{\circ}C$, proteins have been described that will not bind DNA at $4^{\circ}C$, yet bind perfectly well at room temperature; in such cases the temperature at which the affinity chromatography is performed should be adjusted accordingly. Finally, to minimize non-specific adsorption of affinity-purified proteins to plastic and glass, chromatography and storage buffers should contain a nonionic detergent such as NP-40 at a concentration of $\sim 0.01\%$ to 0.1% (v/v).

Binding assays. There are many methods for identifying proteins that are bound to DNA, including DNase I footprinting (Galas and Schmitz, 1978; *UNIT 12.4*), Fe-EDTA footprinting (Tullius et al., 1987), methidiumpropyl-EDTA- Fe^{2+} (MPE; Hertzberg and Dervan, 1982), methylation interference (*UNIT 12.3*), and gel mobility shift assays (*UNIT 12.2*). Although binding information may be obtained from all these techniques, it is most straightforward to use DNase I footprinting to identify a protein binding site. Additionally, DNase I is active over a broad range of buffer conditions, which allows for considerable variation in binding conditions. Visualization of the protected region by footprinting makes designing oligonucleotides for affinity chromatography relatively simple (as discussed later in this section). Both DNase I footprinting and gel mobility shift assays are useful for assaying affinity-column fractions.

Design of oligonucleotides

Many different parameters are important in designing oligonucleotides for an affinity resin. The first step, as described above, is to determine the protein-binding site on the DNA. The DNA affinity resin should be prepared from naturally occurring, high-affinity binding sites. Using a consensus sequence may work in some instances, but in most situations, a "real" binding site is best. Given that the length of the oligonucleotides can be reasonably flexible (14-mers to 61-mers have been used successfully), use of oligonucleotides that include the DNase I footprint as well as some flanking DNA (at least a few bases beyond the borders of the footprint) is recommended. In the early stages, it is better to copurify factors that bind to the flanking region than to fail to purify the desired factor because the binding site is too

short. It may be wise to avoid using oligonucleotides that are 21 or 42 bases in length because the DNA, if bent, might have a greater tendency to circularize during the ligation step. The oligonucleotides should also be designed with a single-stranded overhang, for two reasons: first, the ligation reaction will be more efficient (as compared to a blunt-end ligation), and second, it is likely that the DNA couples to the resin via the primary amine groups of the single-stranded overhang of the ligated multimers. The sequence GATC-XXX-BINDING SITE-XXX (where XXX represents the DNA flanking the binding site) works well, though it may also be convenient to use the sequences flanking the binding site as the overhang.

Inadvertent purification of nonspecific DNA-binding proteins

Throughout this unit, an attempt has been made to emphasize how to avoid inadvertent purification of nonspecific DNA-binding proteins. Unfortunately, this problem is quite common, particularly when the gel mobility shift assay is used to monitor DNA binding. Proper use of the control resin (to identify proteins that bind nonspecifically to DNA-Sepharose), two different affinity resins (to identify proteins that might be interacting with the linker DNA), and competitor DNA (to deplete nonspecific DNA-binding proteins from the extract) should virtually eliminate purification of nonspecific DNA-binding proteins. In addition, DNase I footprinting is recommended for assaying DNA binding because it allows visualization of the actual protein binding site and to confirm sequence specificity. To correlate DNA binding with a particular polypeptide, it would be informative to purify the polypeptide from a polyacrylamide gel by using the denaturation/renaturation procedure described by Hager and Burgess (1980). Two common nonspecific DNA-binding proteins that have been purified from HeLa cells by affinity chromatography are poly(ADP-ribose) polymerase, which has an M_r of 116,100 (Ueda and Hayaishi, 1985; Slattery et al., 1983), and the Ku antigen, which consists of two polypeptides of M_r 70,000 and 80,000 (Mimori et al., 1986).

Anticipated Results

After two rounds of affinity chromatography, it is possible to achieve a 500- to 1000-fold purification with a 30% overall yield. The concentration of affinity-purified proteins is typically 5 to 50 $\mu g/ml$. About 0.2 to 1 μl of protein (2 to 10 ng) can be expected to be sufficient for

a “blanked-out” footprint (with ~10 fmol of DNA probe). Affinity resin is stable for >1 year if stored at 4°C. Affinity-purified proteins are typically stable for >2 years if stored at –80°C in an appropriate buffer and handled properly. Proteins should always be quick-frozen in liquid nitrogen and quick-thawed in either cold or room-temperature water (although if room-temperature water is used to accelerate thawing, the sample must not be allowed to warm up above 4°C). Although many DNA-binding proteins remain active after several freeze-thaw cycles, it is preferable to divide protein preparations into small aliquots rather than to freeze and thaw the entire sample many times.

Time Considerations

The time required to optimize DNA-binding conditions of a particular protein is variable and depends on assay type, probe preparation time, and competitor choices. The time to prepare extracts and to perform conventional chromatography is also variable depending on factors such as starting material and type of chromatography. Beginning with purified oligonucleotides, preparation of the DNA affinity resin takes 2 days (with either commercially available or homemade CNBr-activated resin). If the oligonucleotides are to be gel-purified, an additional day and a half should be added. Affinity chromatography takes ~4 to 8 hr, dependent mainly on the flow rate of the resin: Sepharose CL-2B runs at ~15 ml/hr, while Sepharose-4B runs somewhat slower. Therefore, it is possible to estimate chromatography time by calculating the volume of sample that is to be applied to the column plus 8 ml for the wash steps and 11 ml for the elution steps. If the volume of starting material is not too large, it is possible to assay the affinity column on the day it is run (either by DNA-binding assays, SDS-PAGE, or both). It is important to freeze the affinity fractions in liquid nitrogen and store at –80°C as soon as the column is complete.

Determination of Protein-DNA Sequence Specificity by PCR-Assisted Binding-Site Selection

Binding-site selection is used to determine the target specificity of a sequence-specific DNA-binding protein. The technique has a number of applications, ranging from identifying DNA target sequences for proteins with unknown DNA-binding specificities to providing additional information on the protein-DNA interactions of previously characterized DNA binding domains.

The procedure is outlined in Figure 12.11.1. As indicated in the Basic Protocol, a pool of random-sequence oligonucleotides is used as the source of potential binding sites (see UNIT 2.11 for a discussion of the synthesis of randomized oligonucleotides). The oligonucleotide pool is incubated in a binding reaction with extract containing the DNA-binding protein of interest. Protein-DNA complexes are isolated by immunoprecipitation with an antibody specific for the protein under investigation, and unbound oligonucleotides are removed by gentle washing. Bound oligonucleotides are recovered, amplified by the polymerase chain reaction (PCR), and used as input DNA for a further round of binding,

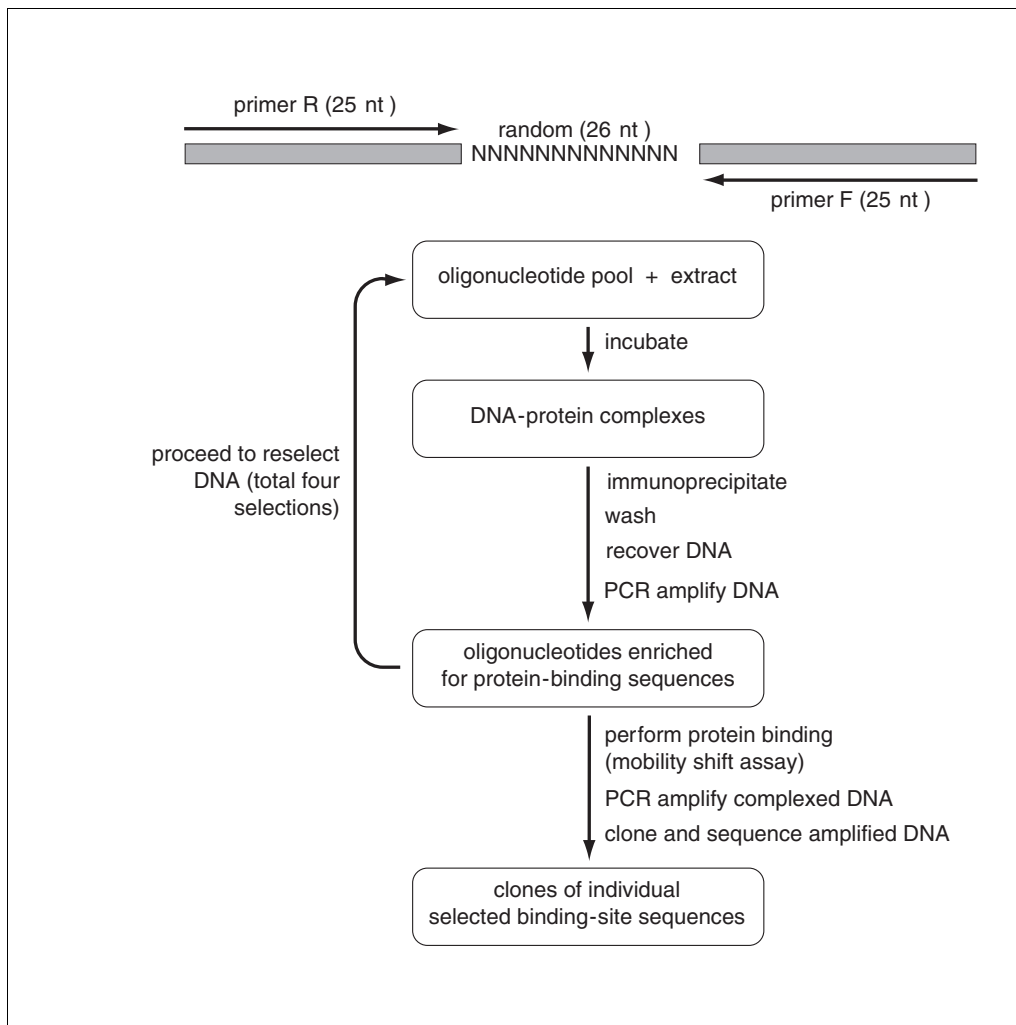

Figure 12.11.1 Flow chart for PCR-assisted DNA binding-site selection.

recovery, and amplification. After four rounds of selection, progress of the procedure is monitored by mobility shift analysis of the selected oligonucleotide pools. In the Support Protocol, individual binding sites are isolated from the appropriate complex on a mobility shift gel, cloned into plasmids, and examined by sequencing.

