Preparation of Cell Cultures and Vaccinia Virus Stocks

This unit describes the maintenance of cell lines used with vaccinia virus, both in monolayer cultures (see Basic Protocol 1) and in suspension (see Basic Protocol 2). The suspended cell culture is then used in the preparation of vaccinia virus stocks (see Basic Protocol 3). The preparation of chick embryo fibroblasts (CEF) is also presented (see Basic Protocol 4), for use in the production of the highly attenuated and host range-restricted modified vaccinia virus Ankara (MVA) strain of vaccinia virus (see Basic Protocol 5). Additionally, support protocols are presented for the titration of standard and MVA vaccinia virus stocks (see Support Protocols 1 and 2, respectively).

Because standard vaccinia virus strains have a broad host range, there is considerable latitude in the selection of cell lines; those described below (see Basic Protocols 1 and 2) have been found to give good results. BS-C-1 cells give the best results for a plaque assay, whereas HeLa cells are preferred for preparation of virus stocks. CV-1 cells can be used for both procedures, but they are generally used for transfection (UNIT 16.17). Human thymidine kinase-negative (TK⁻) 143B cells are used when TK selection is employed (UNIT 16.17), but they can be used for transfection as well as for a plaque assay. Either CEF or BHK-21 cells are used to propagate MVA and prepare recombinant MVA. Table 16.16.1 presents a summary of the uses for specific cell lines.

NOTE: Carry out all procedures in this unit using sterile technique, preferably in a biosafety cabinet.

Table 16.16.1 Cell Lines Used in Specific Vaccinia Protocols

Cell line	Use ^a	Procedure
HeLa S3	Virus stock preparation	UNIT 16.16 Basic Protocol 3
	Virus purification	UNIT 16.17 Support Protocol 1
	Plaque amplification	UNIT 16.17 Basic Protocol 3
BS-C-1	Plaque assay	UNIT 16.16 Support Protocol 1
	Transfection (optional)	UNIT 16.17 Basic Protocol 1
	XGPRT selection	UNIT 16.17 Basic Protocol 2
	Plaque amplification (optional)	UNIT 16.17 Basic Protocol 3
CV-1	Transfection	UNIT 16.17 Basic Protocol 1
	Virus stock preparation (optional)	UNIT 16.16 Basic Protocol 3
	Plaque assay (optional)	UNIT 16.16 Support Protocol 1
HuTK ⁻ 143B	TK selection	UNIT 16.17 Basic Protocol 2
	Plaque assay (optional)	UNIT 16.16 Support Protocol 1
	Transfection (optional)	UNIT 16.17 Basic Protocol 1
CEF	MVA procedures	UNIT 16.16 Basic Protocol 5, Support Protocol 2; UNIT 16.17 Basic Protocol 4
BHK-21	MVA procedures	UNIT 16.16 Basic Protocol 5, Support Protocol 2; UNIT 16.17 Basic Protocol 4

^aThe preferred use(s) for each cell line is listed first; if optional is indicated, the cell line can be used for the indicated procedure, but the results may not be as good as those from the preferred cell line.

CULTURE OF MONOLAYER CELLS

Frozen cells are thawed and grown in appropriate complete medium containing twice the maintenance amount of serum (see below). When the cells are confluent, they are treated with trypsin/EDTA, diluted, and maintained in appropriate complete medium containing 10% FBS (see Table 16.16.2).

Table 16.16.2 Media Used for Growth and Maintenance of Cell Lines^a

Cell line	Maintenance medium	Start-up medium ^a
BHK-21	Complete MEM-10	Complete MEM-20
BS-C-1	Complete MEM-10	Complete MEM-20
CEF	Complete MEM-10	Complete MEM-10
CV-1	Complete DMEM-10	Complete DMEM-20
HeLa S3	Complete spinner medium-5	Complete MEM-10
HuTK ⁻ 143B	Complete MEM-10/BrdU	Complete MEM-20/BrdU

^aSee Reagents and Solutions for recipes.

Materials

Frozen ampule of cells (Table 16.16.2): BS-C-1 (ATCC no. CCL26), CV-1 (ATCC no. CCL70), HuTK⁻ 143B (ATCC no. CRL8303), or BHK-21 (ATCC no. CCL10) cells

70% ethanol

Start-up medium (Table 16.16.2): complete MEM-20, complete DMEM-20, or complete MEM-20/BrdU (see recipes), 37°C

Maintenance medium (Table 16.16.2): complete MEM-10, complete DMEM-10, or complete MEM-10/BrdU (see recipes), 37°C

PBS (optional; APPENDIX 2)

Trypsin/EDTA: 0.25% (w/v) trypsin/0.02% (w/v) EDTA, 37°C

25-cm² and 150-cm² tissue culture flasks

Humidified, 37°C, 5% CO₂ incubator

Begin the culture

1. Thaw a frozen ampule of cells in a 37°C water bath.
2. Sterilize the ampule tip with 70% ethanol, break the neck, and transfer the cells with a pipet into a 25-cm² tissue culture flask containing 5 ml start-up medium. Rotate the flask to evenly distribute the cells and place overnight in a humidified, 5% CO₂ incubator at 37°C.
3. Aspirate the start-up medium and replace with appropriate maintenance medium. Return cells to the CO₂ incubator at 37°C and check daily for confluency.

Cells should be passaged when they become confluent. Generally, if cells are split 1:20, they reach confluence in 1 week and need not be counted.

Maintain the culture

4. When the cells are a confluent monolayer, aspirate medium.
5. Wash cells once with PBS or trypsin/EDTA to remove remaining serum from the cells by covering cells with the solution and pipetting it off.

6. Overlay cells with 37°C trypsin/EDTA using a volume that is just enough to cover the monolayer (e.g., 0.3 ml for a 25-cm² flask). Allow to sit 30 to 40 sec (cells should become detached) and shake the flask to completely detach cells.
7. Add 1.4 ml appropriate maintenance medium. Pipet the cell suspension up and down several times to disrupt clumps (these cells are ready for passage).
8. Remove 0.5 ml cell suspension and add it to a new 150-cm² tissue culture flask containing 30 ml maintenance medium. Rotate the flask to evenly distribute the cells and place in a CO₂ incubator at 37°C until the cells are confluent (~1 week). Maintain the cells by splitting ~1:20 in maintenance medium at approximately weekly intervals.

Cells can be maintained in smaller flasks if desired. If so, volumes should be adjusted proportionately.

CULTURE OF CELLS IN SUSPENSION

HeLa S3 cells are maintained in complete spinner medium-5.

Materials

Frozen ampule of HeLa S3 cells (ATCC no. CCL2.2)
 70% ethanol
 Complete MEM-10 (see recipe), 37°C
 Trypsin/EDTA: 0.25% (w/v) trypsin/0.02% (w/v) EDTA, 37°C
 Complete spinner medium-5 (see recipe), 37°C
 25-cm² tissue culture flask
 Humidified, 37°C, 5% CO₂ incubator
 Sorvall H-6000A rotor (or equivalent)
 100- or 200-ml vented spinner bottles and caps with filters (Bellco)
 Additional reagents and equipment for counting cells with a hemacytometer
 (APPENDIX 3F)

Begin the culture

1. Thaw a frozen ampule of HeLa S3 cells in a 37°C water bath.
2. Sterilize the ampule tip with 70% ethanol, break the neck, and transfer the cells with a pipet to a 25-cm² tissue culture flask containing 5 ml complete MEM-10. Rotate the flask to evenly distribute the cells and place overnight in a humidified, 5% CO₂ incubator at 37°C.
3. Aspirate medium. Overlay cells with 0.5 ml of 37°C trypsin/EDTA and let sit 30 to 40 sec.

Since these cells do not attach firmly to the flask, they should not be washed prior to trypsinization.
4. Add 10 ml complete spinner medium-5 and transfer cells to a 50-ml centrifuge tube. Centrifuge 5 min in a Sorvall H-6000A rotor at 2500 rpm (1800 × g), room temperature, and discard supernatant.
5. Suspend cell pellet in 5 ml complete spinner medium-5 by pipetting up and down to disrupt clumps.
6. Add 50 ml complete spinner medium-5 to a 100- or 200-ml vented spinner bottle and transfer the cell suspension to this bottle.

**BASIC
 PROTOCOL 2**

**Protein
 Expression**

16.16.3

7. Remove 1 ml cell suspension and count the cells using a hemacytometer (*APPENDIX 3F*). Add complete spinner medium-5 to adjust the cell density to $3\text{--}4 \times 10^5$ cells/ml. Place cells in a 37°C incubator without CO_2 and stir continuously.

The initial high density is used because some cells are not viable.

8. Grow cells for two successive days, counting cells daily and adding complete spinner medium-5 as necessary to maintain a concentration of $3\text{--}4 \times 10^5$ cells/ml.

Maintain the culture

9. Remove 1 ml cell suspension and monitor the cells using a hemacytometer.
10. When the density is $4\text{--}5 \times 10^5$ cells/ml, dilute the cells to 1.5 or 2.5×10^5 cells/ml with complete spinner medium-5 for alternate day or daily feeding, respectively.
11. Place a 100- or 200-ml vented spinner bottle containing 50 ml or 100 ml cells, respectively, in 37°C incubator without CO_2 and stir continuously. Passage every 1 to 2 days.

HeLa S3 cells are grown and maintained in complete spinner medium-5 in vented spinner bottles at 37°C without CO_2 . Cells are diluted with fresh medium at 1- to 2-day intervals to keep the cell density between 1.5×10^5 and 5×10^5 cells/ml.

BASIC PROTOCOL 3

PREPARATION OF A VACCINIA VIRUS STOCK

To prepare a vaccinia virus stock, HeLa S3 cells from a spinner culture (see Basic Protocol 2) are plated the day before infection and allowed to attach. They are then infected with trypsinized virus. After several days, the infected cells are harvested and lysed during repeated freeze-thaw cycles. The virus stock is then aliquoted and stored at -70°C . To titer this stock, see Support Protocol 1. The protocol can be modified for monolayer cultures.

Materials

- HeLa S3 cells from suspension culture (see Basic Protocol 2)
- Complete MEM-10 and -2.5 (see recipe), 37°C
- Vaccinia virus (ATCC no. VR1354 or equivalent)
- 0.25 mg/ml trypsin (2 \times crystallized and salt-free; Worthington; filter sterilize and store at -20°C)
- Sorvall H-6000A rotor (or equivalent)
- 150-cm² tissue culture flask
- Humidified, 37°C , 5% CO_2 incubator
- Additional reagents and equipment for counting cells with a hemacytometer (*APPENDIX 3F*)

Prepare cells

1. Count HeLa S3 cells from a suspension culture using a hemacytometer (*APPENDIX 3F*).
2. Centrifuge 5×10^7 cells 5 min in a Sorvall H-6000A rotor at 2500 rpm (1800 \times g), room temperature, and discard supernatant.
3. Resuspend cells in 25 ml of 37°C complete MEM-10, dispense in a 150-cm² tissue culture flask, and place overnight in a humidified, 5% CO_2 incubator at 37°C .

Increase the number of HeLa cells proportionately if more than one 150-cm² flask is to be infected.

As an alternative to HeLa suspension cells, prepare 150-cm² flasks of monolayer cells as described (see Basic Protocol 1) and continue with step 4 below.

Trypsinize virus

4. Just prior to use, mix an equal volume of vaccinia virus stock and 0.25 mg/ml trypsin, and vortex vigorously. Incubate 30 min in a 37°C water bath, vortexing at 5- to 10-min intervals throughout the incubation.

Virus stocks are usually at a titer of $\sim 2 \times 10^9$ pfu/ml, but may be significantly lower depending on the source.

Vortexing usually breaks up any clumps of cells. However, if there are still visible clumps, chill to 0°C and sonicate 30 sec on ice (UNIT 16.17). Sonication can be repeated several times but the sample should be allowed to cool on ice between sonications.

Infect cells

5. Dilute trypsinized virus in complete MEM-2.5 at $2.5\text{--}7.5 \times 10^7$ pfu/ml. Decant or aspirate medium from the 150-cm² flask of cells and add 2 ml diluted, trypsinized virus. Place 2 hr in a CO₂ incubator at 37°C, rocking flask by hand at 30-min intervals.

The optimal multiplicity of infection (MOI) is 1 to 3 pfu/cell. Multiplicities of 0.1 pfu/cell may be necessary if the titer of the initial virus stock is low. The trypsinized virus must be diluted ≥ 10 -fold to avoid detaching the cells.

6. Overlay cells with 25 ml complete MEM-2.5 and place 3 days in a CO₂ incubator at 37°C.
7. Detach the infected cells from the flask by shaking and pour or pipet into a sterile plastic screw-cap tube. Centrifuge 5 min at $1800 \times g$, 5° to 10°C, and discard supernatant.
8. Resuspend cells in 2 ml complete MEM-2.5 (per initial 150-cm² flask) by gently pipetting or vortexing.

Harvest virus stock

9. Lyse the cell suspension by freeze-thaw cycling as follows: freeze in dry ice/ethanol, thaw in a 37°C water bath, and vortex. Carry out the freeze-thaw cycling a total of three times.
10. Keep the virus stock on ice and divide it into 0.5- to 2-ml aliquots. Store the aliquots indefinitely at -70°C.

TITRATION OF VACCINIA VIRUS STOCKS BY PLAQUE ASSAY

Serial dilutions of the trypsinized virus stock (see Basic Protocol 3) are used to infect the appropriate cell line. After several days growth, the medium is removed and the cells are stained with crystal violet. Plaques appear as 1- to 2-mm-diameter areas of diminished staining due to the retraction, rounding, and detachment of infected cells.

Additional Materials (also see *Basic Protocols 1 and 3*)

- BS-C-1 cells from confluent monolayer culture (see Basic Protocol 1)
- Virus stock (see Basic Protocol 3)
- 0.1% (w/v) crystal violet (Sigma) in 20% ethanol (store indefinitely at room temperature)
- 6-well, 35-mm² tissue culture dishes
- Additional reagents and equipment for counting cells with a hemacytometer (*APPENDIX 3F*)

SUPPORT PROTOCOL 1

Protein Expression

16.16.5

Prepare cell and virus stocks

1. Trypsinize confluent monolayer of BS-C-1 cells as described (see Basic Protocol 1, steps 4 to 7).
2. Count the cells using a hemacytometer (*APPENDIX 3F*).
3. Seed wells of a 6-well, 35-mm² tissue culture dish with 5×10^5 cells per well BS-C-1 cells in 2 ml complete MEM-10. Place overnight in a humidified, 5% CO₂ incubator at 37°C to reach confluency.
4. Trypsinize virus stock (see Basic Protocol 3, step 4).
5. Make nine 10-fold serial dilutions (*UNIT 1.11*) of the trypsinized virus in complete MEM-2.5, using a fresh pipet for each dilution.

Perform assay

6. Remove medium from BS-C-1 cells and infect cells in duplicate wells with 0.5 ml of the 10⁻⁷, 10⁻⁸, and 10⁻⁹ trypsinized virus dilutions. Place 1 to 2 hr in a CO₂ incubator at 37°C, rocking dish at 15- to 30-min intervals to spread virus uniformly and keep cells moist.
7. Overlay cells in each well with 2 ml complete MEM-2.5 and place 2 days in a CO₂ incubator at 37°C.
8. Remove medium and add 0.5 ml of 0.1% crystal violet to each well. Incubate 5 min at room temperature.
9. Aspirate crystal violet and allow wells to dry.
10. Determine the titer by counting plaques within the wells and multiplying by the dilution factor.

Most accurate results are obtained from wells with 20 to 80 plaques. In determining the titer, take into account the 1:1 dilution of the virus stock with trypsin.

BASIC PROTOCOL 4

PREPARATION OF CHICKEN EMBRYO FIBROBLASTS

The attenuated, replication-deficient modified vaccinia virus Ankara (MVA) can be used as an alternative to standard strains of vaccinia virus, for use as a vector to express foreign genes. MVA was derived from the vaccinia virus strain Ankara by multiple (>570) passages in chick embryo fibroblasts (CEF). Although MVA expresses recombinant proteins efficiently, the assembly of infectious particles is interrupted in human and most other mammalian cells lines, providing an added degree of safety to laboratory personnel. The NIH Intramural Biosafety Committee has determined that individuals do not need to be vaccinated to work with MVA, and can do so under biosafety level 1 (BL-1) conditions if no other vaccinia virus strains are being manipulated at the same location by other investigators. Recombinant MVA expressing bacteriophage T7 RNA polymerase, which can be used for high level transient expression, has also been constructed (*UNIT 16.19*)

CEF or Syrian hamster kidney cells (BHK-21, see Basic Protocol 1) are permissive for growth of MVA. MVA is titered by immunostaining (see Support Protocol 2), because it does not form distinct plaques for accurate quantitation.

In this protocol, nine-day-old chicken embryos are trypsinized and plated in appropriate medium. After the cells form a confluent monolayer, they are transferred directly to a 31°C incubator where they can be held for 2 to 3 weeks before making secondary CEF for virus infection. With each passage, CEF require longer to become confluent; therefore use of the second passage is recommended.

Materials

Nine-day-old embryonated eggs (Specific Pathogen Free Eggs, SPAFAS)
70% ethanol
MEM with no additives, 37°C
Trypsin/EDTA: 0.25% (w/v) trypsin/0.02% (w/v) EDTA, 37°C
Complete MEM-10 (Table 16.16.2; see recipe), 37°C

Sterile dissecting scissors and forceps
100-cm² sterile petri dishes
10-ml syringes
Sterile trypsinization flask with magnetic stir bar
Humidified, 37° and 31°C, 5% CO₂ incubators
500-ml beakers with two layers of gauze taped over tops
Sorvall RC-3B centrifuge and 250-ml centrifuge bottles (or equivalent)
150-cm² tissue culture flasks

Prepare tissue

1. Position ten 9-day-old embryonated eggs with air space (blunt end) up and spray with 70% ethanol.
2. Crack the top of an egg with sterile dissecting scissors, and cut off shell to just above the membrane while keeping the latter intact. Remove membrane with sterile forceps. Repeat with remaining eggs.

NOTE: Healthy eggs have well-formed blood vessels.

3. Remove the embryo from each egg and combine in a 100-cm² sterile petri dish.
4. Remove head and feet from each embryo and place the rest of the body in a 100-cm² sterile petri dish containing 10 ml MEM with no additives. Mince embryos by squeezing through 10-cc syringes (~5 embryos/syringe) into a sterile trypsinization flask.