Materials

Random-sequence oligonucleotide R76:

5'-CAGGTCAGTTCAGCGGATCCTGTCTG(A/G/C/T)₂₆GAGGCGAATTCAGTG
CAACTGCAGC-3' (see UNIT 2.11)

Primer F: 5'-GCTGCAGTTGCACTGAATTCGCCTC-3'

Primer R: 5'-CAGGTCAGTTCAGCGGATCCTGTCTG-3'

10× *Taq* DNA polymerase buffer (UNIT 3.4)

0.5 mM 3dNTP mix (minus dCTP; UNIT 3.4)

40 μM and 0.5 mM dCTP (UNIT 3.4)

10 mCi/ml [α -³²P]dCTP (800 Ci/mmol)

5 U/μl *Taq* DNA polymerase (UNIT 3.5)

Elution buffer (see recipe)

Glycogen carrier (e.g., Boehringer Mannheim)

TE buffer, pH 7.5 to 8.0 (APPENDIX 2)

Protein A–Sepharose CL-4B (Pharmacia Biotech)

Wash buffer (see recipe), with and without 50 μg/ml BSA

Binding buffer (see recipe), with and without 50 μg/ml BSA

Carrier DNA: e.g., 100 ng/μl poly(dI-dC)·poly(dI-dC)

Protein sample: reticulocyte lysate or nuclear extract containing DNA-binding protein of interest, *or* purified DNA-binding protein (if available)

Antiserum to protein of interest, *or* (if protein is epitope-tagged and monoclonal antibody is available) appropriate ascites fluid

Recovery buffer (see recipe)

2.5 M sodium acetate

5 M ammonium acetate

Scintillation vials and counter

17 × 100–mm polystyrene centrifuge tube with snap-cap

Tumbler or rotating wheel

Whatman 3MM paper

Additional reagents and equipment for purification of oligonucleotides using denaturing (UNIT 2.12) and nondenaturing PAGE (UNIT 2.7), autoradiography (APPENDIX 3A), phenol/chloroform extraction and ethanol precipitation (UNIT 2.1), and mobility shift DNA-binding assay (UNIT 12.2)

Prepare labeled double-stranded random-sequence oligonucleotide

1. Purify oligonucleotides R76, primer F, and primer R by denaturing PAGE, then extract from gel (UNIT 2.12). Dilute R76 to 50 ng/μl and primers F and R to 80 ng/μl in water.
2. Set up the following reaction in a 0.5-ml microcentrifuge tube (20 μl total):
 - 2 μl 50 ng/μl oligonucleotide R76
 - 2 μl 10× *Taq* DNA polymerase buffer
 - 2 μl 0.5 mM 3dNTP mix (minus C)
 - 2 μl 40 μM dCTP
 - 2 μl 80 ng/μl primer F
 - 2 μl 10 Ci/ml (800 Ci/mmol) [α -³²P]dCTP
 - 7 μl H₂O
 - 1 μl 5 U/μl *Taq* DNA polymerase.

3. Carry out one PCR cycle using the following cycling parameters:

1 min 94°C (denaturation)
3 min 62°C (annealing)
9 min 72°C (extension)

Chase extension by adding 2 μ l of 0.5 mM dCTP, then heating 9 min at 72°C.

This reaction will generate double-stranded R76 oligonucleotide (dsR76) labeled to a specific activity of 3200 Ci/mmol, which is appropriate for use in a gel mobility shift assay (step 29).

Probes with higher specific activity can be generated by increasing the ratio of labeled to unlabeled dCTP in the reaction. The reaction volume can be cut to 10 μ l to economize on label.

*R76 may also be rendered double-stranded by annealing primer F and extending with Klenow fragment of *E. coli* DNA polymerase I (UNIT 3.5).*

4. Purify dsR76 on an 8% nondenaturing polyacrylamide gel (UNIT 2.7), then visualize by autoradiography (APPENDIX 3A).

A clearly visible dsR76 band can be obtained after a 60- to 90-sec exposure.

5. Excise gel slice containing labeled dsR76 using a clean scalpel and place in a 1.5-ml microcentrifuge tube containing 250 μ l elution buffer. Incubate overnight at 37°C.
6. Remove elution buffer to a fresh 1.5-ml microcentrifuge tube, add 1 μ g of glycogen carrier, and ethanol precipitate.
7. Resuspend pellet in 10 μ l TE buffer and measure 1 μ l into a scintillation vial. Measure Cerenkov counts in a scintillation counter to determine cpm.

Because the molecular weight and specific activity of the probe oligonucleotide are known, the amount of dsR76 can be quantitated by assuming that 10^6 cpm is approximately equivalent to 1 μ Ci. The double-stranding reaction in step 2 and the PCR amplification reaction in step 22 contain [α - 32 P]dCTP and unlabeled dCTP at concentrations such that four labeled C nucleotides are incorporated into every dsR76 oligonucleotide. The specific activity of dsR76 is therefore four times the specific activity of the [α - 32 P]dCTP itself (4×800 Ci/mmol = 3200 Ci/mmol).

8. Prepare a 0.2 ng/ μ l dilution of dsR76 in TE buffer for use in binding reaction (step 12).

Prepare protein A–Sepharose bead slurry

9. Rehydrate and wash freeze-dried Protein A–Sepharose CL-4B beads in water according to manufacturer's instructions.

Each binding reaction requires only 10 μ l packed volume of beads. There should be no need to prepare more than 500 μ l at a time (equivalent to ~0.125 g dried beads).

10. Wash swollen beads twice in 50 vol wash buffer without BSA.
11. Prepare a 50% (v/v) slurry in wash buffer containing 50 μ g/ml BSA and allow beads to equilibrate 2 to 3 hr at 4°C.

The 50% protein A–Sepharose slurry can be stored for several weeks at 4°C.

Set up binding reaction

12. In a 1.5-ml microcentrifuge tube on ice, prepare the following reaction:

20 μ l binding buffer containing 50 μ g/ml BSA
2 μ l 100 ng/ μ l poly(dI-dC)-poly(dI-dC)
1 to 2 μ l protein sample
2 μ l 0.2 ng/ μ l dsR76 probe oligonucleotide (from step 8)
1 μ l antiserum.

For the first round of selection use 0.4 ng probe per reaction; for subsequent rounds use 0.2 ng (dilute probe solution to 0.1 ng/ μ l in TE buffer before adding to reaction).

Antiserum should be specific for the DNA-binding protein of interest, and should immunoprecipitate protein-DNA complexes without disrupting protein-DNA interactions (see Critical Parameters). The exact quantity to be used must be optimized empirically. For proteins tagged with an epitope to which a monoclonal antibody is available, use 0.1 μ l ascites fluid (~0.1 to 1.0 μ g antibody) diluted $1/10$ with wash buffer.

If available, purified DNA-binding proteins can be used instead of extracts, although the concentration in the binding reaction should be kept low (see Critical Parameters).

13. Allow protein-DNA complexes to form on ice for 20 to 30 min.

Immunoprecipitate and wash

14. Transfer 20 μ l of 50% protein A–Sepharose slurry (step 11) to a 1.5-ml microcentrifuge tube containing 250 μ l 4°C wash buffer without BSA. Pellet protein A–Sepharose by microcentrifuging 15 sec at maximum speed, room temperature, and aspirate off wash buffer.

Loss of the protein A–Sepharose beads themselves is minimized by performing the aspiration through a 200- μ l flat tip.

15. Pipet binding reaction (step 13) into the 1.5-ml microcentrifuge tube containing 10 μ l packed volume protein A–Sepharose. Mix beads and binding reaction by pipetting up and down gently.
16. Insert the microcentrifuge tube into the mouth of a 17 \times 100–mm polystyrene tube and snap on cap. Place on a tumbler or rotating wheel and tumble or rotate overnight in a cold room.

Placing the microcentrifuge tube in the mouth of the larger tube immobilizes it and allows for convenient mixing.