Dissociate cells

5. Add 100 ml of 37°C trypsin/EDTA and incubate 5 min in a humidified, 5% CO₂ incubator at 37°C, with stirring.
6. Decant fluid from the trypsinization flask into a 500-ml beaker covered with gauze. Transfer filtrate to a 250-ml centrifuge bottle.
7. Add 100 ml fresh trypsin/EDTA to the remaining tissue in the trypsinization flask, and incubate 5 min at 37°C.
8. Pour digest into a second 500-ml beaker covered with gauze, and add filtrate to the first filtrate in the 250-ml centrifuge bottle.
9. Centrifuge 10 min at 1200 × *g*, 4°C, in a Sorvall RC-3B centrifuge.
10. Aspirate and discard supernatant from pellet, add 10 ml complete MEM-10, resuspend by pipetting ~10 to 15 times, and adjust volume to 100 ml.
11. Transfer to a 250-ml centrifuge bottle and centrifuge 10 min at 1200 × *g*, 4°C.
12. Resuspend pellet in 5 ml complete MEM-10 and adjust volume to 30 ml.

Prepare confluent culture

13. Add 1 ml cell suspension to each of thirty 150-cm² tissue culture flasks containing 30 ml complete MEM-10.

14. Incubate at 37°C for several days until confluent, and move flasks to a humidified, 31°C, 5% CO₂ incubator for storage.

The CEF cell cultures can be held for 2 to 3 weeks at 31°C without further attention. Primary CEF can also be used directly for virus growth, or the trypsinized stock of CEF can be frozen in liquid nitrogen for future use.

PREPARATION OF AN MVA STOCK

To prepare an MVA stock, CEF (see Basic Protocol 4) or BHK-21 (see Basic Protocol 1) cells are plated several days before infection and allowed to approach confluency. They are then infected with MVA. After several days, the infected cells are harvested, lysed by repeated freezing and thawing, sonicated, dispensed in small aliquots, and stored at -70°C.

NOTE: BHK-21 cells should be acquired from ATCC, as cells from alternative sources may support lower levels of MVA replication.

Materials

150-cm² tissue culture flasks of nearly confluent CEF (see Basic Protocol 4) or BHK-21 cells (see Basic Protocol 1)

Complete MEM-10 and -2.5 (see recipe), 37°C

Modified vaccinia virus Ankara (MVA; A. Mayr, Institut für Med. Mikrobiologie, Munich, Germany, or B. Moss, email *bmoss@nih.gov*)

150-cm² tissue culture flasks

Humidified, 37°C, 5% CO₂ incubator

Sorvall RC-3B centrifuge and sterile 250-ml centrifuge bottles (or equivalent)

Additional reagents and equipment for trypsinizing cells (see Basic Protocol 1)

1. Trypsinize seven 150-cm² tissue culture flasks of nearly confluent CEF *or* two of BHK-21 cells as described (see Basic Protocol 1, steps 4 to 7), using 1.5 ml trypsin/EDTA and 8.5 ml maintenance medium for the larger flask. Distribute to twenty 150-cm² flasks. Incubate at 37°C in a humidified, 5% CO₂ incubator until nearly confluent monolayers have formed (usually 2 days).

CEF and BHK-21 cells are split 1:3 and 1:10, respectively. It is advisable to use monolayers of BHK-21 cells at 90% confluency, as completely confluent cultures degrade within 48 hr.

2. Remove medium and add 30 ml complete MEM-2.5 to each 150-cm² flask.

3. Thaw MVA virus and sonicate 30 sec on ice to break up clumps.

Trypsinization of virus is avoided with MVA because it may lower the titer.

4. Add 1 to 3 infectious units of virus/cell to the medium and place cells in a CO₂ incubator for 3 days at 37°C.

A monolayer of CEF or BHK-21 cells in a 150 cm² flask contains ~1–2 × 10⁷ cells. If there is insufficient virus, then use fewer or smaller flasks of confluent cells.

5. Detach the cells with a cell scraper or, if possible, by shaking. Transfer cells and medium to a sterile 250-ml centrifuge bottle and centrifuge 10 min at 1200 × *g*, 4°C, in a Sorvall RC-3B centrifuge. Discard supernatant.

6. Resuspend cells in 1 ml complete MEM-2.5 (per 150-cm² flask) by pipetting or vortexing.

7. Lyse cells by freeze-thaw cycling: freeze in dry ice/ethanol, thaw in a 37°C water bath, and vortex. Carry out the freeze-thaw cycling a total of three times.

8. Sonicate stock on ice for 1 min, pause for 1 min, and repeat sonication. Dispense in 0.5-ml aliquots and store indefinitely at -70°C .

TITRATION OF MVA STOCKS BY IMMUNOSTAINING

The titer of MVA is routinely determined by immunostaining, because MVA does not form distinct plaques in CEF or BHK-21 cells. To determine the MVA titer, serial dilutions of virus stock are prepared and used to infect CEF or BHK-21 cells. At 24 hr after infection, the cells are fixed with acetone/methanol and immunostained using a polyclonal vaccinia virus antiserum and a secondary peroxidase-conjugated antibody. A focus of infected cells appears as a 0.3- to 0.4-mm reddish brown-stained area. If the cells are left for two days before immunostaining, secondary foci may form by virus spread giving inaccurate titers.

Materials

- CEF (see Basic Protocol 4) or BHK-21 cells (see Basic Protocol 1) in a 150-cm² tissue culture flask
- Complete MEM-10 and -2.5 (see recipe), 37°C
- MVA stock (see Basic Protocol 5)
- 1:1 (v/v) acetone/methanol
- PBS (*APPENDIX 2*), with and without 3% FBS
- Rabbit anti-vaccinia antibody (e.g., Access Biomedical & Diagnostic Research Labs or see Linscott, 1998)
- Horseradish peroxidase-conjugated whole anti-rabbit Ig antibody (HRP-anti-rabbit; Amersham)
- Dianisidine, or premade peroxidase substrate kit (Sigma)
- PBS/H₂O₂ (add 10 μl 30% H₂O₂ to 10 ml PBS immediately before use)
- 6-well, 35-mm² tissue culture dishes
- Humidified, 37°C, 5% CO₂ incubator
- Additional reagents and equipment for trypsinizing cells (see Basic Protocol 1)

Infect and fix cells

1. Trypsinize a 150-cm² tissue culture flask of CEF or BHK-21 cells as described (see Basic Protocol 1, steps 4 to 6), using 1.5 ml trypsin/EDTA for the larger flask. Resuspend cells by repeated pipetting in 5 ml complete MEM-10, and add an additional 60 ml complete MEM-10.
2. Add 2 ml cell suspension to each well of a 6-well, 35-mm² tissue culture dish. Incubate overnight in a humidified, 5% CO₂ incubator at 37°C to reach near confluency.
3. Remove medium and replace with 2 ml complete MEM-2.5.
4. Thaw MVA stock and sonicate 30 sec on ice.
5. Make eight 10-fold serial dilutions of the virus in complete MEM-2.5, using a fresh pipet for each dilution.
6. Add 0.1 ml of each of the 10⁻⁶, 10⁻⁷, and 10⁻⁸ dilutions to cells in duplicate wells. Swirl gently to mix, and incubate 24 hr in a CO₂ incubator at 37°C.
7. Remove fluid and fix cells 2 min with 1 ml of 1:1 acetone/methanol. Remove fixative and add 2 ml PBS to each well.

At this point, the plates can be immunostained immediately or stored at 4°C for several weeks.

Perform immunostaining

8. Dilute rabbit anti-vaccinia antibody in PBS containing 3% FBS and add 1 ml/well. Incubate 1 hr at room temperature, with gentle rocking, if desired.

The optimal dilution for each antibody must be determined empirically, but a 1:500 or 1:1000 dilution is a good place to start.

9. Wash twice with 2 ml PBS.

10. Dilute HRP-anti-rabbit secondary antibody in PBS containing 3% FBS and add 1 ml/well. Incubate for 30 to 45 min at room temperature, with gentle rocking, if desired.

The optimal dilution for each antibody must be determined, but a 1:500 or 1:1000 dilution is a good place to start. If another anti-vaccinia antibody is used in step 8, the appropriate HRP-conjugated anti-species secondary antibody should be substituted here.

11. Wash twice with 2 ml PBS.

12. Make a saturated solution of dianisidine in 0.5 ml ethanol, vortex, incubate 5 min at 37°C, and clarify by microcentrifugation at maximum speed for 1 min. Add 0.2 ml dianisidine solution to 10 ml PBS/H₂O₂. Alternatively, use premade substrate tablets according to manufacturer's instructions.

CAUTION: Dianisidine is carcinogenic and the powder should be manipulated with gloves in a fume hood. 30% H₂O₂ is caustic to skin and should be handled with gloves.

13. Add 0.5 ml dianisidine substrate solution to each well. Rotate dish gently and let stand ~10 min. Check microscopically for foci of infected cells. When development is complete, wash dishes with water and overlay with 1 ml water to preserve stain.

Weaker antibody may take longer to develop.

14. Count the number of stained foci and multiply by the dilution factor to express titer as infectious units/ml.

Most accurate results are obtained from wells with 20 to 100 plaques. In determining the titer as infectious units/ml, be sure to multiply by 10 to take into account the 0.1 ml addition of virus to the wells.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Complete DMEM-10 or -20

Dulbecco's minimum essential medium (DMEM) containing:

10% or 20% fetal bovine serum (FBS)

0.03% glutamine

100 U/ml penicillin

100 µg/ml streptomycin sulfate

Store up to several months at 4°C

Add supplements from stock solutions prepared in water at the following initial concentrations: 3% glutamine (100×), 20,000 U/ml penicillin (200×), and 20 mg/ml streptomycin (200×). Filter sterilize stock solutions. Store 100× glutamine 4 months at 4°C, and 200× penicillin/streptomycin 4 months at -20°C.

Fetal bovine serum is added at 10% to complete medium for maintenance of cells and at 20% to encourage initial growth upon thawing. See Chapter 9 introduction for a full discussion concerning media preparation and use of serum (e.g., heat-inactivation, screening).

Complete MEM-2.5, -10, or -20

Minimum essential medium (MEM) containing:

2.5%, 10%, or 20% FBS

0.03% glutamine

100 U/ml penicillin

100 µg/ml streptomycin sulfate

Store up to several months at 4°C

Add supplements from stock solutions as described for complete DMEM (see recipe). Also see annotation to DMEM recipe concerning growth versus maintenance levels of serum.

Complete MEM-10/BrdU or -20/BrdU

Prepare as for complete MEM-10 or -20 (see recipe) and add a 5 mg/ml solution of 5-bromodeoxyuridine (BrdU) to 25 µg/ml final. Store up to several months at 4°C.

Prepare the 5 mg/ml BrdU stock solution (200×) in water and filter sterilize. Store in the dark at -20°C. After thawing 5 mg/ml BrdU, vortex to be sure it is in solution before adding to MEM.

Complete spinner medium-5

MEM spinner medium

5% horse serum

Store up to several months at 4°C

Supplements are in MEM spinner medium; no addition is necessary. Horse serum is used because it is cheaper than FBS and may give less cell clumping.

COMMENTARY

Background Information

An overview of the vaccinia life cycle and expression system is presented in *UNIT 16.15*.

Because HeLa cells consistently give high yields of virus, they are routinely used for preparation of virus stocks. HeLa S3 cells, as obtained from the ATCC, grow well in monolayer culture but can also be put into suspension culture. After repeated passages in suspension, they do not adhere well to flasks and grow poorly in monolayer cultures. The authors prefer HeLa cells adapted to suspension culture because large numbers can be grown in a single bottle. However, suspension cultures require more maintenance than monolayer cultures and the latter may be more convenient.

Suspension cells are allowed to form a monolayer before infection to increase the chances of cell-to-cell spread if not all cells are initially infected with the viral inoculum. Thus, good yields of virus may be obtained even if the inoculum is <1 pfu/cell. HeLa cells—even those adapted to monolayer culture—are fairly round to begin with and therefore show little visible evidence of infection. BS-C-1 cells, by contrast, are long and spindle-shaped but round up dramatically a few hours after infection. This property accounts for the highly visible plaques obtained with BS-C-1 cells, and their preference for titration by plaque assay.

The Western Reserve (WR) strain of vaccinia virus (ATCC no. VR1354) is widely used for laboratory studies. It gives high yields of cell-associated virus, discrete plaques, and is well adapted to mice and other laboratory animals. Other strains of vaccinia virus are available from the ATCC and private sources.

Horse serum is used for growth of HeLa cells in suspension because it is cheaper than FBS and may give less cell clumping. Horse serum is used in spinner medium for growth of HeLa cells in suspension. All monolayer cells are grown in medium with FBS.

Modified vaccinia virus Ankara (MVA; Mayr et al., 1975) was one of several highly attenuated strains of vaccinia virus that were developed but were not extensively used for smallpox vaccination, in part because of the successful eradication of the disease with the conventional vaccine strains. Restriction enzyme analysis demonstrated that MVA had suffered multiple deletions (Meyer et al., 1991) during its long passage history in CEF that may account for its severe host restriction, including an inability to replicate efficiently in human and most other mammalian cells (Carroll and Moss, 1997). It was somewhat surprising to find that the replication defect occurred at a late stage of virion assembly and consequently that viral or recombinant gene expression was unimpaired

(Sutter and Moss, 1992). Therefore, MVA can be viewed as an efficient single-round expression vector with little potential to spread. Although MVA causes less cytopathic effects than standard vaccinia virus in some cell lines, in others the effect is quite severe (Carroll and Moss, 1997).

Because of its host-range restriction, recombinant MVA were initially made and propagated exclusively in primary or secondary CEF. A recent survey demonstrated that a stable Syrian hamster kidney cell line, BHK-21, was also permissive for MVA growth and could be used for making recombinant viruses (Carroll and Moss, 1997). Although many laboratories may prefer to use a stable cell line, the authors continue to employ CEF because they give slightly higher MVA titers, can be stored in a dormant state for several weeks (whereas BHK-21 cells must be passaged every 5 days), and are better suited to immunostaining because of greater adherence than BHK-21 cells to plastic dishes.

Critical Parameters

Proper maintenance of actively growing cell lines is important in order to achieve efficient infections and high yields of virus. This is especially true for HeLa S3 cell suspension cultures, which should be maintained at $1.5\text{--}5 \times 10^5$ cells/ml (requiring passaging every 1 to 2 days). HeLa cells can achieve a density of $8\text{--}10 \times 10^5$ cells/ml, but exhibit a lag period upon dilution before optimal growth is resumed; prolonged maintenance at high density will lead to cell death. HeLa S3 cells adapted to grow in suspension cultures do not grow well in monolayer cultures. However, the cells will adhere to flasks, which allows the cells to be infected on the following day (see Basic Protocol 3).

Since most progeny viruses remain cell-associated, infected cells must be disrupted by freeze-thaw cycling and trypsinization. These procedures are important for releasing virus from the host cells. An entire stock of virus can be subjected to freeze-thaw cycling, but only the portion to be used should be trypsinized. Sonication also helps in disaggregating virus but is usually unnecessary if the virus stock has been trypsinized. Unlike standard replication-competent vaccinia protocols, trypsin is not used as a pretreatment to enhance the infectivity of MVA. Pretreatment of MVA with trypsin can decrease virus titer.

Although vaccinia virus is relatively stable, stocks should be kept on ice while in use and

should be stored at -70°C . A vaccinia virus stock should have a stable titer for many years when stored at this temperature. Although the stock can be frozen and thawed several times without loss of infectivity, storing in aliquots is recommended.

The preparation of a seed stock of virus that is sufficient for future experiments is strongly recommended. A common mistake is to continually passage the virus.

Anticipated Results

A vaccinia stock should have a titer of $\geq 1\text{--}2 \times 10^9$ pfu/ml. MVA stocks can approach a titer of 1×10^{10} infectious units/ml when prepared as described (see Basic Protocol 5), and recombinant virus can reach $1\text{--}3 \times 10^9$ infectious units/ml. The viral stock should have a stable titer for many years when stored as indicated above (see Critical Parameters).

Time Considerations

Actively growing cells should be prepared in advance, as it will take ≥ 1 week to revive frozen cells. For preparation of a vaccinia virus stock, infected cells should be incubated for 3 days. During this period, the BS-C-1 cells for plaque titration can be prepared. For a small volume of stock (i.e., from one 150-cm² flask), harvesting and freeze-thaw cycling can be done in <1 hr. Determination of the titer of a virus stock requires 2 days of incubation to allow for development of plaques.

Preparation of CEF cells from embryonated eggs requires ~ 2 hr. Thereafter, they can be stored for several weeks with no maintenance. Starting BHK-21 cells from frozen cultures can take >1 week and requires passaging every 5 days. For preparation of MVA stocks, 3 days are required for virus growth, 2 hr for harvesting, freeze-thaw cycling, and dispensing, and 1 day of incubation for determination of the virus titer by immunostaining. The immunostaining procedure takes ~ 3 hr.

This unit first describes how to infect cells with vaccinia virus and then transfect them with a plasmid-transfer vector to generate a recombinant virus (see Basic Protocol 1). Methods are also presented for purifying vaccinia virus (see Support Protocol 1) and for isolating viral DNA (see Support Protocol 2), which can be used during transfection. Also presented are selection and screening methods used to isolate recombinant viruses (see Basic Protocol 2) and a method for the amplification of recombinant viruses (see Basic Protocol 3). Finally, a method for live immunostaining that has been used primarily for detection of recombinant modified vaccinia virus Ankara (MVA) is presented (see Basic Protocol 4).

HeLa S3 cells are used for large-scale growth of vaccinia virus. However, several other cell lines may be required for plaque purification and amplification. For thymidine kinase (TK) selection, HuTK⁻ 143B cells are used; for xanthine-guanine phosphoribosyltransferase (XGPRT) selection, BS-C-1 cells are used. CV-1 or BS-C-1 cells are used for transfection, and either can be used for determination of virus titer (UNIT 16.16). With MVA, all steps are carried out in CEF or BHK-21 cells (see Basic Protocol 4).

CAUTION: Proceed carefully and follow biosafety level 2 (BL-2) practices when working with standard vaccinia virus (see UNIT 16.15 for safety precautions).

NOTE: Carry out all procedures for preparation of virus in a biosafety cabinet.

TRANSFECTION OF INFECTED CELLS WITH A VACCINIA VECTOR

The foreign gene of interest is subcloned into a plasmid transfer vector (Fig. 16.17.1 and Fig. 16.17.2) so that it is flanked by DNA from a nonessential region of the vaccinia genome. This recombinant plasmid is then transfected into cells that have been infected with vaccinia virus. Homologous recombination occurs between the vaccinia virus genome and homologous sequences within the plasmid (Fig. 16.17.1). The recombinant virus is obtained in a cell lysate, which is then subjected to several rounds of plaque purification using appropriate selection and/or screening protocols (see Basic Protocol 2). For modified vaccinia virus Ankara (MVA), the same transfection procedure is used, except that the virus is not trypsinized and either CEF (UNIT 16.16) or BHK-21 cells are substituted for CV-1 or BS-C-1 cells. For live immunostaining to detect recombinant MVA or standard virus, see Basic Protocol 4.

Materials

- pSC11, pRB21, pSC65, pLW9, or other suitable vector (Table 16.17.1)
- CV-1, BS-C-1, BHK-21, or CEF cells (UNIT 16.16)
- Complete MEM-10 and -2.5 media (UNIT 16.16)
- Vaccinia virus stock (UNIT 16.16)
- 0.25 mg/ml trypsin (2× crystallized and salt-free; Worthington; filter sterilize and store at -20°C)
- Transfection buffer (see recipe)
- 2.5 M CaCl₂
- 20 mM HEPES, pH 7.4
- DOTAP liposomal transfection reagent (Boehringer Mannheim)
- OptiMEM medium (Life Technologies)
- Dry ice/ethanol bath
- 25-cm² tissue culture flask

BASIC PROTOCOL 1

Protein Expression

12 × 75-mm polystyrene tubes
 Disposable scraper or rubber policeman, sterile
 15-ml conical centrifuge tubes
 Sorvall centrifuge with H-6000A rotor (or equivalent)

Additional reagents and equipment for subcloning (UNIT 3.16), isolation of plasmid (UNIT 1.7), and tissue culture (APPENDIX 3F)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Figure 16.17.1 Homologous recombination between a transfected plasmid and the vaccinia virus genome. TK_L and TK_R are vaccinia virus DNA sequences flanking the foreign gene. p₁₁ and p_{7.5} are promoters.

Prepare recombinant plasmid DNA

1. Subclone the gene of interest into the multiple cloning site (MCS) in pSC11, pRB21, pSC65, pLW9, or other suitable vector (UNIT 3.16) and isolate plasmid (UNIT 1.7).

Prepare vaccinia-infected cells

2. Seed a 25-cm² flask with 1×10^6 CV-1, BS-C-1, BHK-21, or CEF cells in complete MEM-10 medium. Incubate to near confluency (usually overnight).

UNIT 16.16 details the culture of these cells.

3. Just prior to use, mix equal volumes of vaccinia virus stock and 0.25 mg/ml trypsin, and vortex vigorously. Incubate 30 min in a 37°C water bath, vortexing at 5- to 10-min intervals during the incubation. For MVA, substitute 30 sec sonication on ice for trypsinization to break up clumps (also see UNIT 16.16).

Virus stocks are usually at a titer of $\sim 2 \times 10^9$ pfu/ml, but may be significantly lower depending on the source.

Vortexing usually breaks up any clumps of cells. However, if there are still visible clumps, chill to 0°C and sonicate 30 sec on ice. Sonication can be repeated several times but the sample should be allowed to cool on ice between sonications. Trypsinization of MVA is avoided because it may lower the titer.

Figure 16.17.2 Plasmid transfer vector pSC11.

4. Dilute trypsinized or sonicated virus in complete MEM-2.5 to 1.5×10^5 pfu/ml. Aspirate medium from confluent monolayer of cells and infect with 1 ml diluted vaccinia virus (0.05 pfu/cell). Incubate 2 hr with rocking at ~15-min intervals.

Approximately 30 min before the end of the infection period, prepare DNA according to the CaCl_2 or DOTAP method as described below.

Prepare DNA

For CaCl_2 method

- 5a. Place 1 ml transfection buffer into a 12×75 -mm polystyrene tube and add 5 to 10 μg (in $<50 \mu\text{l}$) of the recombinant plasmid containing the gene of interest (from step 1).

Inclusion of vaccinia DNA (see Support Protocol 2) in the transfection is not required but results in a higher efficiency of recombination. If it is added, combine 1 μg vaccinia DNA

Table 16.17.1 Vaccinia Virus Transfer Vectors

^apRB21 was specifically designed for use with vaccinia virus vRB12, which has a deletion in the F13L gene. The plasmids pG06, pLW-7, pMC03, pLW-9, pLW-17, pLW-21, pLW-22, and pLW-24 were designed for MVA.

^bAbbreviations: E, early; L, late; E/L, early and late. The designation " $\times 2$ " refers to two oppositely oriented promoters that can be used for expression of two genes.

^c*Sma*I digestion gives a blunt end for cloning any fragment that has been blunt-ended. MCS signifies multiple cloning sites.

^dAbbreviations: TK, thymidine kinase locus; F12L/F13L, between F12L and F13L open reading frames; Del III, site of natural deletion in MVA.

^eTransient selection in which XGPRT gene is deleted from recombinant vaccinia virus during recombination; see Background Information.

with 5 to 10 μg recombinant plasmid DNA and vortex vigorously to shear the high-molecular-weight DNA before adding CaCl_2 or DOTAP. A discussion of calcium phosphate transfection can be found in UNIT 9.1; also see Critical Parameters.

- 6a. Slowly add 50 μl of 2.5 M CaCl_2 and mix gently. Leave 20 to 30 min at room temperature.

Gentle mixing is essential; see Critical Parameters. A fine precipitate should appear.

For DOTAP method

- 5b. Add 70 μl of 20 mM HEPES, pH 7.4, and 30 μl DOTAP to a 12 \times 75-mm polystyrene tube. In a second tube, add 5 μg recombinant plasmid containing the gene of interest (from step 1) to 20 mM HEPES for a final volume of 100 μl .

See step 5a regarding optional addition of vaccinia DNA.

- 6b. Add the DNA solution to the DOTAP solution and leave 15 min at room temperature, then add 1 ml OptiMEM medium.

Transfect cells

7. Aspirate virus inoculum from monolayer of cells (step 4).
- 8a. *For CaCl_2 method:* Add the precipitated DNA suspension (step 6a) to the cells and leave 30 min at room temperature, then add 9 ml complete MEM-10 and incubate 3 to 4 hr at 37°C.
- 8b. *For DOTAP method:* Add the DNA/DOTAP solution (step 6b) to the cells and incubate 4 hr at 37°C.
9. Aspirate medium, replace with 5 ml complete MEM-10, and incubate 2 days at 37°C.
10. Dislodge cells with a disposable scraper or sterile rubber policeman and transfer to a 15-ml conical centrifuge tube. Centrifuge 5 min at 1800 $\times g$ (2500 rpm in a Sorvall H-6000A rotor), 5° to 10°C, then aspirate and discard medium.
11. Resuspend cells in 0.5 ml complete MEM-2.5. Lyse the cell suspension by performing three freeze-thaw cycles, each time by freezing in a dry ice/ethanol bath, thawing in a 37°C water bath, and vortexing.
12. Store the cell lysate at -70°C until needed in the selection and screening procedure (see Basic Protocol 2).

PURIFICATION OF VACCINIA VIRUS

Vaccinia is usually purified by zonal sucrose gradient centrifugation. Purified virus is useful for preparation of vaccinia DNA (see Support Protocol 2), in studies in which contaminating infected-cell proteins are undesirable, and as a very high titer stock. For large-scale purification (as in this protocol, which is for 1-liter cultures or multiples thereof) it is preferable to use HeLa cell suspensions for infection rather than monolayer cultures. If monolayer cells are used, follow the alternative procedure for monolayers (see UNIT 16.16, Basic Protocol 3) then continue with step 9 of this protocol. For many purposes, virus that is partially purified (through step 14 of this protocol) may suffice. For purification of MVA, virus is not trypsinized and either CEF or BHK-21 cells are used instead of HeLa.

SUPPORT PROTOCOL 1

Protein Expression

16.17.5

Materials

Vaccinia virus stock (UNIT 16.16)
0.25 mg/ml trypsin (2× crystallized and salt-free; Worthington; filter sterilize and store at -20°C)
HeLa S3 cells growing in suspension culture (UNIT 16.16)
Complete spinner medium-5 (UNIT 16.16)
10 mM and 1 mM Tris·Cl, pH 9.0 (APPENDIX 2)
36% (w/v) sucrose solution in 10 mM Tris·Cl, pH 9.0
40%, 36%, 32%, 28%, and 24% (w/v) sucrose solutions in 1 mM Tris·Cl, pH 9.0
Sorvall centrifuge with H-6000A rotor (or equivalent)
2-liter vented spinner flasks (microcarrier type; Bellco)
Dounce homogenizer, glass, with tight pestle
Cup sonicator (e.g., Ultrasonic Processor VC-600 from Sonics and Materials)
Ultracentrifuge with Beckman SW 27 or SW 28 rotor (or equivalent) and sterile centrifuge tubes
Spectrophotometer
Additional reagents and equipment for tissue culture and counting cells (APPENDIX 3F), and titering virus (UNIT 16.16)

NOTE: All culture incubations should be performed in a humidified 37°C , 5% CO_2 incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Infect the cells

1. Just prior to use, mix equal volumes of vaccinia virus stock and 0.25 mg/ml trypsin and vortex vigorously. Incubate 30 min in a 37°C water bath, vortexing at 5- to 10-min intervals during the incubation.

Virus stocks are usually at a titer of $\sim 2 \times 10^9$ pfu/ml, but may be significantly lower depending on the source.

Vortexing usually breaks up any clumps of cells. However, if there are still visible clumps, chill to 0°C and sonicate 30 sec on ice. Sonication can be repeated several times but the sample should be allowed to cool on ice between sonications.

2. Count HeLa S3 cells using a hemacytometer (APPENDIX 3F).
3. Transfer 5×10^8 HeLa S3 cells into a centrifuge tube, then centrifuge 10 min at $1800 \times g$ (2500 rpm in an H-6000A rotor), room temperature, and discard supernatant.
4. Resuspend cells in complete spinner medium-5 at 2×10^7 cells/ml.
5. Add trypsinized virus (from step 1) at an MOI of 5 to 8 pfu/cell and incubate 30 min with stirring.
6. Transfer cells to a vented spinner flask containing 1 liter complete spinner medium-5 and incubate 2 to 3 days with stirring.
7. Centrifuge cells 5 min at $1800 \times g$, 5° to 10°C , and discard supernatant.
8. Resuspend cells in 14 ml of 10 mM Tris·Cl, pH 9.0. Keep samples on ice for the remainder of the protocol.

Lyse the cells

9. Homogenize cell suspension with 30 to 40 strokes in a glass Dounce homogenizer with tight pestle. Check for cell breakage by light microscopy.
10. Centrifuge 5 min at $300 \times g$ (900 rpm in H-6000A rotor), 5° to 10°C , to remove nuclei. Save the supernatant.
11. Resuspend cell pellet in 3 ml of 10 mM Tris·Cl, pH 9.0. Centrifuge 5 min at $300 \times g$, 5° to 10°C . Save supernatant and pool with supernatant from step 10.
12. Sonicate pooled supernatants (lysate), keeping the lysate cold the entire time, using a cup sonicator as follows.
 - a. Split the sample into 3-ml aliquots to be sonicated separately.
 - b. Fill the cup with ice-water (~50% ice). Place the tube containing the lysate in the ice-water and sonicate 1 min at full power.
 - c. Repeat this three to four times, placing the lysate on ice for ≥ 30 sec between sonications.

Because sonication melts the ice, it is necessary to replenish the ice in the cup.

Obtain purified virus

13. Layer the sonicated lysate onto a cushion of 17 ml of 36% sucrose in a sterile SW 27 (or SW 28) centrifuge tube. Centrifuge 80 min at $32,900 \times g$ (13,500 rpm in an SW 27 rotor), 4°C . Aspirate and discard the supernatant.
14. Resuspend the viral pellet in 1 ml of 1 mM Tris·Cl, pH 9.0.

At this stage, the virus may be sufficiently pure for some purposes—e.g., isolation of DNA.
15. Sonicate once for 1 min as in step 12.
16. Prepare a sterile 24% to 40% continuous sucrose gradient in a sterile SW 27 centrifuge tube the day before it is needed by carefully layering 6.8 ml each of 40%, 36%, 32%, 28%, and 24% sucrose. Let sit overnight in refrigerator.
17. Overlay the sucrose gradient with 1 ml of sonicated viral pellet from step 15. Centrifuge 50 min at $26,000 \times g$ (12,000 rpm in an SW 27 rotor), 4°C .
18. Observe the virus as a milky band near the middle of the tube. Aspirate the sucrose above the band and discard. Carefully collect the virus band (~10 ml) with a sterile pipet, place in a sterile tube, and save.
19. Collect aggregated virus from the pellet at the bottom of the sucrose gradient after aspirating the remaining sucrose from the tube. Resuspend the viral pellet by pipetting up and down in 1 ml of 1 mM Tris·Cl, pH 9.0.
20. Sonicate resuspended pellet once for 1 min as in step 12.
21. Reband the virus from the pellet as in steps 16 to 18 and pool band with band from step 18. Add 2 vol of 1 mM Tris·Cl, pH 9.0, and mix. Transfer to sterile SW 27 centrifuge tubes.

The total volume should be ~60 ml, which is enough to fill two SW 27 centrifuge tubes. If less volume is obtained, fill the tubes with 1 mM Tris·Cl, pH 9.0.
22. Centrifuge 60 min at $32,900 \times g$, 4°C , then aspirate and discard supernatant.
23. Resuspend the virus pellets in 1 ml of 1 mM Tris·Cl, pH 9.0. Sonicate as in step 12 and divide into 200- to 250- μl aliquots. Save one aliquot for step 24 and freeze remainder at -70°C .

Quantitate virus

24. On the unfrozen aliquot, estimate the amount of virus spectrophotometrically at 260 nm. Use this to determine the amount of virus needed in the protocol for isolation of vaccinia virus DNA (see Support Protocol 2).

One optical density unit is $\sim 1.2 \times 10^{10}$ virus particles, which is $\sim 2.5\text{--}5 \times 10^8$ pfu. This value is due to light scattering, not absorbance, and therefore may vary slightly with different spectrophotometers.

25. Titer the virus by sonicating 20 to 30 sec on ice (see step 12), preparing 10-fold serial dilutions down to 10^{-10} , and infecting, in duplicate, confluent BS-C-1 cell monolayers in 6-well tissue culture plates using the 10^{-8} , 10^{-9} , and 10^{-10} dilutions (UNIT 16.16).

SUPPORT PROTOCOL 2

ISOLATION OF VACCINIA VIRUS DNA

If vaccinia DNA is used in the transfection protocol (see Basic Protocol 1, step 5a annotation), it is isolated after a proteinase K digestion and phenol extraction. The extracted DNA is precipitated and then dissolved in water. The DNA concentration is determined by measuring A_{260} .

Materials

Purified vaccinia virus (see Support Protocol 1)
50 mM and 1 M Tris·Cl, pH 7.8 (APPENDIX 2)
10% (w/v) sodium dodecyl sulfate (SDS)
60% (w/v) sucrose
10 mg/ml proteinase K
Buffered phenol: phenol equilibrated with 50 mM Tris·Cl, pH 7.8 (UNIT 2.1)
1:1 (v/v) phenol/chloroform
1 M sodium acetate, pH 7.0
100% and 95% ethanol

Spectrophotometer
Sorvall centrifuge with H-6000A rotor (or equivalent)

Additional reagents and equipment for phenol extraction of DNA (UNIT 2.1) and measuring DNA concentration (APPENDIX 3D)

NOTE: Avoid vortexing the DNA throughout this protocol.

1. Measure the optical density of purified vaccinia virus at 260 nm and bring 20 optical density units of virus (also see Support Protocol 1, step 24) to 1.2 ml final volume with 50 mM Tris·Cl, pH 7.8.

Because the vaccinia virus genome is large, care must be taken to avoid shearing (i.e., by not vortexing) if full-length DNA (such as for restriction digestion analysis) is desired.

2. Add the following to the vaccinia suspension (for 2 ml final volume):

0.1 ml 1 M Tris·Cl, pH 7.8
0.1 ml 10% SDS
0.2 ml 60% sucrose
0.4 ml 10 mg/ml proteinase K

Incubate 4 hr at 37°C.

3. Extract twice with phenol, each time by adding an equal volume of buffered phenol, mixing gently by rocking the tube, centrifuging 10 min at $300 \times g$ (900 rpm in an H-6000A rotor), room temperature, then aspirating and saving the aqueous phase using a pipet with the tip cut off (also see UNIT 2.1).

4. Using the technique described in step 3, extract once with 1:1 phenol/chloroform.
5. Add $\frac{1}{10}$ vol of 1 M sodium acetate, pH 7.0 and 2.5 vol of 100% ethanol. Mix gently and chill several hours at -20°C .
6. Microcentrifuge 10 min at maximum speed, 4°C . Aspirate and discard supernatant.
7. Wash pellet twice with 95% ethanol, each time by adding the ethanol, microcentrifuging at maximum speed, and aspirating the supernatant. Air dry and dissolve in 100 μl water.
8. Prepare dilutions (using only a small amount of the total material) and measure A_{260} to determine DNA concentration (APPENDIX 3D).

SELECTION AND SCREENING OF RECOMBINANT VIRUS PLAQUES

For standard vaccinia virus strains, procedures are described involving xanthine-guanine phosphoribosyltransferase (XGPRT; Falkner and Moss, 1988) or thymidine kinase (TK; Mackett et al., 1984) for selecting virus plaques that contain recombinant DNA. A newer and simpler drug-free method (plaque selection) is based on repair of a mutation that caused the parental virus to form pin-point plaques (Blasco and Moss, 1995; see Background Information regarding choice of procedure). In addition, β -galactosidase screening (Chakrabarti et al., 1985) or β -glucuronidase (GUS) screening (Carroll and Moss, 1995) can be used alone or in conjunction with TK selection to discriminate TK^- recombinants from spontaneous TK^- mutants. For each method, recombinant virus (obtained in the transfection; see Basic Protocol 1) is used to infect a monolayer culture of cells—for XGPRT selection, BS-C-1 cells are used because large plaques are obtained; for TK selection, it is necessary to use a cell line such as HuTK⁻ 143B that is deficient in thymidine kinase. Molten agarose with medium containing the appropriate selective drugs is then pipetted onto the infected cell monolayer. Because of cell-to-cell spread of virus, each productively infected cell gives rise to a plaque. After two days, a second agarose overlay containing neutral red is placed on top of the first agarose overlay, whereupon neutral red is taken up by viable cells. In infected areas of the monolayer, the cells are rounded and dead, and thus appear as colorless plaques after neutral red staining. If β -galactosidase (or GUS) screening is used, the substrate Xgal (or Xgluc) is included in the second agarose overlay. Plaques containing infected cells that have expressed β -galactosidase or GUS turn blue; thus, blue (recombinant) plaques can be distinguished from clear (parental) plaques. A Pasteur pipet is used to aspirate infected cells from the plaques and the virus is released by freeze-thaw cycling and sonication. Several rounds of plaque purification are used to ensure the absence of residual non-recombinant virus.