IMPORTANT NOTE: *End-over-end mixing should be avoided, as protein A–Sepharose beads will smear along the side of the microcentrifuge tube.*

17. Add 250 μ l 4°C binding buffer without BSA to the binding reaction and mix rapidly by brief vortexing followed by inversion of the microcentrifuge tube. Repeat vortexing and inversion twice, then microcentrifuge 15 sec at maximum speed, room temperature, and aspirate off supernatant. Repeat this wash twice more.

These washes should be performed as fast as is reasonably possible, because the time spent performing them can be an important factor in determining the stringency of the selections (see Critical Parameters).

Recover DNA

18. Elute bound DNA from the protein A–Sepharose bead pellet by resuspending in 200 μ l recovery buffer and incubating 1 hr at 45°C.
19. Perform a phenol extraction followed by a chloroform extraction (*UNIT 2.1*).

20. Add 1 μg glycogen carrier and 12 μl of 2.5 M sodium acetate, then recover DNA by ethanol precipitation (UNIT 2.1).
21. Measure pellet for Cerenkov counts in a scintillation counter to determine cpm. Measure 0.2 ng of input probe.

Determination of the proportion of the input probe recovered allows quantitation of selected DNA (i.e., determination of the proportion of input probe recovered as selected DNA). In addition, when background recoveries (i.e., recoveries obtained with negative control extracts) are low, the proportion of input DNA recovered after each round of selection often gives a good indication of the progress of the site selection.

Amplify selected DNA

22. Prepare the following reaction mixture (20 μl total):

2 μl 10 \times *Taq* DNA polymerase buffer
3.2 μl 0.5 mM 3dNTP mix (minus C)
2 μl 40 μM dCTP
2 μl 80 ng/ μl primer F
2 μl 80 ng/ μl primer R
1 μl 10 mCi/ml (800 Ci/mmol) [α - ^{32}P]dCTP
7.3 μl H₂O
0.5 μl 5 U/ μl *Taq* DNA polymerase.

Add this mixture to 1 pg of selected DNA in a 0.5-ml microcentrifuge tube.

23. Carry out 15 of the following PCR amplification cycles:

1 min 94°C (denaturation)
1 min 62°C (annealing)
1 min 72°C (extension)

This step is optimized for amplification of oligonucleotide R76 with primers F and R. It is important to carefully calibrate the amplification reaction with respect to the amount of input DNA and number of PCR cycles performed (see Critical Parameters), particularly when using different random oligonucleotide/primer combinations.

24. Dilute PCR reaction to 150 μl with TE buffer and phenol extract (UNIT 2.1).
25. Add 1 μg of glycogen carrier and $\frac{1}{4}$ vol of 5 M ammonium acetate (to 1 M). Ethanol precipitate (UNIT 2.1).
26. Purify PCR product by electrophoresis on a nondenaturing polyacrylamide gel as described in steps 4 to 6.

Because maximum recovery is not absolutely essential, the elution step can be cut to 2 hr at 45°C.

27. Following ethanol precipitation, resuspend pellet in 10 μl TE buffer and measure 1 μl for Cerenkov counts. Quantitate selected, amplified dsR76, then resuspend at 0.1 ng/ μl .

This procedure typically yields 10 to 20 ng labeled amplified selected dsR76 oligonucleotide.

28. Use the selected and amplified oligonucleotide pool in another round of binding-site selection (steps 12 to 27). After four selection cycles, proceed to step 29 (mobility shift assay) to monitor the success of the binding-site selection procedure.

If successful, four rounds of selection should yield oligonucleotide pools that are capable of forming visible protein-DNA complexes on a mobility shift gel (see Critical Parameters).

Analyze selected oligonucleotide pools by mobility shift assay

29. Set up a series of binding reactions in which the selecting extract is incubated with probes representing oligonucleotide pools from each round of selection. The binding reactions should be identical to that described in step 12 except with the antibody omitted.

Controls are critical, and should include binding reactions in which oligonucleotide pools selected by the test protein are incubated with extracts that do not contain the protein under investigation (see Troubleshooting). They should also include a series of binding reactions representing parallel selections performed with a positive control extract.

30. Incubate 20 to 30 min at room temperature, then load reactions onto a mobility shift gel (UNIT 12.2).

For each selecting extract, binding reactions with probes derived from consecutive rounds of selection should be loaded adjacent to each other on the mobility shift gel. This allows the gradual appearance of specific complexes to be easily visualized.

31. Run gel according to the procedure described for mobility shift gels (UNIT 12.2).

32. Dry unfixed gel onto Whatman 3MM paper, then perform autoradiography overnight (APPENDIX 3A).

If the selections have been successful, mobility shift complexes should begin to appear in lanes representing later rounds of selection.

SUPPORT PROTOCOL

ISOLATION AND ANALYSIS OF BOUND OLIGONUCLEOTIDES FROM MOBILITY SHIFT GELS

Once the success of the site selection procedure has been confirmed by mobility shift analysis, bound oligonucleotides are isolated from appropriate mobility shift complexes by direct amplification from dried gel slices. Bound oligonucleotides are then digested with the appropriate restriction enzymes and subcloned for sequence analysis of individual selected sites.

Additional Materials (also see Basic Protocol)

EcoRI and BamHI restriction endonucleases and appropriate buffer (UNIT 3.1)

1. Cut the region containing the protein-DNA complex from a dried mobility shift gel using a clean scalpel. Divide into four squares.
2. For two of the squares, use a scalpel to separate the dried polyacrylamide gel from the Whatman 3MM paper. Place both squares in a 0.5-ml microcentrifuge tube.

Save the other two squares in case amplification needs to be repeated (see step 4 annotation).

3. Add the following mix to the dried acrylamide (50 μ l total):

5 μ l 10 \times *Taq* DNA polymerase buffer
8 μ l 0.5 mM 3dNTP mix (minus C)
5 μ l 40 μ M dCTP
5 μ l 80 ng/ μ l primer F
5 μ l 80 ng/ μ l primer R
2.5 μ l [α -³²P]dCTP
18 μ l H₂O
1.5 μ l 5 U/ μ l *Taq* DNA polymerase.

The dried acrylamide will rehydrate in the reaction mix as the PCR progresses.

4. Carry out 17 of the following PCR amplification cycles:

- 1 min 94°C (denaturation)
- 1 min 62°C (annealing)
- 1 min 72°C (extension)

The optimal number of PCR cycles will depend upon variables that are difficult to control, such as the amount of DNA in the dried acrylamide. For this reason it is important to save some of the dried complex so that the PCR reaction can be repeated with additional cycles if sufficient product is not generated.

5. Purify PCR product (see Basic Protocol, steps 4 to 6).
6. Digest bound oligonucleotide pool with an excess of *Eco*RI and *Bam*HI restriction endonucleases (UNIT 3.1).
7. Phenol extract digested oligonucleotides, recover by ethanol precipitation, and resuspend at a dilution appropriate for cloning (UNIT 2.1).
8. Ligate oligonucleotides into an appropriate vector and transform into *E. coli* (UNIT 3.16). Perform sequence analysis of individual selected sites (UNITS 7.4-7.6).

CAUTION: Ligations will be moderately radioactive. Take care to dispose of bacterial plates appropriately.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Binding buffer

Wash buffer (see recipe) containing:

- 0.1% Nonidet P-40 (NP-40)
- 1 mM benzamidine
- 0.5 mM phenylmethylsulfonyl fluoride (PMSF)
- 0.5 mM DTT

Add benzamidine, PMSF, and DTT fresh before use. Buffer without those components can be stored several weeks at 4°C.

Elution buffer

- 0.5 M ammonium acetate
- 1 mM EDTA
- 0.1% SDS
- Store several months at room temperature

Recovery buffer

- 50 mM Tris·Cl, pH 8
- 100 mM sodium acetate
- 5 mM EDTA
- 0.5% SDS
- Store several months at room temperature

Wash buffer

- 20 mM HEPES, pH 7.9
- 100 mM KCl
- 0.2 mM EDTA
- 0.2 mM EGTA
- 20% (v/v) glycerol
- Store several weeks at 4°C

COMMENTARY

Background Information

Determination of the DNA binding specificity of a transcription factor is a vital step in the characterization of its interactions with DNA and the identification of its regulatory targets. Before the advent of site selection methods, this was a major problem in the study of DNA-binding proteins identified on the basis of properties other than sequence-specific DNA binding.

A significant advance came with the demonstration by Oliphant et al. (1989) that specific binding sites for a DNA-binding protein could be affinity selected from random sequence oligonucleotides. Another important development was the combination of selection with *in vitro* amplification using the polymerase chain reaction (PCR). Kinzler and Vogelstein (1989) showed that iterative rounds of selection and amplification could be used to isolate specific binding sites from a complex population of small genomic DNA fragments.

Simpler and more efficient site selection methods were soon described in which iterative rounds of selection and amplification were combined with the use of random-sequence oligonucleotides as a source of binding sites. Random-sequence oligonucleotides are used in preference to genomic fragments for three reasons. First, their uniform size allows progress of site selection to be easily monitored on mobility shift gels. Second, a consensus can be derived simply by comparing recovered sequences without the need for binding-site mapping techniques. Third, small oligonucleotides are less likely to contain binding sites for other nuclear proteins, which may increase background recoveries.

Site selection methods differ mainly in the way in which DNA-protein complexes are separated from unbound oligonucleotides. A variety of separation techniques have been successfully used, including affinity columns (Ecker et al., 1991), filter binding (Thiesen and Bach, 1990), precipitation with glutathione-*S*-transferase beads (Chittenden et al., 1991), and mobility shift gels (Blackwell and Weintraub, 1990). The protocol described here uses immunoprecipitation as a means of isolating specific DNA-protein complexes (Pollock and Treisman, 1990).

Immunopurification gives a high degree of enrichment for target protein and can be used to isolate DNA-protein complexes from crude mixtures such as cell extracts. Immunoselection is also quite sensitive, and has been used

to determine the DNA-binding specificities of proteins present at low concentrations in cell extracts. The ability to use crude extracts has several advantages. First, there is no requirement for purified or overexpressed target protein. Second, the technique can be applied to proteins that require postranslational modifications in order to bind DNA. Third, sites can be selected for proteins that bind DNA only as components of heteromeric complexes. A disadvantage of immunoprecipitation is the requirement for an antibody specific for the test protein. In the absence of a specific antibody, an epitope-tagging approach can be used to recover protein-DNA complexes (Pollock and Treisman, 1990).

Site selection techniques can be used to determine consensus binding sites for proteins whose target sequences are unknown. Examples would include proteins isolated on the basis of properties other than sequence-specific DNA binding but suspected to bind DNA by virtue of their affinity for nonspecific DNA, nuclear localization, or homology to known DNA-binding proteins. The same separation techniques can be adapted to different selection protocols.

Site selection can also provide additional information about the protein-DNA interactions of previously characterized DNA-binding domains. For example, selection experiments can help to determine the full range of target sequences for a given DNA-binding domain, provide information on the relative importance of bases within a consensus, and reveal subtle differences in sequence specificity between closely related members of a transcription factor family.

Site selection can also be used in conjunction with mutational studies of DNA-binding domains to examine the contribution of individual amino acids or motifs to sequence recognition.

More recently the use of immunoselection of protein-DNA complexes from nuclear extracts has been extended to identify potential interactions between transcription factors within multicomponent transcription complexes (Funk and Wright, 1992).

Critical Parameters

Probe oligonucleotides

R76 comprises a random 26-base sequence flanked by invariant 25-nucleotide primer-

binding sequences containing *EcoRI* and *BamHI* restriction sites to facilitate cloning of binding oligonucleotides after selection (see Basic Protocol, Materials). Alternative primers may have to be used if the protein under investigation has specificity that overlaps with the forward (F) and reverse (R) primers used here.

The randomized core of R76 is long enough to encompass the consensus binding sites for most if not all known DNA-binding proteins. Longer or shorter random cores can also be used. Use of an oligonucleotide with a random core that is longer than the transcription-factor binding site increases the number of potential binding sites present in a given mass of DNA even though the number of oligonucleotides is decreased. For example, 0.4 ng dsR76 represents $\sim 5 \times 10^9$ oligonucleotides but the 26-bp random core contains 8×10^{10} ($5 \times 10^9 \times 16$) 10-mers, whereas 0.4 ng of an oligonucleotide with a 10-bp random core represents only 6.3×10^9 10-mers. Random cores longer than 26 bp can and have been used, although this may increase the difficulty of perceiving complex unknown motifs.

Binding, immunoprecipitation, and wash

The binding conditions described here are of moderate ionic strength and are designed to support stable protein-DNA complexes. They are included only as a guide and may not be optimal for every DNA-binding protein. If suitable binding conditions for the protein under investigation are already known then these should be used. Binding reactions contain relatively low concentrations of DNA-binding protein and binding probe to prevent the recovery of weak binding sites. The overnight incubation is to ensure efficient adsorption of DNA-protein complexes onto the protein A-Sepharose beads. The time required for this to occur will vary with different antibody/target protein combinations. It is likely that in many cases the incubation time can be cut significantly from that described here. A pilot immunoprecipitation experiment can be performed to determine a minimum incubation period (see Antibodies, below).

The wash step is designed to remove unbound oligonucleotides without disrupting DNA-protein complexes. The ionic strength of the wash buffer is an important factor in determining the stringency of the selections. The time spent performing the washes can also determine the affinity of selected sites, particularly for DNA-binding proteins with high dis-

sociation rates. In the protocol described here washes are performed rapidly with binding buffer under nondenaturing conditions.

DNA amplification

The PCR amplification conditions described here are designed to directly radiolabel the oligonucleotide pool to a known specific activity. This allows the recovered DNA to be quantitated after each round of selection and enables amplified selected DNA to be used directly as a probe in subsequent binding reactions.

There are two potential problems to be aware of when using PCR to amplify oligonucleotide pools. First, as the PCR reaction progresses, the concentration of the oligonucleotide pool can increase to a point at which self-priming of product competes with the re-annealing of the F and R primers. This may lead to artifactual PCR products if too many PCR cycles are performed. Second, overamplification will result in primer or dNTP depletion before thermal cycling has ceased. The resulting population of oligonucleotides is unable to fully renature and cannot be used in further rounds of selection. For these reasons, the PCR reaction should be carefully calibrated with respect to input DNA and number of cycles performed. To do this, set up a series of PCR reactions containing 1 pg input DNA. Subject each reaction to an increasing number of thermal cycles (between 14 and 20) and analyze the radiolabeled products by nondenaturing polyacrylamide gel electrophoresis. Use the maximum number of thermal cycles that gives rise to a single correctly sized product in subsequent site selection PCR reactions.

Even after the correct number of thermal cycles has been determined by calibration, it is recommended that the gel purification step be retained during this protocol to guard against overamplification artifacts.

Number of selection cycles

The exact number of selection cycles required may vary according to the source, amount, affinity, and specificity of the protein under investigation. In practice, visible complexes on a mobility shift gel are usually generated after three to four rounds of selection.

During early rounds of selection, the concentration of DNA-binding protein will be in excess over specific binding sites present in oligonucleotide pools. Under these conditions sites will be selected as long as they are above

a certain affinity determined by the stringency of the binding and wash conditions, and the concentration of DNA-binding protein. As selections are repeated, the proportion of binding sites in the selected pools will increase until the DNA-binding protein is no longer in excess. Once this point is reached selections will begin to discriminate in favor of higher-affinity sites. Because biologically relevant target sites are not necessarily those with the highest affinity, it is advisable to analyze sequences from earlier rounds of selection to ensure that the full spectrum of sequences bound by the protein under the assay conditions is represented.

Antibodies

Antibodies should be specific for the DNA-binding protein of interest and should allow efficient immunoprecipitation of the test protein. The ability of an antibody to immunoprecipitate the test protein can be confirmed in pilot experiments with the extracts and binding conditions to be used in site selections.

It is important to ensure that the antibody to the test protein does not disrupt DNA-protein complexes. For transcription factors with known binding sites this can be directly tested by performing a mobility shift assay in which antibody is included in the binding reaction. Inclusion of antibody should not abolish the protein-DNA complex; rather, a slower migrating or “supershifted” ternary complex containing protein, DNA, and antibody should result.

In cases where the effect of an antibody upon DNA binding cannot be directly assessed, tagging the test protein at the amino or carboxyl terminus with a short epitope to which a monoclonal antibody exists minimizes the risk of interfering with protein-DNA interactions.

Troubleshooting

Troubleshooting is greatly facilitated by performing site selection experiments in parallel using the appropriate control extracts. An extract containing a DNA-binding protein with a known sequence specificity should be included as a positive control. If possible, the positive control protein should be immunoprecipitated with the same antibody as the test proteins, although this may only be feasible if an epitope tagging approach is used. It is also important to confirm that selections performed with an extract that does not contain the target protein do not result in selection of specific binding sites. Such extracts include unprogrammed *in vitro* translation extract, extract

from cells that do not express the protein under investigation, and extract containing test protein without an epitope tag. Finally, when monitoring success of the selections by mobility shift assay, binding reactions should be included in which oligonucleotide pools selected with the test protein are incubated with extracts that do not contain the protein under investigation. This allows identification of appropriate mobility shift complexes from which to isolate DNA (see below).

If selection fails to produce visible complexes on a mobility shift gel, the following possibilities should be considered.

1. Binding conditions may not be optimal for the protein under investigation. Selections can be repeated with a number of different binding conditions tested. The most important parameters to vary are the salt concentration and the nature and amount of nonspecific carrier DNA (it may be possible to leave carrier DNA out of the binding reaction altogether).

2. The protein under investigation binds DNA only as part of a heteromeric complex.

This applies if selections were performed with purified proteins or proteins produced by *in vitro* translation. In this case, selections can be repeated with nuclear extracts prepared from cells transfected with a cDNA encoding the test protein.

3. The test protein may not form stable DNA-protein complexes in mobility shift gels.

This possibility should be seriously considered if probe recovery increases in later cycles, indicating that binding-site enrichment has occurred. In this case, it may be worth running mobility shift gels under different buffer conditions or bypassing the mobility shift step by sequencing sites cloned from the entire selected oligonucleotide pool.

4. The protein under investigation may be sensitive to repeated cycles of freezing and thawing.

It is always advisable to use a fresh aliquot of extract for each round of selection.