For MVA, the virus is not trypsinized and the XGPRT, β -galactosidase, and GUS methods are used with CEF or BHK-21 cells. TK selection has not been used with MVA. Basic Protocol 4 describes live immunostaining of recombinant MVA.

Materials

BS-C-1, HuTK⁻ 143B, BHK-21, or CEF confluent monolayer cells (UNIT 16.16) and appropriate complete medium

Complete MEM-2.5 medium (UNIT 16.16)

Selective agents (for XGPRT selection; filter sterilize, and store at -20°C):

10 mg/ml (400 \times) mycophenolic acid (MPA; Calbiochem) in 0.1 N NaOH

10 mg/ml (40 \times) xanthine in 0.1 N NaOH

10 mg/ml (670 \times) hypoxanthine in 0.1 N NaOH

Transfected cell lysate (see Basic Protocol 1)

2% LMP agarose (Life Technologies) in H_2O , sterilized by autoclaving

BASIC PROTOCOL 2

Protein Expression

16.17.9

Complete 2× plaque medium-5 (see recipe)
5 mg/ml 5-bromodeoxyuridine (BrdU) in H₂O (for TK selection; filter sterilize and store at -20°C)
10 mg/ml neutral red in H₂O
4% Xgal in dimethylformamide (optional, for β-galactosidase screening; Table 1.4.2)
2% Xgluc in dimethylformamide (optional, for GUS screening)
Dry ice/ethanol bath
6-well, 35-mm tissue culture plates
Cup sonicator (e.g., Ultrasonic Processor VC-600 from Sonics and Materials)
45°C water bath
Cotton-plugged Pasteur pipets, sterile
Additional reagents and equipment for tissue culture and counting cells (*APPENDIX 3F*) and serial dilution of virus (*UNIT 1.11*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Prepare the cells

1. Trypsinize confluent monolayer culture and resuspend in appropriate complete medium as in *UNIT 16.16*, steps 4 to 7 of Basic Protocol 1.
 - a. For XGPRT selection, plaque selection, or color screening, use BS-C-1 cells.
 - b. For TK selection, use HuTK⁻ 143B cells.
 - c. For MVA, use BHK-21 or CEF cells.
2. Count cells using a hemacytometer (*APPENDIX 3F*).
3. Plate 5 × 10⁵ cells/well in a 6-well tissue culture plate (2 ml/well final). Incubate until confluent (this should take <24 hr).
4. Prepare cells as follows.
 - a. For XGPRT selection, preincubate monolayer for 12 to 24 hr in filter-sterilized complete MEM-2.5 containing 1/400 vol 10 mg/ml MPA, 1/40 vol 10 mg/ml xanthine, and 1/670 vol 10 mg/ml hypoxanthine.
 - b. For plaque or TK selection or color screening methods, do not preincubate.

Prepare the lysate and infect cells

5. Just prior to use, mix 100 μl of transfected cell lysate and 100 μl of 0.25 mg/ml trypsin, and vortex vigorously. Incubate 30 min in a 37°C water bath, vortexing at 5- to 10-min intervals during the incubation, then sonicate 20 to 30 sec on ice. For MVA, omit trypsinization but sonicate 20 to 30 sec on ice to break up clumps.
6. Make four 10-fold serial dilutions (ranging from 10⁻¹ to 10⁻⁴; *UNIT 1.11*) of the trypsinized and/or sonicated cell lysate in complete MEM-2.5 as follows.
 - a. For XGPRT selection, add MPA, xanthine, and hypoxanthine at the concentrations indicated in step 4, substep a, above.
 - b. For plaque or TK selection or color screening methods, make no additions.

7. Aspirate medium from the cell monolayers (from step 3) and infect with 1.0 ml diluted lysate per well. Incubate 2 hr, rocking at 30-min intervals.

Use dilutions between 10^{-2} and 10^{-4} .

Perform agarose overlays

8. Before the 2-hr infection is finished, melt 2% LMP agarose (1.5 ml \times number of wells) and place in a 45°C water bath to cool (be sure it cools to 45°C before using it to overlay cells). Prepare and warm to 45°C the necessary amount of selective plaque medium (1.5 ml \times number of wells) by making the following additions to complete 2 \times plaque medium-5.
 - a. For XGPRT selection, include MPA, xanthine, and hypoxanthine at twice the concentrations indicated in step 4, substep a.

Twice the concentration is necessary because the 2 \times plaque medium will be mixed 1:1 with agarose.
 - b. For TK selection, include $\frac{1}{100}$ vol of 5 mg/ml BrdU.
 - c. For plaque selection or color screening, make no additions.
9. Prepare appropriate selective agarose by mixing equal volumes of 2% LMP agarose and selective plaque medium from step 8, substep a or b.
10. Aspirate the viral inoculum from the infected cells (from step 7). Overlay each well with 3 ml appropriate selective agarose and allow to solidify at room temperature or 4°C. Incubate 2 days.
11. Prepare the second agarose overlay by mixing equal volumes of 2% LMP agarose (1 ml \times number of wells, melted and cooled to 45°C as in step 8) and 2 \times plaque medium-5 (1 ml \times number of wells, warmed to 45°C) with $\frac{1}{100}$ vol of 10 mg/ml neutral red. If β -galactosidase screening is to be used, add $\frac{1}{120}$ vol of 4% Xgal to the agarose/plaque medium. If GUS screening is to be used, add $\frac{1}{100}$ vol of 2% Xgluc. Overlay each well with 2 ml of this second agarose overlay, allow to solidify, and incubate overnight.

There is no need to add any FBS, glutamine, penicillin/streptomycin, or any selection drugs to this overlay medium.

Obtain the plaques

12. Add 0.5 ml complete MEM-2.5 to sterile microcentrifuge tubes. When incubation period is complete (step 11), pick well-separated plaques by squeezing the rubber bulb on a sterile, cotton-plugged Pasteur pipet and inserting the tip through the agarose to the plaque. Scrape the cell monolayer and aspirate the agarose plug into the pipet. Transfer to a tube containing 0.5 ml complete MEM-2.5. Repeat for six to twelve plaques with separate pipets, placing each in a separate tube.
13. Vortex each virus-containing tube, then perform three freeze-thaw cycles, each time by freezing in a dry ice/ethanol bath, thawing in a 37°C water bath, and vortexing.
14. Place tube containing virus into a cup sonicator containing ice-water and sonicate 20 to 30 sec at full power.

If TK selection only has been used, plaque isolates should be tested by PCR, DNA dot-blot hybridization, or immunostaining (all procedures described in UNIT 16.18), because some plaques will contain spontaneous TK⁻ mutations and not recombinant virus.

Carry out several rounds of plaque purification

15. Prepare monolayers of the appropriate cell line as described in steps 1 to 4.

One 6-well plate is needed for each plaque isolate.

16. Make three 10-fold serial dilutions at 10^{-1} , 10^{-2} , and 10^{-3} , of each of several plaque isolates as described in step 6.

If XGPRT selection is used, cells must be preincubated with selective drugs and serial dilutions of the viral isolates must also contain selective drugs (step 4, substep a).

17. Aspirate medium from cell monolayers and infect two wells with 1.0 ml of each dilution of virus. Incubate 2 hr, rocking by hand at 30-min intervals.
18. Repeat steps 8 to 14 for three or more rounds of plaque purification to ensure a clonally pure recombinant virus.

AMPLIFICATION OF A PLAQUE

A recombinant plaque isolate (obtained after the selection and screening protocol; see Basic Protocol 2) is amplified by infection of successively larger numbers of cells. Medium containing drugs for XGPRT or TK selection is usually used, up to and including the infection of cells in a 25-cm² flask. Freeze-thaw cycling is carried out to release the recombinant virus from the cells. The titer of the virus stock is determined as described in UNIT 16.16. For amplification of MVA, see Basic Protocol 4.

Materials

- Resuspended recombinant plaque (see Basic Protocol 2)
- Confluent monolayer cultures of appropriate cells in both a 12-well, 22-mm tissue culture plate and a 25-cm² tissue culture flask (UNIT 16.16)
- Complete MEM-2.5 and -10 media (UNIT 16.16)
- Selective agents (for XGPRT selection; filter sterilize, and store at -20°C):
 - 10 mg/ml (400 \times) mycophenolic acid (MPA; Calbiochem) in 0.1 N NaOH
 - 10 mg/ml (40 \times) xanthine in 0.1 N NaOH
 - 10 mg/ml (670 \times) hypoxanthine in 0.1 N NaOH
- 5 mg/ml 5-bromodeoxyuridine (BrdU) in H₂O (for TK selection; filter sterilize and store at -20°C)
- Dry ice/ethanol bath
- Spinner culture of HeLa S3 cells (UNIT 16.16)
- Cup sonicator (e.g., Ultrasonic Processor VC-600 from Sonics and Materials)
- 15-ml conical centrifuge tubes
- Sorvall centrifuge with H-6000A rotor (or equivalent)
- 150-cm² tissue culture flask
- Additional reagents and equipment for tissue culture and counting cells (APPENDIX 3F)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Infect a monolayer culture of cells with a plaque

1. Place tube containing resuspended recombinant plaque into a cup sonicator containing ice-water and sonicate 20 to 30 sec at full power.
2. Infect appropriate confluent monolayer culture in 12-well plate with 250 μl ($\frac{1}{2}$) of each plaque isolate. Incubate 1 to 2 hr, rocking at \sim 15-min intervals.

If XGPRT selection is used, the monolayer culture is preincubated for 12 to 24 hr in complete MEM-2.5 containing MPA, xanthine, and hypoxanthine (see Basic Protocol 2, step 4, substep a). Infection should also be done in the presence of these drugs.

3. Overlay with 1 ml complete MEM-2.5 medium containing the appropriate selective agents.
 - a. For XGPRT selection, include $\frac{1}{400}$ vol 10 mg/ml MPA, $\frac{1}{40}$ vol 10 mg/ml xanthine, and $\frac{1}{670}$ vol 10 mg/ml hypoxanthine.
 - b. For TK selection, include $\frac{1}{200}$ vol of 5 mg/ml BrdU.

Incubate 2 days or until cytopathic effect (cell rounding) is obvious.

4. Scrape cells, transfer to microcentrifuge tube, and microcentrifuge 30 sec at maximum speed. Aspirate and discard medium.
5. Resuspend cells in 0.5 ml complete MEM-2.5 then perform three freeze-thaw cycles, each time by freezing in a dry ice/ethanol bath, thawing in a 37°C water bath, and vortexing.
6. Place tube containing cell suspension into a cup sonicator and sonicate 20 to 30 sec at full power.

Scale up the culture

7. Dilute 0.25 ml of lysate from step 6 with 0.75 ml complete MEM-2.5 containing selective agents (see steps 2 and 3). Infect appropriate confluent monolayer culture in a 25-cm² flask and incubate 30 min.
8. Overlay with 4 ml complete MEM-2.5 containing the appropriate selective agents (step 3). Incubate 2 days or until cytopathic effect is obvious.
9. Scrape cells, transfer to 15-ml conical centrifuge tube, and centrifuge 5 min at 1800 × g (2500 rpm in H-6000A rotor), 5° to 10°C. Resuspend cells in 0.5 ml complete MEM-2.5 and repeat freeze-thaw cycling and sonication as described in steps 5 and 6.
10. Count HeLa S3 cells from a spinner culture using a hemacytometer (*APPENDIX 3F*).

Alternatively, prepare monolayer cells as described in UNIT 16.16 and proceed to step 13, below.

11. Place 5×10^7 HeLa S3 cells in a centrifuge tube. Centrifuge 5 min at 1800 × g, room temperature, and discard supernatant.
12. Resuspend cells in 25 ml complete MEM-10, dispense in one 150-cm² flask, and incubate overnight (for infection the following day).
13. Remove medium from cells and replace with a mixture of 0.25 ml lysate (from step 9) and 1.75 ml complete MEM-2.5. Incubate 1 hr, rocking the flask at 15- to 30-min intervals.
14. Overlay with 25 ml complete MEM-2.5 (selection is not required at this step) and incubate 3 days.
15. Detach cells from the flask by shaking or scraping if necessary. Transfer to centrifuge tube by pipetting, then centrifuge 5 min at 1800 × g, 5° to 10°C. Aspirate and discard supernatant.
16. Resuspend cells in 2 ml complete MEM-2.5 and carry out freeze-thaw cycling three times as described in step 5.
17. Determine titer of the viral stock as described in *UNIT 16.16*. Freeze viral stock at -70°C.

LIVE IMMUNOSTAINING OF MVA RECOMBINANTS

Live immunostaining was developed for modified vaccinia virus Ankara (MVA) because this strain does not form discrete, easily recognizable plaques and because this technique helps to avoid the incorporation of selectable or screening marker genes. Immunostaining can be used for recombinant proteins that are expressed on the cell surface or in the cytoplasm. These protocols are also applicable to standard strains of vaccinia virus.

The strong adherence of chicken embryo fibroblasts (CEF) to concavalin A-coated plastic dishes make them superior to BHK-21 or other cell lines that the authors have tried.

Materials

- 150-cm² flask of confluent CEF (*UNIT 16.16*)
- Complete MEM-2, -2.5, and -10 media (*UNIT 16.16*)
- Transfected cell lysate (see Basic Protocol 1)
- Dry ice/ethanol bath
- Primary antibody to protein product of foreign gene
- Horseradish peroxidase-conjugated secondary antibody (to species of primary antibody)

- Concanavalin A-coated 6-well tissue culture plates (see Support Protocol 3)
- Cup sonicator (e.g., Ultrasonic Processor VC-600 from Sonics and Materials)
- Inverted microscope
- Sterile toothpicks
- Cell scraper or plunger of 1-ml syringe
- 75- and 150-cm² tissue culture flasks

- Additional reagents and equipment for culture, trypsinization, and immunostaining of CEF cells, titering of MVA, and preparation of MVA stocks (*UNIT 16.16*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Prepare, infect, and immunostain CEF cells

1. Trypsinize confluent CEF monolayer cultures, seed cells in concanavalin A-coated 6-well tissue culture plates, and incubate until nearly confluent (*UNIT 16.16*).
2. Thaw transfected cell lysate and sonicate in a cup sonicator for 30 sec at full power, on ice. Add 100, 10, 1, or 0.1 µl of lysate to duplicate wells of CEF containing 2 ml of complete MEM-2.5 medium. Gently swirl to mix. Incubate 2 days.
3. Immunostain the unfixed cells using antibody to the protein product of the foreign gene (see *UNIT 16.16*, Support Protocol 2, steps 8 to 13).

If the protein of interest is expressed intracellularly, remove the fluid from the wells and place plate at -70°C for 1 hr. Allow to thaw and begin staining as described in UNIT 16.16. This procedure ruptures the cells in situ and allows the antibody to penetrate.

Isolate recombinant virus

4. Aspirate the medium and examine the cell monolayer using an inverted microscope. Touch immunostaining foci with sterile toothpicks. Place toothpicks individually in small vials containing 0.5 ml of complete MEM-2.5, and break off each toothpick so that the sterile part is inside the tube.

5. Perform three freeze/thaw cycles on each tube, each time by freezing in a dry ice/ethanol bath, thawing in a 37°C water bath, and vortexing. Place tube into a cup sonicator and sonicate 30 sec at full power.
6. Replate onto new CEF monolayers and plaque purify the MVA recombinant a second time as in steps 2 to 5. Plaque purify an additional three times.

In this protocol, plaque-purification is done under a liquid overlay instead of agarose to allow immunostaining. To check stability and purity, an extra plate can be held for 3 days and then fixed and immunostained as in UNIT 16.16, Support Protocol 2. The presence of nonstaining foci, which may be detected at this time because of cytopathic effects, are due to wild-type virus or an unstable recombinant.

Amplify plaque-purified virus

7. Infect 1 well of a concanavalin A-coated 6-well plate of CEF or BHK-21 cells with 0.25 ml of plaque-purified MVA recombinant in a total volume of 2 ml MEM-2.5. Incubate 2 days.
8. Remove and discard 1 ml of medium covering the cell monolayer. Dislodge cells into the 1 ml of remaining medium with a cell scraper (or plunger of a 1 ml syringe) and transfer to a vial. Carry out three freeze/thaw cycles as in step 5 to produce a lysate.
9. Amplify the virus by inoculating 0.5 ml of lysate into 75-cm² flask of CEF or BHK-21 cells containing 15 ml MEM-2.5. After 2 days harvest and lyse cells as in step 8.
10. Inoculate a 150-cm² flask of CEF or BHK-21 cells containing 30 ml MEM-2.5 with 0.5 ml of lysate from step 9.
11. Determine titer and prepare large stock of recombinant MVA (UNIT 16.16, Basic Protocol 5). Freeze viral stock in aliquots at -70°C.

COATING PLATES WITH CONCAVALIN A

This protocol describes the preparation of concanavalin A-coated plates to be used growing CEF monolayers for live immunostaining as in Basic Protocol 4.

Materials

Concanavalin A (Sigma)
Phosphate-buffered saline (PBS; APPENDIX 2)
6-well, 35-mm tissue culture dishes
Plastic bags for storage

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

1. Add 12 mg concanavalin A to 120 ml sterile PBS for a final concentration of 100 µg/ml.
2. Add 1 ml of the PBS/concanavalin A solution to each well of twenty 6-well plates. Incubate 1 hr at room temperature.
3. Aspirate the liquid from each well and rinse with 2 ml PBS.
4. Remove the fluid from each well and let plates dry by storing open in a biological safety hood (to keep sterile).
5. Store plates in a plastic bag (to preserve sterility) at room temperature (will keep for months).