Another potential pitfall is the appearance of multiple complexes on mobility shift gels following selection. These may be due to selection by proteins in the extract that cross-react with the selecting antibody or to recognition of a subset of sites selected by the test protein by other DNA-binding proteins in the extract. It is therefore important to identify the appropriate complex. Bound oligonucleotides should be isolated only from complexes that do not appear with negative control extracts.

Anticipated Results

Recovered sequences should contain binding sites for the DNA protein under investigation and give rise to a consensus recognition sequence when appropriately aligned. The frequency with which a base occurs in a particular position will be proportional to its relative importance for binding. The derived consensus and the predicted relative importance of individual bases within the consensus can be tested by performing binding assays with oligonucleotides containing appropriate wild-type and mutant binding sites.

Contamination or PCR errors may occasionally give rise to sequences that do not conform to the derived consensus.

Time Considerations

It is possible to recover DNA from an overnight binding reaction in the morning and have amplified, purified DNA ready to add to another binding reaction in the evening. Four rounds of selection can therefore be performed in 4 days, although this becomes much harder to achieve if more than six selections are performed in parallel.

The mobility shift gel can be run on day 5 and DNA isolated from complexes on day 6. It is therefore possible to have templates ready for sequencing by day 8.

Yeast One-Hybrid Screening for DNA-Protein Interactions

One-hybrid screening in yeast is a powerful method to rapidly identify heterologous transcription factors that can interact with a specific regulatory DNA sequence of interest (the bait sequence). Essentially, one-hybrid screens are derived from the two-hybrid concept. In this technique, the interaction between two proteins (bait and prey) is detected via *in vivo* reconstitution of a transcriptional activator that turns on expression of a reporter gene. In the one-hybrid system, detection is based on the interaction of a transcription factor (prey) with a bait DNA sequence upstream of a reporter gene. To ensure that DNA binding results in reporter-gene activation, cDNA expression libraries are used to produce hybrids between the prey and a strong *trans*-activating domain. The advantage of cloning transcription factors or other DNA-binding proteins via one-hybrid screenings, compared to biochemical techniques, is that the procedure does not require specific optimization of *in vitro* conditions. In fact, yeast is being used as a “eukaryotic test tube” to demonstrate interactions. This may circumvent possible difficulties, e.g., incorrect protein folding or lack of post-transcriptional modifications, that may occur in screenings for transcription factors via a prokaryotic expression system such as that used in the *E. coli*-based southwestern procedure (Singh et al., 1988).

In the one-hybrid screening procedure described in this unit, cDNA libraries are screened using specific yeast reporter strains. The detection of the interaction between transcription factor and bait sequence is via activation of the positive growth selection marker *HIS3*. The bait sequence can be a well defined *cis*-acting element, but larger regulatory sequences can also be used. For example, complete promoters can be used in a random search for regulators. The precise recognition sequences of transcription factors isolated in such a screening can subsequently be mapped, and this strategy can lead back to identification of the *cis*-acting elements. The yeast reporter strains are constructed using the efficient pHIS3/pINT1 vector system. This vector system consists of two components. First, the bait sequence is cloned in front of the *HIS3* reporter gene in either pHIS3NB or pHIS3NX (Table 12.12.1 and Fig. 12.12.3). Secondly, the *HIS3* reporter cassettes with upstream bait sequence are transferred to the integrative vector, pINT1. The complete *HIS3* reporter is then transformed to yeast and integrated via double cross-over in the genome using homologous sequences from pINT1. Apart from the *HIS3* gene itself, the system does not use any other auxotrophic markers, which are thus kept free for other purposes, including the selection for library plasmids and, for example, the construction of dual-reporter strains as discussed in the Commentary. Another important feature of the pHIS3/pINT1 system is that selection for integration of the reporter is via the dominant selection gene, *APT1*. In some other described methods, integration is dependent on the low level of so-called leaky expression that *HIS3* reporter genes often show in the absence of a *trans*-acting factor binding the bait sequence. However, the fact that not all bait sequences confer this leaky expression is a severe limitation of these other procedures. For construction and verification of a pINT1-*HIS3* reporter strain, see Basic Protocol 1.

Also described in detail is a procedure for performing one-hybrid screenings (see Basic Protocol 2). For this procedure, a cDNA expression library is required, usually made in an *E. coli*-yeast shuttle vector that contains the sequences required for replication in both organisms. In a typical screen (Fig. 12.12.1), pools of library plasmid DNA are transformed into the pINT1-*HIS3* reporter strain. Selection for presence of the library plasmid is via the auxotrophic marker on the vector (usually *LEU2*). If an expressed transcription factor recognizes the bait sequence, the *HIS3* reporter will be activated. This complements

the auxotrophic *his3* mutation, allowing colonies to grow on selective medium lacking leucine and histidine. Library vectors used in the one-hybrid system are designed to express cDNAs as translational fusions with a strong constitutive *trans*-activation domain from a transcription factor (e.g., Gal4p, VP16). Therefore, the method is not limited to isolation of transcription factors that contain an intrinsic activation function, but also allows identification of repressors or other DNA-binding proteins. The one-hybrid method described in this unit is fully compatible with the many existing Gal4p- or *LexA*-based hybrid libraries that have been constructed for two-hybrid applications (e.g., UNIT 20.1). Most commercially available libraries were produced by direct cloning in plasmid vectors. Alternatively, expression libraries can more efficiently be made in lambda phage-based vectors. The Support Protocol refers to available library construction vectors and the procedure for conversion of lambda phage into plasmid libraries via *in vivo* mass excision.

Following the actual screening, the discrimination between true and false positives is an important step. The unit describes how to analyze the positive colonies with simple molecular methods and how to develop strategies to determine whether or not an isolated prey indeed represents a transcription factor that specifically interacts with the bait sequence (see Basic Protocol 3).

All steps for making the necessary preparations to perform a one-hybrid screening and to analyze the outcome are summarized in a flowchart (Fig. 12.12.2). Furthermore, a schematic representation of the procedure is shown in Figure 12.12.1. Many foreseeable complications or possible unexpected results are extensively discussed in the Comm-

Figure 12.12.1 Schematic overview of the yeast one-hybrid screening procedure to clone transcription factors or other DNA-binding proteins. A cDNA expression library in an *E. coli*-yeast shuttle vector is required. In the example shown here, the cDNA is expressed from the yeast *ADH1* promoter and is fused to the activation domain (AD) sequence of the yeast transcription factor Gal4p. With a unidirectional cDNA library, one-third of the clones should produce in-frame fusions with the AD coding sequence (hybrid proteins). The detection of the clones is via activation of the *HIS3* growth marker. Recognition and binding of a transcription factor to the bait sequence cloned upstream of the *HIS3* gene will result in *HIS3* expression. This complements for a chromosomal *his3* mutation, thereby allowing colony formation on histidine-deficient medium. The *LEU2* marker on the cDNA library vector complements for a chromosomal mutation in the *leu2* gene.