SUPPORT PROTOCOL 3

**Protein
Expression**

16.17.15

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Complete 2× plaque medium-5

2× plaque medium (Life Technologies) containing:
5% fetal bovine serum (FBS; APPENDIX 3F)
0.03% (w/v) glutamine
100 U/ml penicillin
100 µg/ml streptomycin
Store up to 3 months at 4°C

Transfection buffer

0.14 M NaCl
5 mM KCl
1 mM Na₂HPO₄·2H₂O
0.1% (w/v) dextrose
20 mM HEPES
Adjust to pH 7.05 with 0.5 M NaOH and filter sterilize
Store indefinitely at -20°C

The pH of this buffer is critical and should be between 7.0 and 7.1.

COMMENTARY

Background Information

Plasmid-transfer vectors have three essential components: an expression cassette consisting of a natural or synthetic vaccinia promoter, restriction endonuclease sites for insertion of foreign genes, and flanking vaccinia virus DNA that determines the site of homologous recombination. An additional component may provide antibiotic selection or color screening. Various transfer vectors are listed in Table 16.17.1 and one is presented in detail in Figure 16.17.2.

Homologous recombination (Fig. 16.17.1) is the usual way of generating recombinant vaccinia viruses. Initially, recombination may result from a single cross-over event, resulting in integration of the circular plasmid and the creation of a tandem duplication; however, this intermediate is highly unstable. A second recombination event then occurs between the tandem repeats, resolving the structure into a small circular DNA molecule and either a wild-type or recombinant viral genome. An alternative method of direct ligation using an unique restriction endonuclease site in the vaccinia genome has also been described (Pfleiderer et al., 1995; Merchlinsky et al., 1997). This method avoids an *E. coli* cloning step and can potentially be used for direct cloning of cDNA libraries in vaccinia virus.

Considerable attention has been devoted to promoters because they affect both the time and

level of expression (UNIT 16.15). The most widely used promoter, *p*_{7.5}, actually contains tandem late and early promoters (Cochran et al., 1985) and provides a moderate level of expression throughout infection. The modified *p*_{H5} promoter provides higher levels of both early and late expression than *p*_{7.5} (Wyatt et al., 1996). Strong natural late promoters include *p*₁₁ (Bertholet et al., 1985) and *p*_{CAE} (Patel et al., 1988). About a two-fold increase in expression may be achieved with the synthetic late promoter in pMJ601 and pMJ602 (Davison and Moss, 1990) or the synthetic early/late compound promoter in pSC59 and pSC65 (Chakrabarti et al., 1997; Table 16.17.1).

The ability to synthesize many different kinds of proteins, including those with transmembrane domains, is one advantage of the vaccinia virus expression system. Nevertheless, very high expression of certain genes might adversely affect virus replication. If difficulty is experienced in obtaining recombinant vaccinia with strong promoters, the weaker *p*_{7.5} or *p*_{H5} promoter or the inducible vaccinia virus/bacteriophage T7 hybrid system should be tried (UNIT 16.19).

Several different methods for selecting recombinant viruses are available. The widely used TK selection method is based on the insertional inactivation of the thymidine kinase gene (UNIT 9.5). In the presence of active TK, added BrdU is phosphorylated and incorpo-

rated into viral DNA, where it causes lethal mutations. If TK⁻ cells are used, then TK⁻ virus will replicate normally in the presence of BrdU, whereas TK⁺ virus will not. Because the product of a single cross-over event is still TK⁺, only double cross-over events are selected. However, not all TK⁻ viral plaques will be recombinants because spontaneous TK⁻ mutants arise at a frequency of 1:10,000. Depending on the transfection efficiency, recombinants may comprise 10% to >90% of the TK⁻ plaques.

β-galactosidase or β-glucuronidase (GUS) screening is based on the coinserion of the *E. coli lacZ* (UNIT 1.4) or *GUS* gene, under the control of a vaccinia virus promoter, into the vaccinia virus genome along with the gene of interest. If the TK gene is insertionally inactivated by such an event, recombinant viruses will be TK⁻ and will make blue plaques on medium containing Xgal or Xgluc. This combination of color screening and TK selection will discriminate TK⁻ recombinants from spontaneous TK⁻ mutants. An example of an insertion vector that provides both TK⁻ and β-galactosidase screening is shown in Figure 16.17.2.

XGPRT selection uses mycophenolic acid (MPA), an inhibitor of purine metabolism (see UNIT 9.5). Because MPA blocks the pathway for GMP synthesis, it interferes with the replication of vaccinia and severely reduces the size of vaccinia plaques. This effect can be overcome, however, by expression of the *E. coli gpt* gene in the presence of xanthine and hypoxanthine (i.e., XGPRT can use either of these as substrate for synthesis of GMP). Thus, coexpression of XGPRT provides a useful selection system. Usually the *XGPRT* gene is placed adjacent to the gene of interest and within the vaccinia virus DNA flanking sequences. Unlike the TK⁻ situation, the viral products arising from both single and double cross-over events will be selected. Therefore, it is important to do successive plaque isolations so that the single cross-over events will be resolved. A reverse-selection procedure can be used to delete the *XGPRT* gene from a recombinant vaccinia virus or replace it with another gene (Isaacs et al., 1990). Another procedure, transient XGPRT selection, is performed using a transfer vector with the *XGPRT* gene outside of the vaccinia virus DNA flanking sequences (Falkner and Moss, 1990). Under these conditions, only the single cross-over recombinant virus will express XGPRT, providing substantial enrichment over the parental virus. However, when MPA selection is removed, the desired double cross-over recombinant virus without the

XGPRT gene will have to be differentiated from the parental virus by PCR, immunostaining, or other methods.

Plaque selection (Blasco and Moss, 1995) provides an extremely simple method of selecting recombinant vaccinia viruses that involves neither drugs nor reporter genes. The parental virus (vRB12) contains a deletion of most of the F13L gene, which prevents vaccinia virus from making normal-size plaques. The transfer vector pRB21 contains a segment of the F13L gene adjacent to the gene of interest, so that recombinant viruses will have a functional F13L gene and will make normal-size plaques that are easily distinguished from the pin-point plaques of vRB12. Therefore, one merely needs to pick large plaques to isolate recombinant viruses. However, it is important to check that the virus is a double cross-over recombinant.

To avoid further impairment of MVA, foreign genes have been targeted to existing deletion sites. Deletion II encompasses parts of the *HindIII* N-K fragments; deletion III lies within the *HindIII* A fragment (Meyer et al., 1991). The TK gene has been successfully used as an insertion site for MVA (Carroll and Moss, 1997; T. Blanchard, pers. comm.), although there have been reports of some difficulties in isolating stable TK⁻ MVA (Scheiflinger et al., 1996). Since there are no MVA-permissive TK⁻ cell lines, the main attraction for using the TK site is the large number of available transfer vectors that target this site. When some foreign genes were placed under the control of the very strong synthetic early/late promoter, the resulting recombinant MVA were difficult to isolate or unstable (Wyatt et al., 1996). To date, the examples have been membrane proteins. In most cases, stable recombinants could be made by using a promoter of lower strength, e.g., *p*_{H5} or *p*_{7.5}.

Critical Parameters

During purification of vaccinia virus (see Support Protocol 1) it is important to check the extract after Dounce homogenization to be sure that cells are broken; if they are not, repeat with more force for ten more strokes and check again. In addition, be sure to perform all steps on ice (this is particularly important when sonicating). Use sterile technique throughout.

Calcium phosphate transfections are described in detail in UNIT 9.1. As discussed there, obtaining a very fine precipitate of calcium phosphate and DNA is critical for efficient transfection. Several factors can influence the quality of the precipitate. First, the pH of the

transfection buffer should be between 7.0 and 7.1. Second, if wild-type vaccinia DNA is used, it should be vortexed vigorously to shear the high-molecular-weight DNA prior to precipitation. Although coprecipitation of viral DNA with the insertion vector increases the efficiency of recombination, it is not required if a selection procedure is used. Third, the CaCl_2 should be added slowly and mixed gently (not vortexed), only until full mixing is achieved. The tube should then be left undisturbed until the solution is layered on the cells. Cationic lipids are simpler to use and provide similar or better transfection efficiencies. Although the DOTAP procedure was described in this unit, other cationic lipids are also effective.

During plaque purification and amplification of a new recombinant virus, it is important to maintain the appropriate selective pressure to prevent growth of any contaminating wild-type virus. After isolation, selection is not required. Check the purity of a recombinant virus by PCR or Southern blot analysis of a *Hind*III digest of the virus; the fragment into which the foreign gene has been cloned (the 5.1-kb *Hind*III J fragment for TK selection) should have increased by the size of the insert.

Freezing vaccinia stocks causes clumping of virus particles; thus, stocks should be trypsinized and/or sonicated after thawing. This is particularly important when plaque-purifying a virus, as each plaque should have arisen from a single virus. Trypsinization has been avoided with MVA because preliminary experiments suggested a loss in titer. Some lots of agarose contain contaminants that are toxic to cells (the authors have used low-melting-point agarose from Life Technologies successfully).

It is prudent to save half of each stock at each step in case of contamination or failure at a succeeding step. The authors strongly recommend preparation of a seed stock of the final recombinant virus that will be adequate for future needs. A common mistake is to continually passage the virus.

If immunostaining is used instead of selection or color screening, the antibody must give a good signal to initially pick out the few small foci of cells infected with recombinant virus among a great excess of cells infected with the parental nonstaining virus. Before using an antibody for isolation of recombinant MVA, it can be tested by staining the MVA-infected cells after the first transfection step.

See *UNIT 16.15* for safety precautions that need to be taken when working with vaccinia virus.

Anticipated Results

Approximately $1-5 \times 10^{10}$ pfu of purified virus should be obtained per liter of 5×10^8 HeLa cells.

Depending on the efficiency of the transfection, single, well-isolated plaques should be visible in cells infected with one of the recommended virus dilutions. With TK selection, from 10% to 90% of the plaques will contain recombinant virus. If β -galactosidase or GUS screening is also used, only blue recombinant virus plaques should be picked. With XGPRT selection, all plaques picked should contain recombinant virus. If the titer of recombinant virus is low, amplification can be achieved by a round of growth in the presence of MPA prior to plaquing (use the procedure described in amplification of a plaque).

Cytopathic effects should be clearly visible at each step of amplification except with final infection (infected HeLa cells do not exhibit clear cytopathic effects). The titer of the final crude stock should be $1-2 \times 10^9$ pfu/ml.

Time Considerations

During purification of vaccinia virus, the viral amplification takes 2 to 3 days. After harvesting the infected cells, the entire purification can be done in 1 day. However, the protocol can be stopped after resuspension at step 12 or after collecting the band at step 16. The virus can be stored overnight at 4°C or at -70°C for longer periods.

The infection/transfection procedure for generation of recombinant virus takes ~ 6 hr and cells are harvested after 2 days.

Each round of selection and plaque purification takes 3 days, although little working time is required. Plaques can be picked and reinfections performed on the same day.

Amplification of a single plaque isolate to a small high-titer crude stock will take ~ 7 days. Large stocks should then be prepared as described in *UNIT 16.17*.

Transfection of cells with the plasmid transfer vector requires ~ 2 hr to complete, and the cells are harvested after 2 days. Each round of isolation and plaque purification requires about 30 min for infection, 2 days for incubation, 3 hr for color or immunostaining, and 2 hr for isolating new recombinants and freeze-thaw cycling. Recombinant isolates can be picked and reinfections performed on the same day. From completion of plaque purification to the preparation and titering of a virus stock takes another 10 days.

Characterization of Recombinant Vaccinia Viruses and Their Products

UNIT 16.18

After a recombinant vaccinia virus is made (UNIT 16.17), its DNA and protein products can be analyzed in several ways. Identification of the recombinant virus can be carried out by PCR (see Basic Protocol 1), with verification of correct insertion of the DNA by Southern blotting (see Basic Protocol 2). Vaccinia DNA can also be detected by dot-blot hybridization (see Basic Protocol 3). Finally, when antibodies are available, protein expression can be analyzed by immunological methods such as dot blotting with an antibody (see Alternate Protocol) or immunoblotting (see Basic Protocol 4) and/or immunoprecipitation (see Basic Protocol 5). In addition, immunostaining can be used for identification of recombinant plaques as well as for determination of the purity of a recombinant virus stock. For these purposes, the support protocol for immunostaining in UNIT 16.16 should be used; however an antibody to the foreign protein should be substituted for anti-vaccinia antibody.

All of the protocols in this unit can be used for characterization of modified vaccinia virus Ankara (MVA) recombinant viruses (UNIT 16.17).

CAUTION: Proceed carefully and follow biosafety level 2 (BL-2) practices when working with vaccinia virus (see UNIT 16.15 for safety guidelines).

NOTE: Carry out all procedures for growth of vaccinia virus using sterile technique in a biosafety cabinet.

DETECTION OF VACCINIA DNA USING PCR

The presence of recombinant virus in isolated plaques can be determined by infecting cells with the virus, extracting the DNA, and performing PCR analysis utilizing oligonucleotide primers in the flanking vaccinia DNA. Although PCR analysis can be done directly on DNA in picked virus plaques (Zhang and Moss, 1991), individual researchers sometimes have problems with this shorter procedure. PCR is also useful for determining the purity of a viral stock, as both wild-type and recombinant DNAs are amplified using this protocol. Here a method is described for isolation of DNA from infected cells. An alternative to this protocol is to use a commercial kit such as Qiagen QIAamp Blood Kit for extraction of DNA.

Materials

- Confluent BS-C-1 or HuTK⁻ 143B cell monolayer (UNIT 16.16)
- Phosphate-buffered saline (PBS; APPENDIX 2)
- Trypsin/EDTA (0.25%:0.02%), 37°C
- Complete MEM-10, -2.5, and -5 media (UNIT 16.16)
- Complete MEM-10/BrdU medium (UNIT 16.16)
- Recombinant virus plaques, picked and resuspended in tubes (UNIT 16.17)
- Selective agents (filter sterilize and store at -20°C; also see UNIT 16.17):
 - 10 mg/ml (400×) mycophenolic acid (MPA; Calbiochem) in 0.1 N NaOH (for XGPRT selection)
 - 10 mg/ml (40×) xanthine in 0.1 N NaOH (for XGPRT selection)
 - 10 mg/ml (670×) hypoxanthine in 0.1 N NaOH (for XGPRT selection)
 - 5 mg/ml (200×) 5-bromodeoxyuridine (BrdU) in water (for TK selection)
- Dry ice/ethanol bath
- DNA extraction buffer (see recipe)
- 3 M sodium acetate, pH 6.0 (APPENDIX 2)

**BASIC
PROTOCOL 1**

**Protein
Expression**

95% and 70% ethanol, ice-cold
10× MgCl₂-free PCR amplification buffer (*UNIT 15.1*)
10 mM 4dNTP mix (*UNIT 15.1*)
100 μM primer (sequence depends on where foreign gene is inserted; see *UNIT 2.11*
for oligonucleotide synthesis strategies)
15 mM MgCl₂
24-well tissue culture plates
Cup sonicator
Additional reagents and equipment for tissue culture and counting cells
(*APPENDIX 3F*), phenol/chloroform extraction of DNA, PCR amplification
(*UNIT 15.1*), and agarose gel electrophoresis (*UNIT 2.5*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Set up cells for infection

1. Aspirate medium from a confluent cell monolayer.
 - a. For XGPRT selection, use BS-C-1 cells.
 - b. For TK selection, use HuTK⁻ 143B cells.
 2. Wash cells once with 37°C PBS or trypsin/EDTA to remove the remaining serum.
 3. Overlay cells with 37°C trypsin/EDTA using a volume that is just enough to cover the monolayer (1.5 ml for a 150-cm² flask). Allow to sit ~30 sec (the cells should become detached). Shake to detach cells completely.
 4. Add 8.5 ml of the appropriate medium.
 - a. For BS-C-1 cells, use complete MEM-10.
 - b. For HuTK⁻ 143B cells, use complete MEM-10/BrdU.
- Pipet cell suspension up and down several times to disrupt clumps.
5. Count cells using a hemacytometer (*APPENDIX 3F*).
 6. Plate 1.25×10^5 cells/well in 24-well tissue culture dishes (0.5 ml/well final). Incubate until confluent (this should take <24 hr).

Infect cells with virus

7. Place tube containing virus into a cup sonicator containing an ice/water mixture and sonicate 20 to 30 sec at full power.
8. Aspirate medium from each confluent well and infect each well with one recombinant virus plaque, using half the volume in which each plaque is suspended (i.e., 0.25 ml where 0.5 ml is used to resuspend the plaque). Incubate 1 to 2 hr, rocking at 15- to 30-min intervals.

Perform selection

9. Overlay with 1 ml complete MEM-2.5 to which appropriate selection drugs have been added. Incubate until cytopathic effect (cell rounding) is evident (usually 24 to 48 hr).
 - a. For XGPRT selection, add $\frac{1}{400}$ vol of 10 mg/ml MPA, $\frac{1}{40}$ vol of 10 mg/ml xanthine, and $\frac{1}{670}$ vol of 10 mg/ml hypoxanthine.
 - b. For TK selection, add $\frac{1}{200}$ vol of 5 mg/ml BrdU.

10. Scrape cells and transfer to a microcentrifuge tube. Microcentrifuge 30 sec at maximum speed. Aspirate medium, add 1 ml PBS, vortex to resuspend, then microcentrifuge again, 30 sec at maximum speed. Aspirate PBS, then resuspend pellet in 0.5 ml PBS.

Cells in a 24-well plate can be scraped using the plunger of a 1-ml syringe.

Prepare DNA for PCR amplification

11. Lyse the cell suspension by carrying out three freeze-thaw cycles, each time by freezing in a dry ice/ethanol bath, thawing in a 37°C water bath, and vortexing.
12. Place tube containing lysate into a cup sonicator containing an ice/water mixture and sonicate 20 to 30 sec at full power.
13. Place 50 to 100 µl of the lysate into a microcentrifuge tube. Add 1/10 vol of DNA extraction buffer. Mix by gently inverting the tube several times. Incubate 2 hr to overnight at 37°C.
14. Extract once with an equal volume of buffered phenol and once with an equal volume of chloroform (*UNIT 2.1*).
15. Add 1/10 vol of 3 M sodium acetate, pH 6.0 (0.3 M final) and 2.5 vol of 95% ethanol. Place at -20°C for 20 min.
16. Microcentrifuge 15 min at maximum speed, 4°C. Aspirate and discard supernatant. Wash pellet with ice-cold 70% ethanol, then air dry.
17. Dissolve pellet in 20 µl deionized water. Prepare the following reaction mix on ice:

10 µl redissolved (template) DNA pellet
5 µl 10× MgCl₂-free PCR amplification buffer
5 µl 10 mM 4dNTP mix
0.5 µl 100 µM primer
5 µl 15 mM MgCl₂
24.5 µl H₂O

Overlay with mineral oil.