12.12.2

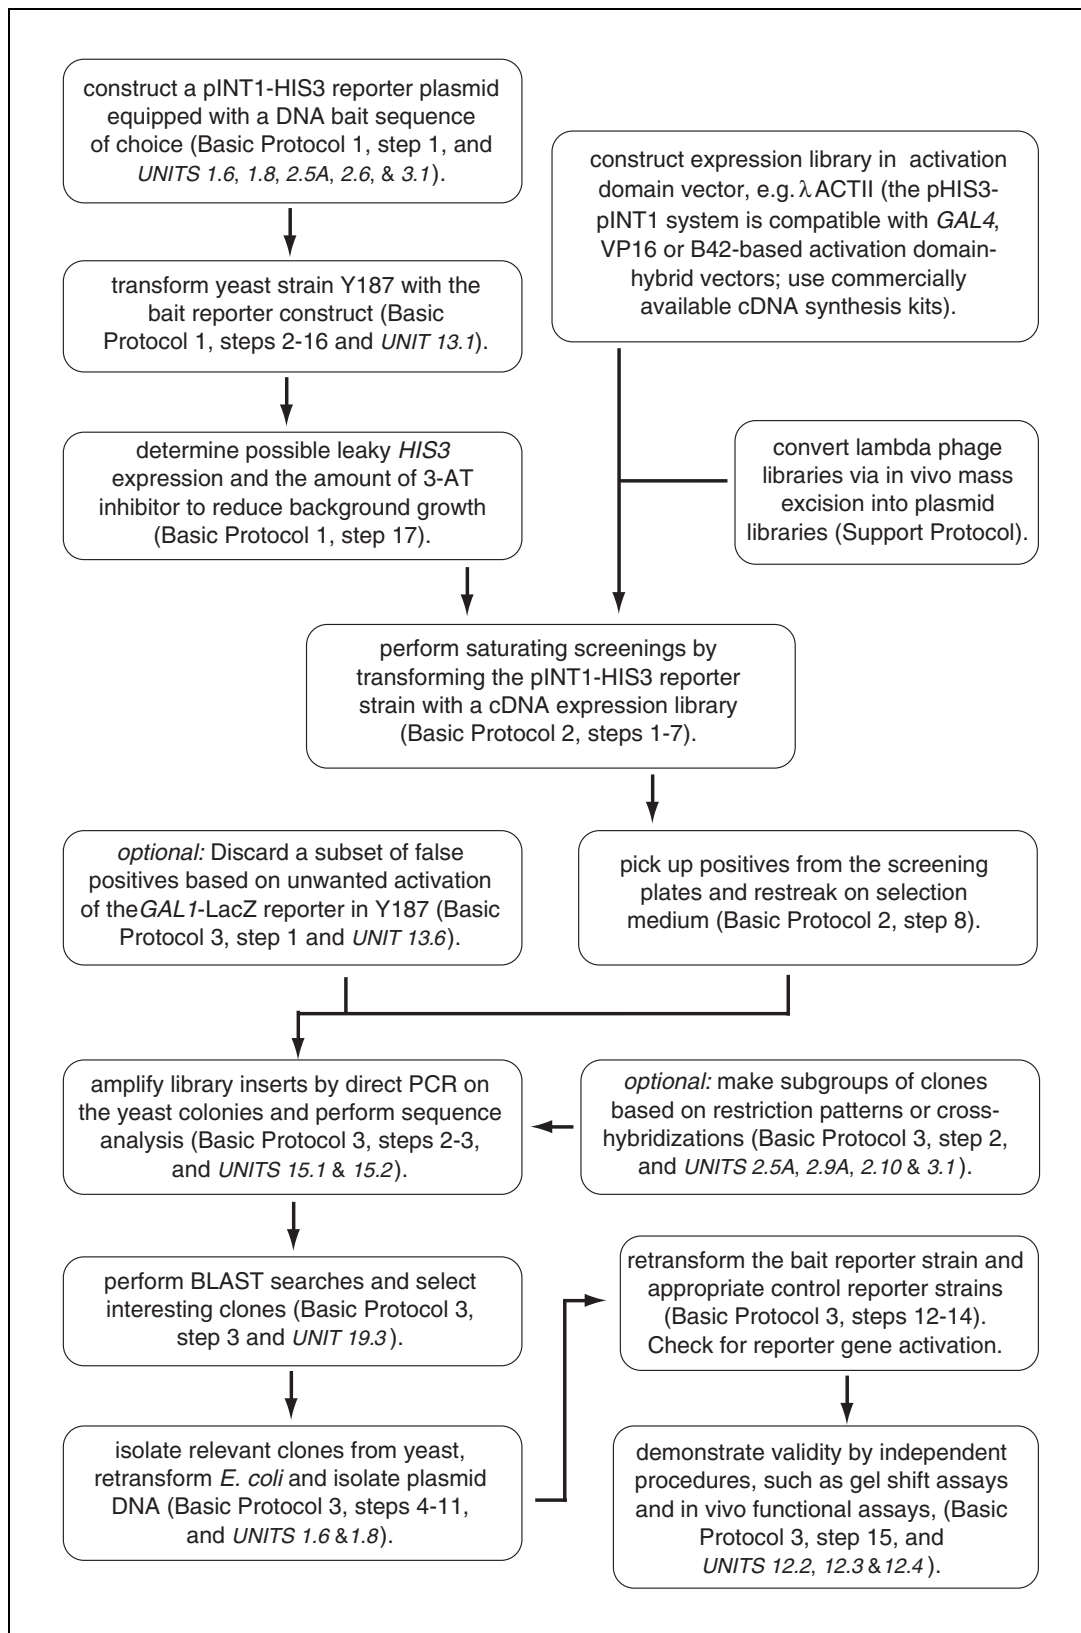

Figure 12.12.2 Flow chart for performing yeast one-hybrid screenings.

tary. The information in this unit is based on results from various screenings performed with different bait sequences and cDNA libraries from both animals and plants.

CONSTRUCTION AND CHARACTERIZATION OF YEAST REPORTER STRAINS

The first step in a one-hybrid screening is to construct a yeast strain that is equipped with a *HIS3* reporter gene construct. In this construct, the *HIS3* gene is preceded by a DNA bait sequence, which can be a defined *cis*-acting sequence, a heterologous promoter, or regulatory sequences from exon, intron, or 5'- or 3'-noncoding regions. Also, it may be desired to screen for proteins interacting with centromere or telomere regions. The *HIS3* reporter construct is integrated at the nonessential *PDC6* locus using the integrative vector, pINT1. Once this strain is obtained, its growth characteristics on His-lacking medium have to be determined in a series of control experiments. Some sequences confer a certain amount of *trans*-activation on the *HIS3* gene that is sufficient for growth on His-lacking medium. Such possible background growth due to leaky expression can be reduced by the addition of 3-amino-1,2,4-triazole (3-AT), a competitive inhibitor of the His3p enzyme. Once the required 3-AT concentration is established, the yeast strain can be used to screen cDNA expression libraries. Using the same integration procedure as described here for the bait construct, control reporter strains should be constructed that will be useful after the library screening for investigation of the specificity of putative positives. Basic Protocol 3 and the Commentary section give directions for control reporter design and application.

Materials

- DNA fragment or oligonucleotides, containing the bait sequence
- Plasmids pHIS3NB or pHIS3NX and pINT1 (Table 12.12.1, Fig. 12.12.3; available from P.B.F. Ouwkerk or A.H. Meijer; ouwkerk@rulbim.leidenuniv.nl and meijer@rulbim.leidenuniv.nl)
- Yeast strain Y187 (Table 12.12.2)
- Liquid YAPD medium: YPD medium (UNIT 13.1) supplemented with 20 mg/liter adenine hemisulfate
- 10× TE buffer, pH 7.5 (see recipe)
- 10× lithium acetate stock (see recipe)
- 50% (w/v) polyethylene glycol (PEG) stock (see recipe)
- 10 mg/ml YEASTMAKER carrier DNA (Clontech; also see UNIT 13.7 or UNIT 20.1)

Table 12.12.1 Overview of Vectors Used for Yeast Reporter Strain Construction

Vector ^a	<i>E. coli</i> selection	Yeast markers	Genbank accession no. ^b
pHIS3NB	Cb ^r	<i>HIS3</i>	AF275029
pHIS3NX	Cb ^r	<i>HIS3</i>	AF275030
pINT1	Cb ^r , Km ^r	<i>APT1</i> ^c	AF289993

^aPlasmids pHIS3NB, pHIS3NX, and pINT1 are described by Meijer et al. (1998) and can be obtained from P.B.F. Ouwkerk or A.H. Meijer. All plasmids replicate with high copy in *E. coli*.

^bAnnotated sequence information is deposited in the NCBI database.

^cThe *APT1* marker confers resistance to a relatively low concentration (25 mg/liter) of kanamycin in *E. coli*, and to G418 (150 mg/liter in YPAD) in yeast.

Table 12.12.2 Yeast Strain Genotypes

Strain	Genotype	Reference
Y187 ^a	<i>MATα ura3-52 his3-Δ200 ade2-101 trp1-901 leu2-3,112 me⁻ gal4Δ gal80Δ URA3::GAL1_{UAS}-GAL1_{TATA}-lacZ MEL1</i>	Harper et al., 1993; Clontech
YPH500 ^a	<i>MATα ura3-52 lys2-801 ade2-101 trp1-Δ63 his3-Δ200 leu2-Δ1</i>	Sikorski and Hieter, 1989
YJO ^a	<i>MATα gal4Δ gal80Δ ura3-52 his3 ade2-101 trp1 leu2-3,112 MEL1</i>	Leuther and Johnston, 1992 ^b
YM954 ^a	<i>MATα ura3-52 his3-Δ200 ade2-101 lys2-801 trp1-901 leu2-3, 112 gal4-Δ512 gal80-Δ538 tyr1-501</i>	Wilson et al., 1991
YM4271 ^a	<i>MATα ura3-52 his3-Δ200 ade2-101 lys2-801 trp1-901 leu2-3, 112 gal4-Δ512 gal80-Δ538 tyr1-501 ade5::hisG</i>	Liu et al., 1993
YPO101 ^c	Y187 <i>PDC6::pINT1-HIS3</i>	P.B.F. Ouwkerk (unpub. observ.)

^aThese strains are suitable hosts for one-hybrid screenings and are mentioned in the text. Use of Y187 is recommended for the procedure described in this unit.

^bThis reference refers to YJO-Z which is a derivative of YJO, containing a *GAL1-lacZ* fusion chromosomally integrated.

^cIn strain YPO101 a *HIS3* reporter lacking an upstream bait sequence was integrated via the pHIS3/pINT1 system. This strain can serve as a control strain for the analysis of library clones.

YAPD-G418 plates; YPD plates (*UNIT 13.1*) supplemented with 20 mg/liter adenine hemisulfate and G418 (150 mg/liter; add from 1000-fold stock solution) 87% (v/v) glycerol (sterilize by autoclaving for 20 min; store indefinitely at room temperature)

Complete minimal medium (CM) plates (*UNIT 13.1*) prepared with Difco Bacto-Agar or Duchefa Micro-Agar

CM –His plates (*UNIT 13.1*) with a concentration series of 3-amino-1,2,4-triazole (3-AT) (see recipe for 3-AT)

30°C incubator, with and without shaker

50-ml centrifuge tubes

Low-speed tabletop centrifuge (preferably swing-out) for 50-ml tubes

1.5-ml microcentrifuge tubes (e.g., Eppendorf or equivalent)

42°C water bath

10- to 15-ml tubes or flasks

Additional reagents and equipment for miniprep DNA isolation procedures (*UNIT 1.6*), transformation of *E. coli* (*UNIT 1.8*), gel electrophoresis (*UNIT 2.5A*), gel extraction procedures (*UNIT 2.6*), and restriction analyses (*UNIT 3.1*)

Clone the DNA bait sequence in the pHIS3-pINT1 vector system

1. Design a cloning strategy and clone the bait sequence in the polylinker of either pHIS3NB or pHIS3NX (Table 12.12.1, Fig. 12.12.3) to make a transcriptional fusion. For the cloning steps, use the standard techniques described in *UNITS 1.6, 1.8, 2.5A, 2.6 & 3.1*. Next, clone a fragment containing the *HIS3* reporter gene including the bait sequence as *NotI-BamHI* or *NotI-XbaI* fragment in the corresponding sites of the integrative vector pINT1.

It is not necessary to include other regulatory sequences such as the TATA box, transcription start site, and leader sequence. In the pHIS3 vectors, the HIS3 reporter gene is preceded by a minimal promoter (100-bp length) that already contains these features. When using the BclI site in pINT1, the vector needs to be isolated from a dam, dcm strain (GM48 or any of its derivatives, e.g., JM110). BclI cuts at 50°C and it is strongly recommended that

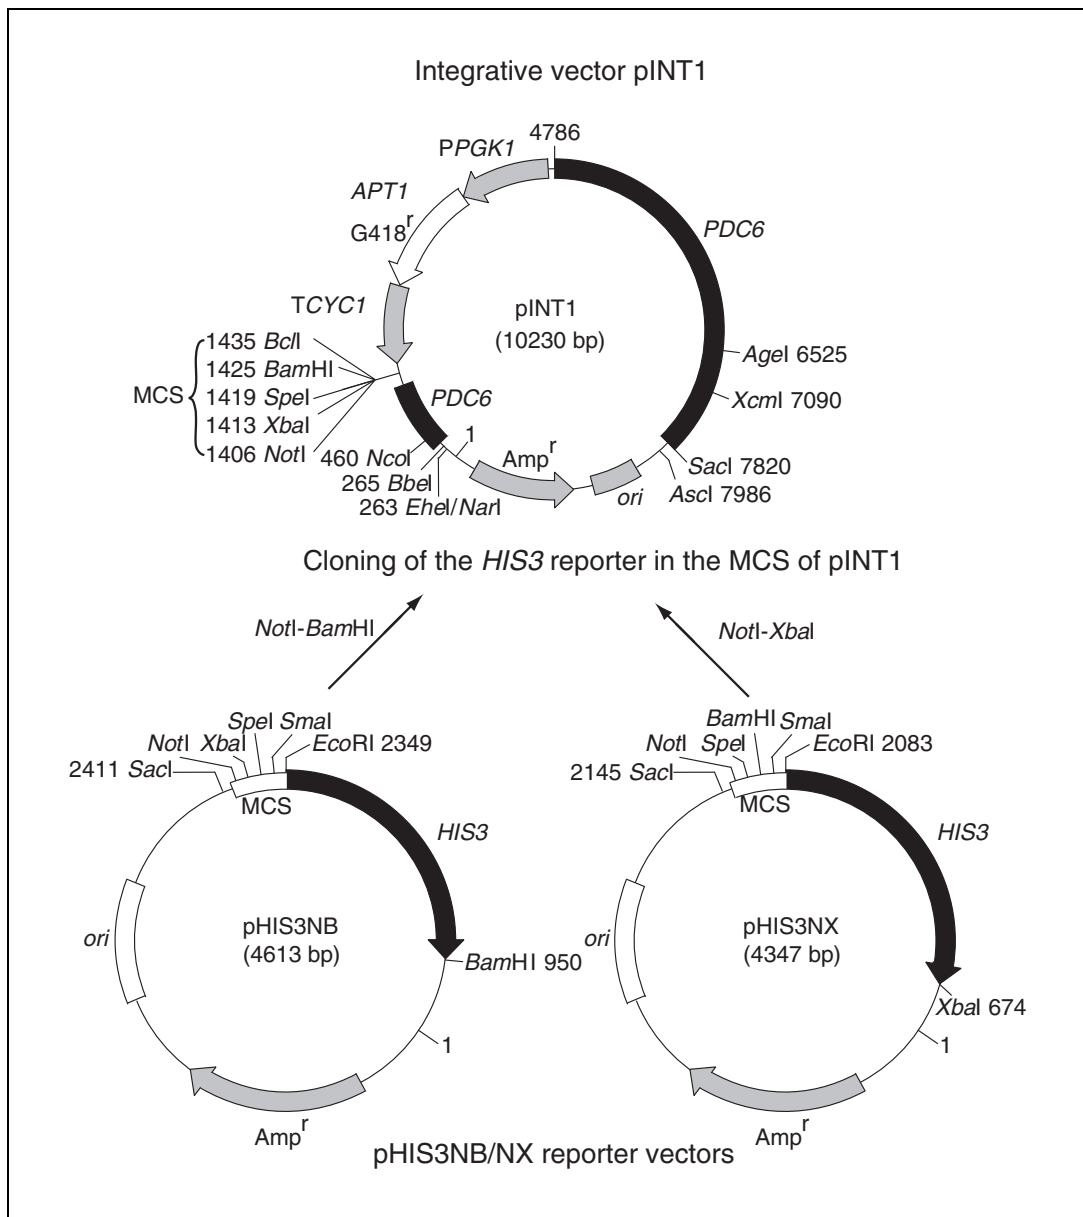

Figure 12.12.3 The pHIS3/pINT1 vector system for construction of reporter yeast strains for one-hybrid screening. The *HIS3* reporter plasmids pHIS3NB and pHIS3NX are based on SK II Bluescript (Stratagene). The *HIS3* gene is preceded by its own minimal promoter and a multiple cloning site with several unique sites for insertion of the bait sequence. Inserts can be sequenced using the M13 reverse primer. pINT1 is pUC29-based and contains the sequences necessary for integration in the yeast *PDC6* locus via double crossover. Selection for integration is via the dominant marker *APT1* that confers resistance in yeast to the antibiotic G418 (also termed gentamycin G418 or Geneticin), or kanamycin in *E. coli*. The *APT1* gene is controlled by the yeast *PGK1* promoter and the *CYC1* terminator. *APT1* was originally derived from the bacterial transposon Tn *g03* and codes for an aminoglycoside phosphotransferase (Hadfield et al., 1990). Several unique restriction sites are present downstream of the *APT1* expression cassette, which can be used for the unidirectional cloning of a bait-*HIS3* construct that is derived from either pHIS3NB or pHIS3NX. For integration of pINT1 in the *PDC6* locus, a fragment lacking the pUC29 sequences is isolated by restriction with *NcoI* (alternatively *BbeI*, *EheI* or *NarI*) and *SacI* (alternatively *Ascl*, *XcmI*, or *AgeI*). The choice for the pHIS3NB or -NX variant and for the restriction enzymes to linearize pINT1 is dependent on the sequence of the bait.

CsCl- or column-purified DNA (UNITS 1.7 or 2.1B) be used. The *APT1* marker in *pINT1* is also expressed in *E. coli* where it confers resistance to a low concentration of kanamycin (25 mg/liter). It can therefore be used in cloning strategies as an extra marker gene in addition to the carbenicillin resistance gene of *pINT1*.

2. Isolate 100 to 500 ng of the fragment from *pINT1* containing the bait sequence hooked up to the *HIS3* gene, the *APT1* marker gene, and the flanking *PDC6* sequences for homologous recombination (UNIT 2.6). Use the restriction sites indicated in Figure 12.12.3.

If necessary, it is possible to use only one restriction site for linearizing. However, this can lead to integration via single cross-over, which may affect the stable maintenance of the construct. Therefore, the use of two restriction sites is recommended. In most cases, the authors have used the combination of NcoI and SacI to linearize the pINT1 vector prior to yeast transformation, and have obtained integrations by double cross-over.

Grow and prepare yeast cells for transformation

3. Transform yeast with a lithium acetate transformation procedure as described in the following steps. First, grow a 50-ml YAPD culture of a yeast host strain of choice (e.g., Y187) in YPD medium supplemented with 20 mg/liter adenine hemisulfate overnight at 30°C.

The authors recommend the use of Y187 (Table 12.12.2) as host strain for efficient one-hybrid screenings. Y187 is a gal4gal80 strain, which is desirable since most hybrid libraries contain the Gal4p activation domain (AD). GAL4GAL80 strains such as YPH500 (Table 12.12.2) can be used, but in that case galactose should be the carbon source to avoid inhibition of Gal4p AD by Gal80p. Disadvantages of using galactose are that growth is slower and it is quite expensive. A useful aspect of Y187 is that it gives higher transformation efficiencies compared to other gal4gal80 strains such as YM954, YM4271, or YJO (Table 12.12.2). Some strains, including YPH500 and YJO, tend to become pink on YAPD medium due to the ade2-101 mutation, but Y187 remains white, although it also has this mutation.