A PCR kit such as the Expand High Fidelity PCR System (Boehringer Mannheim) is appropriate for this step.

18. Carry out PCR (*UNIT 15.1*) using the following thermal cycling parameters:

35 cycles:	20 sec	95°C	(denaturation)
	20 sec	55° to 60°C	(annealing)
	1 to 2 min	72°C	(extension)
1 cycle:	5 min	72°C	(extension)
Final step:	indefinitely	4°C	(hold).

These conditions are for a 1-kb fragment.

19. Analyze PCR product on agarose gel (*UNIT 2.5*).

DETECTION OF VACCINIA DNA USING SOUTHERN BLOT HYBRIDIZATION

Historically, vaccinia virus DNA has been characterized by its *Hind*III restriction endonuclease digestion pattern. The TK gene, into which most foreign genes are inserted in recombinant viruses, is located in the 5.1-kbp *Hind*III J fragment. Thus in a recombinant virus, if the inserted gene has no *Hind*III sites, this fragment should be increased in size. The 5.1-kbp *Hind*III J fragment should be absent, indicating lack of contamination with wild-type vaccinia virus. Southern blot analysis can be done with DNA from purified virus (UNIT 16.17) or, more easily, from a crude lysate of infected cells as described below.

Materials

Confluent BS-C-1 cell monolayer (UNIT 16.16)
Complete MEM-10 and -5 media (UNIT 16.16)
Recombinant vaccinia virus stock (UNIT 16.16)
0.25 mg/ml trypsin (2× crystallized and salt-free; Worthington; filter sterilize and store at -20°C)
Phosphate-buffered saline (PBS; APPENDIX 2)
Low-salt buffer (see recipe)
20 mg/ml proteinase K
Buffered phenol (UNIT 2.1)
1:1 phenol/chloroform
3 M sodium acetate, pH 6.0 (APPENDIX 2)
95% and 70% ethanol, ice-cold
TE buffer, pH 7.8 (APPENDIX 2)
*Hind*III restriction endonuclease (UNIT 3.1) and appropriate buffer
12-well tissue culture plates

Additional reagents and equipment for preparing BS-C-1 cells for vaccinia infection (see Basic Protocol 1), tissue culture and counting cells (APPENDIX 3F), phenol/chloroform extraction of DNA (UNIT 2.1), restriction endonuclease digestion of DNA (UNIT 3.1), Southern blotting (UNIT 2.9A), and hybridization (UNIT 2.10)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Prepare cell cultures and infect cells

1. Set up cell cultures for infection (see Basic Protocol 1, steps 1 to 5) starting with a confluent BS-C-1 cell monolayer.
2. Plate 2.5×10^5 cells/well in 12-well tissue culture plates (1 ml/well final) using complete MEM-10 medium. Incubate until confluent (this should take <24 hr).
3. Just prior to use, mix equal volumes of recombinant vaccinia virus stock and 0.25 mg/ml trypsin and vortex vigorously. Incubate 30 min in a 37°C water bath, vortexing at 5- to 10-min intervals during the incubation.

Virus stocks are usually at a titer of $\sim 2 \times 10^9$ pfu/ml but may be significantly lower depending on the source.

Vortexing usually breaks up any clumps. However, if clumps still remain, chill to 0°C and sonicate 30 sec on ice. Sonication can be repeated several times but the sample should be allowed to cool on ice between sonications.

4. Aspirate medium and infect monolayer culture at a multiplicity of infection (MOI) of 10 to 20 pfu/cell in 250 μ l complete MEM-5. Incubate 1 to 2 hr, rocking at ~30-min intervals.
5. Overlay with 1 ml complete MEM-5 and incubate ~24 hr.

Harvest cells

6. Scrape cells and transfer to a microcentrifuge tube. Microcentrifuge 30 sec at maximum speed, room temperature, then aspirate and discard supernatant.

The plunger of a 1-ml syringe can be used to scrape cells.

7. Resuspend pellet in 50 μ l PBS and vortex.
8. Add 300 μ l of low-salt buffer and 10 μ l of 20 mg/ml proteinase K to a microcentrifuge tube. Add cell suspension to this same tube. Vortex, then incubate 5 hr to overnight at 37°C.

Extract DNA and analyze by Southern blotting

9. Extract once with an equal volume of buffered phenol, then once with an equal volume of 1:1 phenol/chloroform (UNIT 2.1).

If the solution is viscous after phenol extraction, pass it through a 25-G needle to shear DNA and reduce viscosity.

10. Add $\frac{1}{10}$ vol 3 M sodium acetate, pH 6.0 (0.3 M final) and 2.5 vol 95% ethanol. Place 30 min on dry ice or overnight at -20°C.
11. Microcentrifuge 10 min at maximum speed, 4°C. Aspirate and discard supernatant.
12. Wash pellet with ice-cold 70% ethanol, then air dry.
13. Dissolve pellet in 100 μ l TE buffer, pH 7.8.
14. Digest 15 μ l of DNA solution with *Hind*III (UNIT 3.1) and analyze by Southern blotting (UNIT 2.9A) and hybridization (UNIT 2.10).

DETECTION OF VACCINIA DNA USING DOT-BLOT HYBRIDIZATION

In addition to PCR and Southern blotting, DNA dot-blot hybridization, as described in this protocol, may be used for identifying recombinant virus in isolated plaques.

Materials

0.5 N NaOH
1 M Tris·Cl, pH 7.5 (APPENDIX 2)
2 \times SSC (APPENDIX 2)

Nitrocellulose membrane (see Table 2.9.1)
Whatman 3MM filter paper
80°C vacuum oven

Additional reagents and equipment for preparing cells, infecting with vaccinia virus, and performing selection (see Basic Protocol 1), dot blotting (UNIT 2.9B), and hybridization (UNIT 2.10)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

**BASIC
PROTOCOL 3**

**Protein
Expression**

16.18.5

Prepare and infect cells and harvest cell suspension

1. Infect cells with virus and perform selection (see Basic Protocol 1, steps 1 to 9).
2. Scrape cells and transfer to a microcentrifuge tube. Microcentrifuge 30 sec at maximum speed, then aspirate and discard medium. Resuspend cell pellet in 200 μ l PBS.

Cells in a 24-well plate can be scraped using the plunger of a 1-ml syringe.
3. Freeze thaw and sonicate cell suspension (see Basic Protocol 1, steps 11 and 12).

Perform blotting procedure

4. Cut nitrocellulose membrane to the appropriate size to fit in the dot-blot apparatus. Wet the membrane by immersing it in water and place in the apparatus. Add 20 to 100 μ l cell lysate (from step 3) to each well. Draw the liquid through the membrane by applying suction, then remove the nitrocellulose from the apparatus.
5. Cut six pieces of Whatman 3MM filter paper so they are larger than the nitrocellulose membrane. Soak one piece of 3MM paper with 0.5 N NaOH. Lay the nitrocellulose membrane on top of the wet 3MM paper and let sit for 1 min. Remove membrane and place it on a separate piece of dry 3MM paper for 1 min. Repeat this procedure two times using the same piece of 3MM paper.

Forceps should be used to transfer the membrane. See UNIT 2.1B for additional discussion of dot blotting.
6. Repeat step 5 (three times per membrane) with Whatman 3MM paper soaked in 1 M Tris·Cl, pH 7.5.
7. Repeat step 5 (three times per membrane) with 3MM Whatman paper soaked in 2 \times SSC.
8. Bake membrane 2 hr at 80°C under vacuum.

Baking fixes the DNA to the filter.
9. Proceed with DNA hybridization as described in *UNIT 2.10*.

ALTERNATE PROTOCOL

DETECTION OF EXPRESSED PROTEIN BY A DOT-BLOT PROCEDURE

This protocol is an alternative to DNA dot-blot hybridization for checking plaques to identify recombinant virus. Infected cell lysates are spotted onto a nitrocellulose membrane as in DNA dot-blotting (see Basic Protocol 3). The membrane is then incubated with an antibody that recognizes the expressed foreign gene product. ¹²⁵I-labeled protein A is used to detect the bound antibody. Alternatively, a chemiluminescent detection system such as Amersham ECL can be used. The membrane is then exposed to X-ray film.

Note that infected cells comprising a plaque can be stained in situ by following the protocol in *UNIT 16.16* (Basic Protocol 4, titration of MVA by immunostaining) except that antibody to the recombinant protein should be substituted for antibody to vaccinia virus.

Additional Materials (also see *Basic Protocol 3*)

- PBS/Tween (see recipe) with and without 4% (w/v) BSA
- Antibody to foreign protein
- 100 μ Ci/ml [¹²⁵I]-labeled protein A (30 mCi/mg; Amersham)
- Additional reagents and equipment for autoradiography (*APPENDIX 3A*)

1. Prepare cells and blot cell lysate (see Basic Protocol 3, steps 1 to 4).
2. Soak membrane ~30 min in PBS/Tween containing 4% BSA. Wash once with PBS/Tween without BSA.

Washing is done by pouring liquid off and replacing it.

3. Dilute antibody to foreign protein 1:50 to 1:5000 in a minimal volume of PBS/Tween. Incubate membrane in this solution ≥ 1 hr at room temperature.
4. Wash approximately five times with an excess volume of PBS/Tween.
5. Incubate membrane for 30 min in a minimal volume of PBS/Tween containing 1 μ Ci of [125 I]-labeled protein A.

Alternatively, a chemiluminescent detection kit (e.g., Amersham ECL) may be used to detect the antibody

6. Wash membrane approximately five times with an excess volume of PBS/Tween.
7. Wrap membrane in plastic wrap and autoradiograph by exposing to X-ray film (APPENDIX 3A).

DETECTION OF EXPRESSED PROTEIN USING IMMUNOBLOTTING

After a recombinant virus has been plaque purified and amplified, immunoblotting can be used to determine if the recombinant protein is of the expected size and whether or not it is secreted from infected cells. The steps below are for nonsecreted (intracellular) proteins, but annotations describe procedures when working with cells in which the recombinant protein is secreted into the medium.

Materials

- Confluent BS-C-1 cell monolayer (UNIT 16.16)
- Complete MEM-5 medium (UNIT 16.16)
- Recombinant vaccinia virus stock (UNIT 16.16)
- 0.25 mg/ml trypsin (2 \times crystallized and salt-free; Worthington; filter sterilize and store at -20°C)
- Cell lysis buffer (see recipe)
- 5 \times SDS sample buffer (UNIT 10.2)
- 6-well tissue culture plates
- Sorvall centrifuge with H-6000A rotor (or equivalent)
- 95 $^{\circ}\text{C}$ water bath
- Additional reagents and equipment for preparing cell cultures for infection (see Basic Protocol 1) and immunoblotting (UNIT 10.8)

NOTE: All culture incubations should be performed in a humidified 37 $^{\circ}\text{C}$, 5% CO_2 incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

1. Set up cell cultures for infection (see Basic Protocol 1, steps 1 to 5) starting with a confluent BS-C-1 cell monolayer.
2. Plate 5×10^5 cells/well in a 6-well tissue culture plate (2 ml/well final) using MEM-5 medium. Incubate until confluent (this should take <24 hr).
3. Just prior to use, mix equal volumes of recombinant vaccinia virus stock and 0.25 mg/ml trypsin and vortex vigorously. Incubate 30 min in a 37 $^{\circ}\text{C}$ water bath, vortexing at 5- to 10-min intervals during the incubation.

BASIC PROTOCOL 4

Protein Expression

16.18.7

Virus stocks are usually at a titer of $\sim 2 \times 10^9$ pfu/ml but may be significantly lower depending on the source.

Vortexing usually breaks up any clumps. However, if clumps still remain, chill to 0°C and sonicate 30 sec on ice. Sonication can be repeated several times but the sample should be allowed to cool on ice between sonications.

4. Aspirate medium and infect monolayer culture at a multiplicity of infection (MOI) of 10 to 30 pfu/cell in 1 ml (final volume) complete MEM-5. Incubate 1 to 2 hr, rocking at ~ 30 -min intervals.

If purified virus is used, sonicate 30 sec on ice prior to use (see Basic Protocol 1, step 7).

If analyzing proteins that are secreted into the medium, it is important to infect and overlay the cells with medium that does not require the addition of serum or to use only 1% serum, since a high concentration of serum proteins interferes with gel analysis.

5. Overlay with 2 ml complete MEM-5 and incubate 24 to 48 hr.
6. Scrape cells and transfer to a centrifuge tube. Centrifuge 5 min at $1800 \times g$ (2500 rpm in a H-6000A rotor), 5° to 10°C. Aspirate and discard supernatant.

For secretory proteins, concentrate the medium by spinning in a Centricon 10 microconcentrator (Amicon) until the volume is reduced ~ 5 -fold. Alternatively, proteins can be precipitated from the medium by trichloroacetic acid (TCA) precipitation as follows: (1) Add Triton X-100 to the sample to 0.03% (v/v) final; (2) add an equal volume of 20% TCA; (3) place 15 min on ice; (4) microcentrifuge 15 min at maximum speed, 4°C; (5) aspirate supernatant and wash the pellet with 70% ethanol, (6) air dry the pellet, add 5 μ l 1 M Tris base, and dissolve in 1 \times SDS/sample buffer.

7. Resuspend cell pellet in 200 μ l cell lysis buffer and transfer to a microcentrifuge tube. Vortex and let sit 10 min on ice.

Cell lysis buffer contains nonionic detergent only. This may not be sufficient for extraction of some proteins. In such cases, SDS-containing buffer (UNIT 16.11) may be necessary.

8. Microcentrifuge 10 min at maximum speed, 4°C. Separate supernatant (cytoplasm) and pellet (nuclei).
9. To 20 μ l of the supernatant, add 5 μ l of 5 \times SDS/sample buffer and heat 5 min at 95°C. Dissolve pellet in 200 μ l of 1 \times SDS/sample buffer and heat 5 min at 95°C.
10. Proceed with immunoblotting (UNIT 10.8).

BASIC PROTOCOL 5

DETECTION OF EXPRESSED PROTEIN USING IMMUNOPRECIPITATION

When strong late promoters are used, the expressed recombinant protein can be labeled with radioactive amino acids and detected by polyacrylamide gel electrophoresis. Immunoprecipitation of the labeled proteins can be used to increase sensitivity and specificity when early or late promoters are used.

Materials

Complete MEM-5 medium (UNIT 16.16)

Complete methionine- or cysteine-free MEM-5 medium (see recipe in UNIT 16.16 but use methionine- or cysteine-free MEM, e.g., from Life Technologies) prepared with dialyzed FBS (e.g., HyClone)

[³⁵S]methionine or [³⁵S]cysteine (depending on which amino acid was omitted from the medium; see Critical Parameters)

Phosphate-buffered saline (PBS; APPENDIX 2)

Cell lysis buffer (see recipe)

Additional reagents and equipment for preparing cells and infecting with vaccinia virus (see Basic Protocol 4) and immunoprecipitation (UNIT 10.16)

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

1. Set up cell cultures and infect cells (see Basic Protocol 4, steps 1 to 4).
2. Overlay with 2 ml complete MEM-5 medium and continue incubation for the appropriate period of time.

The time after infection at which metabolic labeling is performed will depend upon which promoter is used to express the gene of interest. If an early promoter only is used, labeling should be done between 1 and 6 hr post infection. If a late promoter is used, labeling should be done between 4 and 20 hr post infection. With a compound early/late promoter, either time may be used.

3. At the appropriate time after infection, aspirate medium and replace with 0.5 ml complete methionine- or cysteine-free MEM-5 containing 25 to 50 µCi of [³⁵S]methionine or [³⁵S]cysteine and 35 µl complete MEM-5. Incubate 2 to 3 hr to overnight.
4. Add 0.15 ml complete MEM-5 as chase. Continue incubation for 1 hr.
5. Remove medium and save if the expressed protein is secreted.
If the medium is to be analyzed, remove any free cells by microcentrifuging 3 min.
6. Overlay cells with 1 ml PBS, scrape, and transfer to a microcentrifuge tube. Microcentrifuge 3 min at maximum speed, room temperature. Aspirate and discard supernatant.
7. Resuspend cells in 200 µl cell lysis buffer. Vortex and place 10 min on ice.
8. Microcentrifuge 10 min at maximum speed, 4°C. Remove supernatant and proceed with immunoprecipitation (beginning with Basic Protocol, step 4, in UNIT 10.16).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cell lysis buffer

100 mM Tris·Cl, pH 8.0 (APPENDIX 2)
100 mM NaCl
0.5% (v/v) Triton X-100 or NP-40
Store indefinitely at room temperature

Add PMSF (or other protease inhibitors; optional) from a 100× stock to 0.2 mM final just before use. Store 100× inhibitor stock at -20°C.

DNA extraction buffer

20 mM EDTA
20 mM Tris·Cl, pH 7.5 (APPENDIX 2)
0.5% (w/v) SDS
0.5 to 1.0 mg/ml proteinase K (add immediately before use)
Store components without proteinase K indefinitely at room temperature

Low-salt buffer

20 mM Tris·Cl, pH 8.0 (APPENDIX 2)
10 mM EDTA
0.75% (w/v) sodium dodecyl sulfate (SDS)
Store indefinitely at room temperature

PBS/Tween

Add 0.5% (v/v) Tween-20 to PBS (APPENDIX 2). Store indefinitely at room temperature.

COMMENTARY

Background Information

Several different methods of characterizing recombinant vaccinia viruses are available. Each is suitable at a different time during isolation and characterization of a recombinant virus. During plaque purification of a new virus, PCR, DNA dot-blot hybridization, or immunoblotting of individual plaque isolates are quick and easy ways of determining which plaque contains the foreign gene. This is particularly important if TK selection only is used, since not all plaques will contain recombinant virus.

After an isolate has been plaque purified several times and amplified, analysis of the DNA by PCR or Southern blotting can be used to determine whether or not a pure isolate has been obtained. Restriction endonuclease digestion of vaccinia DNA with *Hind*III gives a specific pattern. The *Hind*III fragment into which the foreign gene has been inserted should be increased in size by the size of the foreign gene (unless the latter contains a *Hind*III site). The TK gene, which is the most commonly used region for insertion of a foreign gene, is located in the 5.1-kbp *Hind*III J fragment.

Western blotting or radioimmunoprecipitation using an antibody specific for the gene of interest will determine whether the correct gene product is made. Analysis of the extracellular medium will show whether the protein is secreted. If a nuclear localization signal is present, the protein may be translocated into the nucleus. In this case, the nuclei should also be analyzed (see Basic Protocol 4, step 8).