4. Dilute the overnight culture to an OD_{600} of ~0.25 in liquid YAPD medium prewarmed to 30°C and grow the culture(s) for an additional 3 hr with shaking at 30°C. Grow one culture for every 10 planned transformation reactions.

*For optimal transformation efficiency, it is important that the cells be harvested during the exponential phase (OD_{600} 0.4 to 0.8). Therefore, it may be necessary to adjust the incubation time when using other strains. Usually step 4 is not necessary for *pINT1*-*HIS3* transformations, but the authors certainly advise that step 4, above, be included during the library transformations (see Basic Protocol 2).*

5. Harvest the yeast cells of the overnight culture in 50-ml centrifuge tubes by centrifuging for 1 min at $2400 \times g$ in a swing-out tabletop centrifuge (e.g., Heraeus Megafuge 1.0R, 2500 rpm) at room temperature.
6. Discard the supernatant fluid, resuspend the cells in 50 ml sterile water by vigorous shaking, and repeat centrifugation as in step 5.
7. Discard the supernatant fluid and resuspend the yeast cells in 1 ml of $1 \times TE/1 \times$ lithium acetate prepared from the $10 \times$ stock solutions.
8. Transfer the yeast suspension to a 1.5-ml microcentrifuge tube, microcentrifuge for 30 sec at maximum speed, and resuspend in 250 μ l of $1 \times TE/1 \times$ lithium acetate.

At this stage the cells are ready to be transformed. Please note that none of the steps should be carried out on ice. Lithium acetate-competent cells can be stored up to several weeks at 4°C, although their competency will gradually decrease. This transformation procedure is performed, with some modifications, according to Gietz et al. (1992).

Transform the pHIS3-pINT1 reporter construct to yeast

9. Directly prior to the transformation reactions, denature the required amount of YEASTMAKER carrier DNA (25 µg per reaction) by boiling for 10 min and, then place the DNA on ice. Also prepare a solution of 40% (w/v) PEG/1× TE buffer/1× lithium acetate by mixing 8 parts 50% (w/v) PEG, 1 part 10× TE buffer, and 1 part 10× lithium acetate solution in quantity sufficient for use in step 10.
10. Mix 100 to 500 ng of the isolated fragment from the pINT1-HIS3 vector (step 2) with 25 µg of 10 mg/ml carrier DNA in a maximum total volume of 10 µl in a 1.5-ml microcentrifuge tube. Add 50 µl of the yeast suspension and 300 µl of freshly prepared 40% PEG/1× TE/1× lithium acetate solution, and vortex to mix.

The authors have found the YEASTMAKER carrier DNA from Clontech to be a reliable (and not too expensive) source of high-quality carrier DNA for yeast transformations. Alternatively, a protocol to prepare carrier DNA can be found in UNIT 13.7 or UNIT 20.1. However, depending on the source of the starting material, the quality of the prepared batches can vary considerably.

11. Incubate for 30 min at 30°C with shaking.
12. Transfer and incubate the tubes for 15 min in a 42°C water bath.
13. Harvest the cells by microcentrifuging for 30 sec.
14. Allow the yeast cells to recuperate by resuspending in 1 ml YAPD medium, and transfer them to 10- to 15-ml tubes or flasks. Incubate for 3 to 6 hr at 30°C with shaking.

The recuperation step is necessary to allow the yeast cells to express the APT1 marker carried on the pINT1-HIS3 fragment, in order to gain resistance towards G418. The recuperation step in YAPD cannot be carried out in microcentrifuge tubes because pressure is built up due to CO₂ formation.

15. After the recuperation step, transfer the cells to a 1.5-ml microcentrifuge tube and harvest by microcentrifuging for 30 sec. Decant supernatant and resuspend cells in 100 µl of 1× TE buffer, then plate on YAPD-G418 plates. Incubate for 2 to 3 days at 30°C.
16. Pick and restreak G418-resistant colonies on YAPD-G418 plates and incubate for 2 to 3 days at 30°C. Keep the strains thus obtained at 4°C, and restreak every 2 to 3 months. For long-term storage, prepare glycerol stocks (final concentration of 30%) by adding 500 µl of 87% glycerol to 1-ml YAPD cultures grown overnight at 30°C. Snap-freeze the cultures in liquid nitrogen and keep at –80°C.

Be careful not to restreak very small transformants (petites), as these sometimes carry a spontaneous mitochondrial mutation. Due to their considerably slower growth, they are not useful in the screening. The obtained strains can be checked for correct integration of the reporter construct by PCR (UNIT 15.1) or Southern blot analysis (UNIT 2.9A). From this stage on, it is no longer necessary to grow the yeast strains on G418 since the insert is maintained stably. Apart from that, far more G418 would be required in CM than in YAPD, which makes its use very expensive.

Determine the concentration of 3-AT required to reduce possible leaky expression of the HIS3 gene

17. Streak G418-resistant colonies on CM and on CM –His plates containing a concentration series of 3-amino-1,2,4-triazole (3-AT)(0, 5, 10, 25 to 50 mM). Grow the plates for a week at 30°C. Determine the concentration that is required to reduce growth.

Note that the optimal 3-AT concentration required under screening conditions is also somewhat dependent on the plating density. Therefore, it can be useful to fine tune the

amount of 3-AT in test transformations with an empty library vector or in pilot library screenings under the conditions described in Basic Protocol 2. It is not strictly necessary to eliminate the growth completely.

LIBRARY SCREENING

The screening involves the large-scale transformation of the cDNA expression library to the pINT1-HIS3 reporter strain made in Basic Protocol 1. With the recommended Y187 host strain, ~20 to 30 individual transformation reactions will be required. Based on a transformation efficiency of $\geq 10^5$ clones per reaction, this will result in ≥ 2 to 3 million clones. This should be sufficient for saturating screenings of cDNA libraries, usually consisting of ~1 million independent recombinants. The yeast cells are plated on selective CM dropout plates deficient for leucine and histidine. The leucine deficiency is complemented via the *LEU2* gene on the library plasmid, but the histidine deficiency can only be complemented if the *HIS3* reporter gene is switched on, due to recognition of the bait sequence by a DNA-binding hybrid protein from the transformed library. If the *HIS3* reporter gene shows leaky expression, this should be inhibited by addition of 3-AT as outlined in Basic Protocol 1. Within 3 to 10 days after the transformations, His⁺ colonies will be obtained. After that, experiments have to be carried out to assess whether these represent true DNA-binding proteins or are false positives (see Basic Protocol 3). The required cDNA libraries can be made by direct cloning of cDNA into a plasmid vector or, more efficiently, by using a lambda vector containing an *E. coli*-yeast shuttle vector between the phage arms. Such lambda phage libraries are subsequently converted via in vivo mass excision into a plasmid library. More details concerning these types of library vectors and guidelines for handling can be found in the Support Protocol. Most of the useful cDNA library vectors (e.g., pACTII', pACT2, pGAD10, pGAD424, pAD-GAL4; see Table 12.12.3) contain the *LEU2* marker, but the choice for another type of vector requires only the adaptation of the marker usage in this protocol.

10× TE buffer, pH 7.5 (see recipe)
Complete minimal medium (CM) standard-size plates, minus leucine (CM –Leu plates; *UNIT 13.1*) prepared with Difco Bacto-Agar or Duchefa Micro-Agar
CM –Leu –His standard and large (15-cm wide) plates (*UNIT 13.1*), with optimal concentration of 3-AT (see Basic Protocol 1, step 17; see recipe for 3-AT)
30°C incubator, with and without shaker

Transform a cDNA expression library to the pINT1-HIS3 reporter strain

1. Inoculate the pINT1-HIS3 reporter strain in YAPD medium and grow overnight at 30°C with shaking.
2. Follow Basic Protocol 1, steps 4 to 13, to prepare lithium acetate-competent yeast cells and to perform the desired number of transformation reactions with 1 µg of cDNA library plasmid each.

The use of exponentially growing cells instead of an overnight culture increases the transformation efficiency. It is not recommended that the transformation reactions be scaled up, because the use of larger volumes will require adjustment of incubation times, e.g., at the heat-shock step.

3. Resuspend the transformed yeast cells in 200 µl of 1× TE buffer, pH 7.5, per transformation.

A recuperation step is not necessary for expression of auxotrophic marker genes.

4. Randomly choose 2 to 3 of the identical transformation reactions and plate 100 µl of 100- and 1000-fold dilutions on CM –Leu plates to determine the transformation efficiency.
5. Plate each transformation reaction on a large (15-cm) CM –Leu, –His plate with the appropriate amount of 3-AT as determined in Basic Protocol 1, step 17.
6. After 3 days of incubation at 30°C, count the number of colonies on the transformation efficiency plates from step 4. Calculate the total number of transformants to determine if the screening was saturating.

When using Y187, the transformation efficiency should be at least 10⁵ per µg library plasmid. The efficiency can be dependent on the type of agar used in the CM plates. Good choices of agar include Bacto Agar (Difco) and Micro Agar (Duchefa Biochemie).

7. Grow the library screening plates from step 5 for up to 2 weeks in a 30°C incubator.

During this period, positives will appear as faster-growing colonies among the background.