For large-scale production of protein, HeLa cell suspension cultures may be infected as described in the support protocol for purification of vaccinia virus in UNIT 16.17, and harvested after 48 to 72 hr. Alternatively, microcarrier cultures of Vero cells may be used (Barrett et al., 1989).

Critical Parameters

In all protocols for identifying plaques containing recombinant virus, it is important to include positive and negative controls. For PCR or DNA dot-blot hybridization, the plasmid used for transfection is an appropriate positive control, while cells infected with wild-type vaccinia virus can serve as a negative control. For immunoblotting, an extract of cells known to express the foreign gene can be used (e.g., influenza virus-infected cells could be used as a positive control for analysis of a recombinant vaccinia virus expressing an influenza gene). Cells infected with wild-type vaccinia virus can be used as a negative control.

In planning an immunoprecipitation, check the amino acid composition of the expressed protein for numbers of methionine and cysteine residues and then label with the appropriate amino acid(s).

If lysates are frozen prior to immunoprecipitation, it is important to microcentrifuge 5 min at maximum speed to pellet subcellular debris before mixing a sample of the supernatant with antibody.

Anticipated Results

The Southern blotting protocol in this unit is a quicker, easier method than the one in UNIT 2.9. Since the most common region used for insertion of foreign genes into vaccinia virus is the TK locus within the 5.1-kbp *Hind*III J fragment, the size of this fragment should be larger in a recombinant virus (if there is no *Hind*III site within the inserted DNA). Hybridization of a second blot or rehybridization of the original blot with ³²P-labeled vaccinia virus DNA will show the overall *Hind*III restriction digestion pattern. The 5.1-kbp *Hind*III J fragment should be absent, indicating that the virus isolate does not contain any contaminating wild-type recombinant virus. A control of wild-type *Hind*III-digested vaccinia DNA is helpful for a

comparison to the original restriction endonuclease pattern.

Visualization of protein bands from an immunoblotting procedure is usually accomplished with an X-ray film exposure of 1 to 24 hr. Additional time may be required if the antibody recognition is poor; if this is the case, cells can be lysed in a smaller volume, allowing more lysate to be analyzed in one lane. Additional incubation time or a lower dilution of antibody may also help to intensify the signal. A western blot that has been exposed to X-ray film but has not been completely dried can be reincubated with the same antibody (if the original antibody concentration was too low) or with a different antibody. Negative and positive controls should be included to help identify specific protein bands.

For an immunoprecipitation, the gel exposure time will depend on several factors, including the amount of label incorporated into the protein and the affinity of the antibody for the protein. It may be necessary to optimize results by adjusting the amount of labeled amino acid used, the amount of antibody used, or the time of incubation of the lysate with the antibody.

Time Considerations

The PCR, DNA dot-blot hybridization, and immunoblotting protocols require 2 days for amplification of the virus. An additional day is necessary for PCR amplification and agarose gel analysis or for hybridization and washing. Time of exposure to X-ray film for DNA dot-blot and immunoblotting protocols varies depending upon the hybridization probe or antibody used.

Gene Expression Using the Vaccinia Virus/T7 RNA Polymerase Hybrid System

UNIT 16.19

This unit describes a transient cytoplasmic expression system that relies on the synthesis of the bacteriophage T7 RNA polymerase in the cytoplasm of mammalian cells. To begin, a gene of interest is inserted into a plasmid such that it comes under the control of the T7 RNA polymerase promoter (p_{T7}). Using liposome-mediated transfection, this recombinant plasmid is introduced into the cytoplasm of cells infected with vTF7-3, a recombinant vaccinia virus encoding bacteriophage T7 RNA polymerase (see Basic Protocol 1). During incubation, the gene of interest is transcribed with high efficiency by T7 RNA polymerase. This transfection protocol is adequate for analytical purposes and is simple because no new recombinant viruses need to be made.

For large-scale work, the p_{T7} -regulated gene can be inserted into a second recombinant vaccinia virus by homologous recombination (UNIT 16.17) and used in combination with vTF7-3 to coinfect cells grown in suspension (see Basic Protocol 2) or used to infect OST7-1 cells (a stable cell line that constitutively expresses the T7 RNA polymerase; see Basic Protocol 3). Expressed protein is then analyzed by pulse-labeling (see Support Protocol) or by the methods detailed in UNIT 16.18, and purified as described in UNIT 10.10.

There have been several innovations to this vaccinia virus/T7 RNA polymerase hybrid expression system (see Background Information). One new development is the VOTE inducible expression system, which eliminates the need to use two recombinant viruses or a special cell line (see Basic Protocol 4).

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

LIPOSOME-MEDIATED TRANSFECTION FOLLOWING RECOMBINANT VACCINIA VIRUS (vTF7-3) INFECTION

**BASIC
PROTOCOL 1**

This protocol begins with a plasmid vector containing the gene of interest at a site between p_{T7} and the T7 terminator (Figs. 16.19.1 & 16.19.2; also see Critical Parameters). This recombinant plasmid is then introduced via liposome-mediated transfection (UNIT 9.4) into cells already infected with vaccinia virus vTF7-3 (a recombinant virus expressing the T7 RNA polymerase gene). After harvesting, the cells are analyzed for expression of the gene product as described in UNIT 16.18 or by pulse-labeling (see Support Protocol).

Materials

Recombinant plasmid: gene of interest subcloned (UNIT 3.16) into pTF7-5 or pTM1 vectors (available from B. Moss, e-mail bmoss@nih.gov; Figs. 16.19.1 and 16.19.2) or other plasmid containing the T7 promoter (e.g., pBluescript, Stratagene; see UNIT 16.2 Critical Parameters and Fig. 1.10.8)

Confluent CV-1 cell monolayer (ATCC #CCL70; UNIT 16.16)

Complete DMEM-10 (UNIT 16.16)

vTF7-3 vaccinia virus stock (ATCC #VR-2153)

Opti-MEM I reduced serum medium (Life Technologies)

Liposome suspension (Lipofectin or TransfectAce; Life Technologies)

6-well tissue culture dishes with 35-mm-diameter wells

**Protein
Expression**

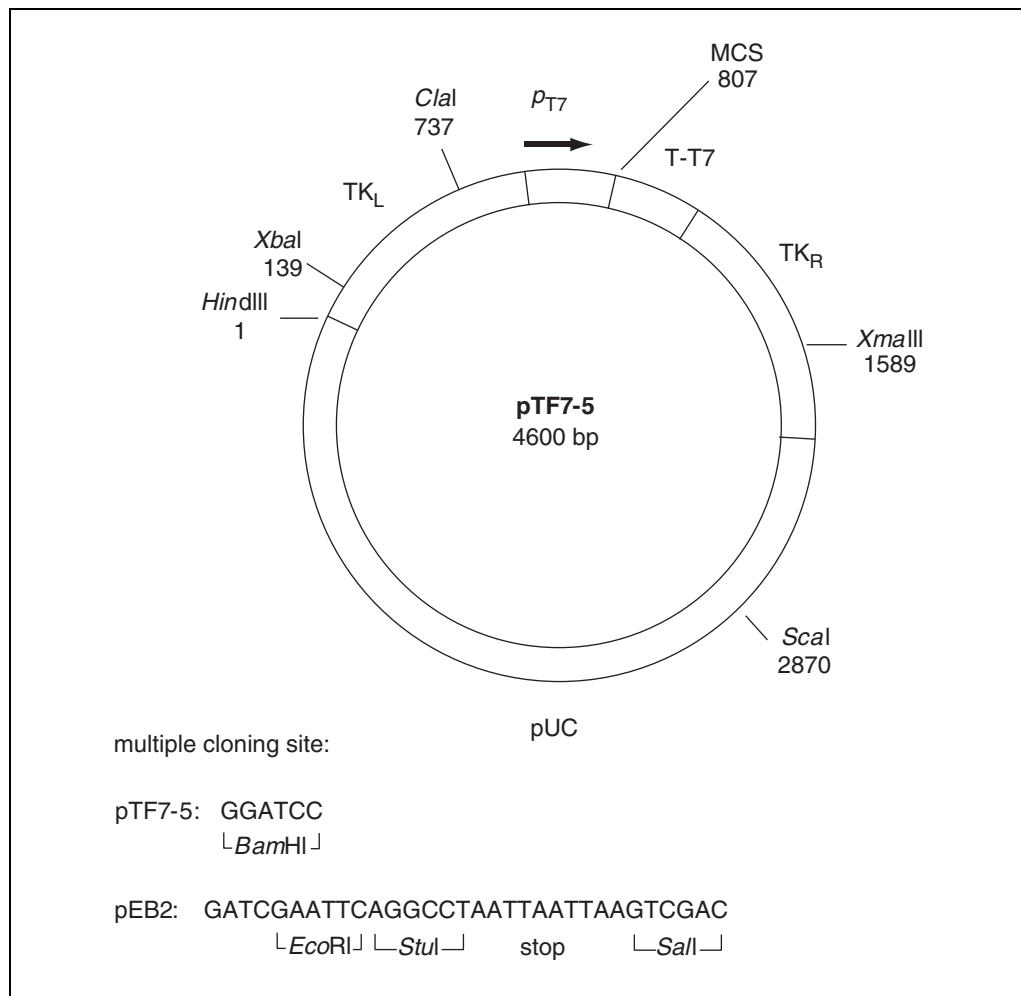

Figure 16.19.1 pTF7-5 (Fuerst et al., 1986) contains p_{T7} and a terminator, between which is a unique *Bam*H1 site for insertion of a gene. The derivative, pEB2 (Berger et al., 1988) contains unique *Eco*RI and *Stu*I sites followed by translation stop codons in all three reading frames. The expression cassette is flanked by segments of the vaccinia virus TK gene; thus, TK⁻ selection can be used for isolation of recombinant plaques (UNIT 16.17).

Cup sonicator (385-W)
12 × 75-mm polystyrene tubes (Falcon)

Additional reagents and equipment for purification of plasmid (UNIT 1.7)

1. Purify recombinant plasmid for transfection by CsCl/ethidium bromide centrifugation or PEG precipitation (UNIT 1.7).

Transfection will require 5 μg DNA/well of cells.

When using the pTM1 plasmid (Fig. 16.19.2), make sure that the initiator ATG of the gene of interest is the ATG of the pTM1 NcoI site (see Critical Parameters). Determine that the correct construction has been obtained by restriction mapping and DNA sequencing (UNIT 3.2).

2. The day before infection, seed wells of a 6-well tissue culture dish with 5×10^5 CV-1 cells/well in complete DMEM-10. Incubate until cells are near confluency (usually overnight).

Cells should be counted with a hemacytometer (APPENDIX 3F).

3. Vortex stock of vTF7-3 to disperse clumps. Sonicate the lysate using a cup sonicator as follows: (a) fill the cup with ice water (~50% ice); (b) place tube containing vTF7-3

Figure 16.19.2 pTM1 contains the encephalomyocarditis virus untranslated leader region (EMCV-UTR) downstream of p_{T7} . The *NcoI* site contains the translation initiation codon and should be used for insertion of the 5' end of the protein-coding DNA segment. The 3' end of the DNA can be inserted into any downstream sites preceding the T7 terminator. The expression cassette is flanked by segments of the vaccinia virus TK gene; thus, TK⁻ selection can be used for isolation of recombinant virus (UNIT 16.17). pTM3 is the same as pTM1 except it includes the guanine phosphoribosyltransferase (*gpt*) gene to permit mycophenolic acid selection for recombinant virus (Moss et al., 1990; UNIT 9.5).

stock in the ice water; and (c) sonicate full power, 30 sec. Place lysate on ice ≥ 30 sec, then repeat sonication.

Because sonication melts the ice, it is necessary to replenish the ice in the cup.

4. Dilute an aliquot of the virus to 2×10^7 pfu/ml in Opti-MEM I.
5. Infect subconfluent monolayer of CV-1 cells from step 2 with 0.5 ml/well diluted virus stock (i.e., 10 pfu/cell). Incubate 30 min, rocking every 5 to 10 min.
6. Approximately 5 min before the end of the infection, prepare liposome suspension. Place 1 ml Opti-MEM I in separate 12×75 -mm polystyrene tubes (one for each well to be tested). Vortex liposome suspension and add 15 μ l to the medium; vortex briefly. Add 5 μ g recombinant plasmid (from step 1) and mix gently.

Vortex the liposome suspension before use to suspend the liposomes, which gradually settle during storage. Do not use a polypropylene tube, as the DNA/liposome complex may adhere to the surface.

7. Aspirate virus inoculum from CV-1 cells and add the DNA/liposome complex directly to the cells. Incubate 5 to 24 hr, then analyze expressed protein by pulse labeling (see Support Protocol) or by methods described in *UNIT 16.18*.

The time needed for incubation depends on the analysis that will be done. Although expression is detectable within a few hours after transfection, pulse-labeling at late times is preferred because host protein synthesis is inhibited and synthesis of the recombinant protein is increased (UNIT 16.15).

COINFECTION WITH TWO RECOMBINANT VACCINIA VIRUSES

The recombinant plasmid containing the gene of interest under control of p_{T7} (Basic Protocol 1) is incorporated into vaccinia virus by homologous recombination (*UNIT 16.17*) and a stock is made (*UNIT 16.16*). This stock is used together with vTF7-3 to coinfect cells in monolayer or suspension cultures. During incubation, the gene of interest is efficiently transcribed by T7 RNA polymerase and translated in the cytoplasm of the infected cells. The protein is then analyzed (*UNIT 16.18*) or purified (*UNIT 10.10*).

This coinfection protocol is recommended for mass production of proteins. For this purpose, cells in suspension (i.e., Vero or HeLa S3 cells) are used.

Materials

- vTF7-3 vaccinia virus stock (ATCC #VR-2153)
- Stock of recombinant vaccinia virus encoding the gene of interest under control of p_{T7} (*UNITS 16.16 & 16.17*)
- Confluent monolayer culture of CV-1 cells (*UNIT 16.16*) or HeLa S3 cells from a spinner culture (*UNIT 16.16*)
- 0.25 mg/ml trypsin (Worthington 2× crystalline and salt-free; filter sterilize and stored at -20°C)
- Complete DMEM-10, MEM spinner-5, or MEM-2.5 (depends on cell type; see below and *UNIT 16.16*)
- Sorvall H-6000 rotor or equivalent
- 6-well tissue culture dishes with 35-mm-diameter wells or larger tissue culture flasks for scaled-up analysis
- Additional reagents and equipment for counting cells with a hemacytometer (*APPENDIX 3F*), vaccinia virus analysis (*UNIT 16.18*), and protein purification (*UNIT 10.10*)

Prepare the cells

- 1a. *For infection of a CV-1 monolayer:* The day before infection, seed wells of a 6-well tissue culture dish with 5×10^5 cells in complete DMEM-10. Incubate until cells are near confluency (usually overnight).

Increase volumes proportionally if large-scale production is desired.

- 1b. *For infection of HeLa S3 suspension cells:* Just prior to infection, count cells using a hemacytometer (*APPENDIX 3F*) and centrifuge the desired amount 5 min at $1800 \times g$ (2500 rpm in Sorvall H-6000 rotor), room temperature. Discard supernatant, resuspend cells in MEM spinner-5 medium at 2×10^7 cells/ml, and transfer to a smaller sterile tissue culture flask or Erlenmeyer flask.

2. Trypsinize virus stocks. Place an aliquot of each stock in a separate tube and add an equal volume of 0.25 mg/ml trypsin. Vortex vigorously. Incubate 30 min, vortexing at 5- to 10-min intervals.

The highest level of expression using this system is obtained with an MOI of 10 pfu/cell for each virus.

Vortexing usually breaks up any clumps of cells. However, if any visible clumps remain, chill to 0°C and sonicate 30 sec on ice. Sonication can be repeated several times but the sample should cool on ice between sonications (see Basic Protocol 1).

3. Combine the two trypsinized virus stocks.

Infect the cells

For cells in monolayer culture

- 4a. Dilute trypsinized virus mixture with complete MEM-2.5 to 4×10^7 pfu/ml.

This represents 2×10^7 pfu/ml from each virus stock.

- 5a. Aspirate medium from cells and infect wells of a 6-well dish with 0.5 ml virus mixture per well. Incubate 1 to 2 hr, rocking dish at 15- to 30-min intervals.
- 6a. Overlay cells with 2 ml DMEM-10 and incubate. Analyze gene expression 5 to 24 hr after infection, depending on the method used. Alternatively, harvest 2 to 3 days after infection for protein purification.

Although expression is detectable within a few hours after infection, analysis by immunoprecipitation, immunoblotting, or northern blotting is preferred at late times because the T7-regulated gene product accumulates to a higher level. Earlier analysis may be preferred for assaying the biological activity of the expressed protein.

For suspension cells

- 4b. Add trypsinized virus mixture to the concentrated cells. Stir with a sterile magnetic stir bar 30 min at 37°C.
- 5b. Transfer infected cells to a larger vented spinner flask and dilute with MEM spinner-5 to bring the cell density to 5×10^5 cells/ml. Stir 1 to 3 days at 37°C.
- 6b. Harvest cells and analyze or purify the expressed protein (see annotation to step 6a above).

INFECTION OF OST7-1 CELLS WITH A SINGLE VIRUS

OST7-1 cells are derived from mouse L929 cells and constitutively express the bacteriophage T7 RNA polymerase in the cytoplasm. Thus, using this cell line eliminates the need for infection with ν TF7-3. This protocol describes the infection of OST7-1 cells with a single recombinant virus containing the gene of interest.

Materials

Confluent monolayer of OST7-1 cells (available from B. Moss, e-mail bmoss@nih.gov)

Complete DMEM-10 (UNIT 16.16) containing 400 potent μ g/ml Geneticin (G418, UNIT 9.5; Life Technologies; prepared from 80 mg/ml stock in PBS, filter sterilized and stored at -20°C)

Stock of recombinant vaccinia virus containing the gene of interest under the control of p_{T7} promoter (UNITS 16.16 & 16.17)

0.25 mg/ml trypsin (Worthington 2 \times crystalline and salt-free; filter sterilize and store at -20°C)

Complete MEM-2.5 (UNIT 16.16)

6-well tissue culture dish with 35-mm-diameter wells

**BASIC
PROTOCOL 3**

**Protein
Expression**

16.19.5

**BASIC
PROTOCOL 4**

1. Seed wells of a 6-well tissue culture dish with 1×10^6 OST7-1 cells/well in complete DMEM-10 containing 400 potent $\mu\text{g/ml}$ Geneticin. Incubate until cells reach confluency (usually overnight).
Complete DMEM-10 containing Geneticin is used to maintain the culture, but Geneticin is not required for the expression experiment itself.
2. Mix an equal volume of the virus stock and 0.25 mg/ml trypsin by vortexing vigorously. Incubate 30 min at 37°C, vortexing at 5- to 10-min intervals.
Use an MOI of 10 pfu/cell.
3. Dilute the trypsinized virus to 2×10^7 pfu/ml with complete MEM-2.5.
4. Infect confluent monolayer of OST7-1 cells with 0.5 ml virus mixture/well. Incubate 1 to 2 hr, rocking at 15- to 30-min intervals.
5. Add 1.5 ml/well complete MEM-2.5 and continue to incubate.
6. Analyze the cells 3 to 24 hr after infection (see Basic Protocol 2, annotation to step 6a).

GENE EXPRESSION USING THE VOTE SYSTEM

In this more recently developed method for vaccinia virus/T7 RNA polymerase hybrid expression, the gene of interest is cloned into the plasmid pVOTE.1 or pVOTE.2 and then incorporated into the genome of vaccinia virus vT7lacOI by homologous recombination (UNIT 16.17) and a stock is made (UNIT 16.16). Cells are then infected with the recombinant vaccinia virus in the presence of isopropyl-1-thio- β -D-galactoside (IPTG) and the gene of interest is efficiently transcribed by T7 RNA polymerase and translated in the cytoplasm of infected cells. Figure 16.19.3 illustrates this system.

Materials

Vaccinia virus vT7lacOI (available from B. Moss, e-mail *bross@nih.gov*)
DNA containing gene of interest
pVOTE.1 or pVOTE.2 (available from B. Moss)
CV-1 or BS-C-1 confluent monolayer (UNIT 16.16)
Cells for protein expression (e.g., HeLa)
Isopropyl-1-thio- β -D-galactoside (IPTG)

Additional reagents and equipment for PCR (UNIT 15.1), restriction enzyme digestion (UNIT 3.1), preparation of vaccinia virus stock (UNIT 16.16), infection of cells with vaccinia virus, transfection of infected cells with a vaccinia vector, harvest of vaccinia virus, selection of recombinant vaccinia virus plaques, and plaque purification of virus (UNIT 16.17), and determination of protein expression in the vaccinia system (UNIT 16.18; also see Support Protocol in this unit)

Insert gene into pVOTE.1 or pVOTE.2

1. Amplify the open reading frame from the gene of interest by PCR (UNIT 15.1) so that the translation-initiation codon is part of an *NcoI* (CCATGG) site for cloning into pVOTE.1 or a *NdeI* (CATATG) site for cloning into pVOTE.2.
*The other end of the PCR product should be compatible with a unique restriction endonuclease site present in the MCS (*XhoI*, *SacI*, *SmaI*, *EcoRI*, *PstI*, *Sall*, or *BamHI*).*
For high expression, the translation start codon must be adjacent to the encephalomyocarditis virus ribosome entry site.
2. Digest the PCR product and either pVOTE.1 or pVOTE.2 with the chosen restriction endonucleases (UNIT 3.1) and ligate the PCR product and plasmid together.

Transfer gene to vT7lacOI

3. Prepare a stock of vT7lacOI (UNIT 16.16) and use the stock to infect CV-1 or another cell line (UNIT 16.17).
4. Transfect recombinant plasmid derived from pVOTE.1 or pVOTE.2 (from step 1) into the cells infected with vT7lacOI (from step 3). Harvest the virus.

All of these procedures are described in UNIT 16.17.

5. Select recombinant virus for expression of XGPRT and plaque purify virus (UNIT 16.17).

Because the gene is inserted into the hemagglutinin site of vT7lacOI, the cells infected with recombinant virus can be recognized with the light microscope by their formation of syncytia.

6. Prepare a stock of the plaque-purified virus (UNIT 16.16).

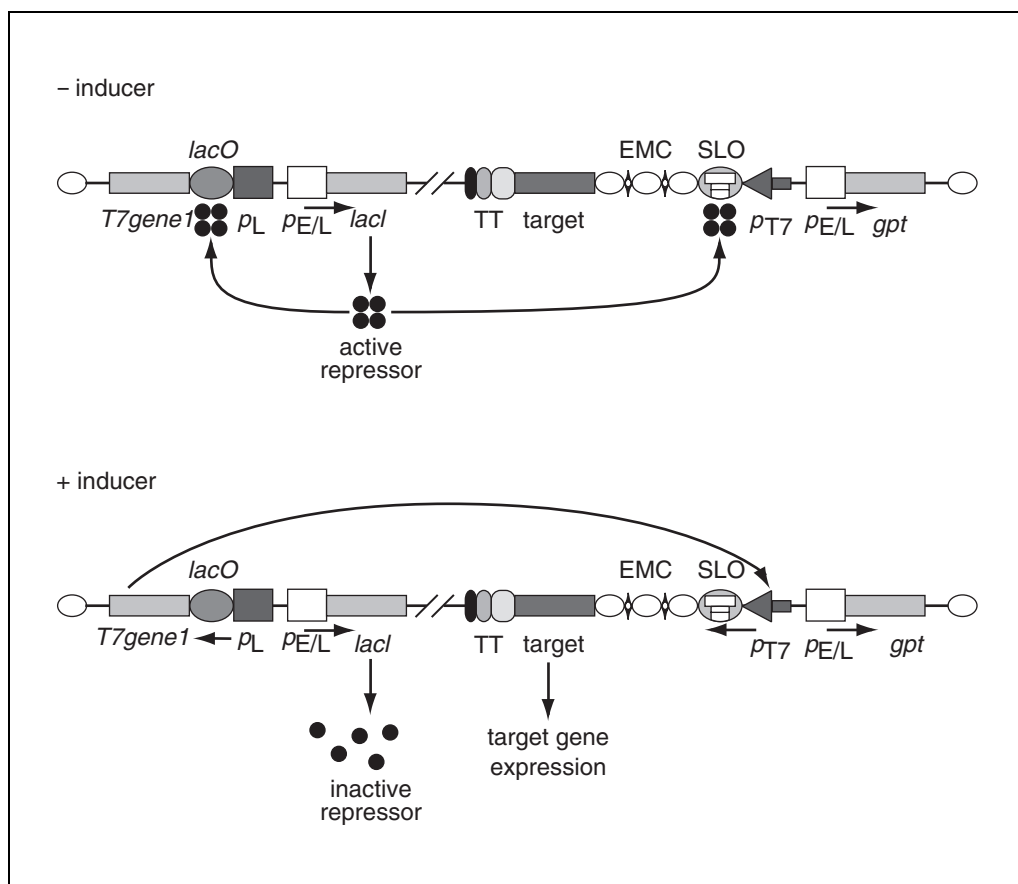

Figure 16.19.3 Schematic representation of the VOTE expression system. Portions of a recombinant vaccinia virus genome containing regulatory elements are diagrammed. Transcription of the *lacI* gene under control of a vaccinia virus early/late promoter ($p_{E/L}$) results in continuous synthesis of repressor monomers (represented by solid circles) which assemble into tetramers and bind to the *lacO* adjacent to a vaccinia virus late (p_L) promoter, preventing transcription of the bacteriophage T7 RNA polymerase gene (*T7gene1*), and to the modified *lacO* (SLO) next to the T7 promoter (p_{T7}), preventing transcription of the target gene should leaky synthesis of the T7 RNA polymerase occur. Upon induction, the repressor is inactivated, vaccinia virus RNA polymerase transcribes T7 gene 1, and T7 RNA polymerase is made. The latter binds to the T7 promoter and transcribes the target gene from the SLO to the triple terminator (TT). Translation of the target gene mRNA is enhanced by the EMC leader. From Ward et al., 1995; reprinted with permission of the National Academy of Sciences.

**SUPPORT
PROTOCOL**

Express the gene by infecting cells in the presence of IPTG

7. Infect monolayer or suspension cultures of HeLa or other cells with 10 pfu/cell of the recombinant virus and add 5 μ M to 2 mM IPTG to the medium at the start of infection.
8. Determine expressed proteins by standard methods (*UNIT 16.18*; also see Support Protocol in this unit).

DETECTION OF EXPRESSED PROTEIN USING PULSE LABELING

Pulse labeling infected cells is a quick and sensitive way to monitor expression of the T7-regulated gene relative to expression of vaccinia late proteins. When performed 24 hr post-infection under optimal conditions, up to 80% of the [³⁵S]methionine is incorporated into the product of the T7-regulated gene. This protein is detected using SDS-PAGE. If the EMC untranslated leader is present (e.g., if the pTM1 plasmid is used), hypertonic conditions may be used to selectively enhance cap-independent translation.

Additional Materials

- Infected cells expressing the desired T7-regulated gene of interest (see Basic Protocols 1, 2, 3, or 4) in a 6-well tissue culture dish
- Methionine- or cysteine-free, serum-free MEM (Life Technologies, Select-Amine Kit)
- 10 mCi/ml [³⁵S]methionine (1175 Ci/mmol; Amersham) *or* 15 mCi/ml [³⁵S]cysteine (600 Ci/mmol; Amersham)
- Phosphate-buffered saline (PBS; *APPENDIX 2*), ice-cold
- Cell lysis buffer (*UNIT 16.18*)
- 6 \times SDS/sample buffer (*UNIT 10.2*)
- Fixing solution (*UNIT 10.6*)
- Fluorographic solution (EN³HANCE from Du Pont NEN; *or* Amplify from Amersham)
- Cell scraper
- 95°C water bath
- Additional reagents and equipment for denaturing (SDS) gel electrophoresis (*UNIT 10.2*) and autoradiography (*APPENDIX 3A*)

Label the cells

1. Obtain infected cells expressing the desired T7-regulated gene of interest 24 hr after infection. Aspirate medium and replace it with 0.3 ml methionine- or cysteine-free MEM per well. Incubate 20 min.

Hypertonic conditions selectively enhance cap-independent translation. Therefore, if the EMC leader is present in the plasmid used in the infection (e.g., pTM1; Fig. 16.19.2), add 4.8 μ l of 5 M NaCl to each well (190 mM final).

2. Add 30 μ Ci of [³⁵S]methionine or [³⁵S]cysteine to each well. Incubate 30 min.

Lyse the cells

3. Aspirate medium and add 1 ml ice-cold PBS to each well.
4. Scrape cells with a disposable cell scraper and transfer to a 1.5-ml microcentrifuge tube. Microcentrifuge 1 min at high speed. Aspirate and discard supernatant.
5. Resuspend cell pellet in 100 μ l cell lysis buffer. Vortex briefly and incubate 5 min on ice.

6. Microcentrifuge 5 min at maximum speed and transfer supernatant to a clean microcentrifuge tube.

Analyze proteins

7. Remove 10 μ l lysate and place in another microcentrifuge tube with 2 μ l of 6 \times SDS/sample buffer. Heat 5 min at 95°C.
8. Load sample on single well of denaturing SDS-polyacrylamide gel and perform electrophoresis (UNIT 10.2).

A 10% polyacrylamide gel is recommended for separation of vaccinia late proteins that will appear as background bands on the autoradiogram.

It is important to use a control of infected cells that do not express the gene of interest.

9. Fix gel 20 min in fixing solution.
10. Incubate gel in fluorographic solution according to manufacturer's instructions.
11. Dry gel and autoradiograph by exposing to X-ray film.

If the pTM1 vector is used, the gene product is usually at a high enough level to appear as a major band among the vaccinia virus late gene products. If the T7-regulated gene product co-migrates with a vaccinia gene product, it will be necessary to analyze the expression using other methods as described in UNIT 16.18.

COMMENTARY

Background Information

The most efficient procedures for expression of genes in the cytoplasm of mammalian cells utilize a recombinant vaccinia virus encoding the bacteriophage T7 RNA polymerase. Many of the properties of T7 RNA polymerase that contribute to its successful use in prokaryotic gene expression (UNIT 16.2) are also relevant to its application for expression in eukaryotic cells. These properties include (1) the single subunit structure of T7 RNA polymerase, (2) the processive transcriptase activity of the enzyme, and (3) stringent promoter specificity in the eukaryotic cytoplasm.

In one version of the hybrid expression system described in this unit, plasmid DNA containing a gene of interest under the control of the p_{T7} promoter is transfected into cells infected with the recombinant vaccinia virus, after which the gene is transcribed efficiently by T7 RNA polymerase (Fuerst et al., 1986). Alternatively, DNA can be transfected into a cell line that constitutively expresses T7 RNA polymerase in the cytoplasm. However, for reasons that remain unclear, high-level expression in this cell line still requires infection with wild-type vaccinia virus (even when the cap-independent EMC virus untranslated region is used; Elroy-Stein and Moss, 1990). Therefore, the T7 RNA polymerase–cell line does not offer a clear advantage over the T7 RNA polym-

erase–vaccinia virus recombinant for transfection experiments.

In the vaccinia/T7 system, mRNA derived from the transfected gene can be as much as 10% to 30% of total cytoplasmic RNA. However, although mRNA levels of the T7-regulated gene are often quite high, only moderate amounts of protein are made. This limited translation is presumably due to the low efficiency of capping the transcripts made by T7 RNA polymerase (Fuerst and Moss, 1989). This difficulty was addressed by incorporating a feature of picornavirus mRNAs—a long untranslated leader region (UTR or “ribosomal landing pad”) that facilitates cap-independent ribosome binding—just downstream of the T7 promoter in certain vectors. The use of such vectors (e.g., pTM1; Fig. 16.19.2) in the vaccinia/T7 system enhances expression 5- to 10-fold (Elroy-Stein et al., 1989).

Transfection of DNA can be mediated by calcium phosphate or cationic liposomes. The latter method has reproducibly allowed 80% to 90% of the cells to be transfected (Felgner et al., 1987; Elroy-Stein and Moss, 1990; Rose et al., 1991; see also UNIT 9.4).

There have been several more recent innovations in the vaccinia virus/T7 RNA polymerase hybrid expression system. One is the use of the highly attenuated MVA strain of vaccinia virus to express the T7 RNA polymerase gene.

Overall, the levels of expression of transfected plasmids are similar using vTF7-3 and MVA/T7pol, but one may be higher than the other in certain cells (Wyatt et al., 1995). The main advantages of MVA/T7pol over vTF7-3 are lower biosafety requirements and the expression of genes in the absence of virus replication in nonpermissive cells (UNIT 16.16). Stocks of MVA/T7pol are prepared as described for MVA in UNIT 16.16. Liposome-mediated transfection is carried out as described in Basic Protocol 1 of this unit.

Recombinant vaccinia viruses that express SP6 RNA polymerase have been made, and are used in conjunction with plasmid vectors that use SP6 promoters for gene regulation (Usdin et al., 1993).

Another innovation is the development of the VOTE inducible expression system (see Basic Protocol 4 and Ward et al., 1995). This system should supersede the two-virus system and the need for cell lines expressing T7 RNA polymerase (UNIT 16.19). The VOTE system is tightly regulated, because there is an *E. coli lacO* regulating the T7 RNA polymerase gene and another one regulating the T7 promoter adjacent to the gene of interest. The level of expression can be titrated with IPTG. Another version of the VOTE system has a thermolabile *E. coli lac* repressor, so that induction occurs by temperature elevation (Ward et al., 1995).

Critical Parameters

To maximize protein expression, the gene of interest is cloned into a plasmid vector (e.g., pTF7-5 or pTM1) that contains both p_{T7} and the T7 terminator (Figs. 16.19.1 & 16.19.2). Better expression (5- to 10-fold) is obtained by using the encephalomyocarditis virus (EMCV)-UTR downstream of p_{T7} in pTM1. Alternatively, any plasmid that carries the T7 promoter (e.g., pBluescript; see UNIT 16.2 critical parameters) can be used but may give lower expression levels.

When the “ribosomal landing pad” within the EMCV-UTR is used, translation initiation occurs at the ATG, which is in the *NcoI* site of pTM-1. If native protein is to be expressed, the initiator ATG codon must be in the *NcoI* site. If necessary, the *NcoI* site may be mutated but the position of the initiator ATG should not be changed. If a fusion protein is desired, the coding sequence is inserted into one of the multiple cloning sites, in frame with the ATG of the *NcoI* site.

For some methods of detection (e.g., immunofluorescence; Earl et al., 1990), it is pref-

erable to harvest the cells ≤ 24 hr after transfection. If the incubation continues much beyond this point, the cells may detach from the monolayer and be lost during washing or staining.

For analytical purposes, expression can be achieved by transfecting the recombinant plasmid into cells that have been infected with a recombinant vaccinia virus, such as vTF7-3, which expresses the T7 RNA polymerase gene. For mass production of proteins—e.g., 8 μg CAT/ 10^6 cells (Elroy-Stein et al., 1989) or 11 mg HIV envelope protein/liter (Barret et al., 1989)—a recombinant vaccinia virus that contains the p_{T7} -regulated target gene should be generated by homologous recombination (UNIT 16.17). It should be introduced into cells constitutively expressing the T7 RNA polymerase, or used with vTF7-3 to coinfect any mammalian or avian cell line. Alternatively, the VOTE system eliminates the need for special cell lines or vTF7-3.

Anticipated Results

In most cases, 60% to 90% of transfected cells (following infection with vTF7-3) or 99% of infected cells (when the gene of interest is incorporated in a vaccinia virus) are observed to express the desired protein. If protein is being detected by pulse labeling, an overnight exposure should result in the protein product appearing as a dominant band over the background of vaccinia proteins.

Time Considerations

Starting with a plasmid containing the gene of interest cloned in the appropriate vector, the entire procedure from infection or infection/transfection to harvesting and analyzing the expressed product requires 2 to 3 days.

Expression of Proteins Using Semliki Forest Virus Vectors

UNIT 16.20

Semliki Forest virus (SFV) vectors have been developed to provide a convenient system to express protein-encoding sequences in virtually any animal cell. This unit presents two strategies for protein expression using SFV vectors. In both cases the protein-coding sequence of interest is cloned into a plasmid vector, which is subsequently used to produce recombinant RNA *in vitro*. This RNA, which is of positive polarity, is transfected into cells and there is amplified by virtue of its self-encoded RNA replicase. The same replicase also produces a shorter RNA species that encodes the protein of interest.

Protein expression can be achieved in two ways. In the first strategy, cells are transfected and directly analyzed for expression of the heterologous protein. The other strategy employs *in vivo* packaging of the RNA into SFV particles; recombinant RNA is cotransfected with a special helper RNA that codes for the structural proteins needed for virus assembly. SFV particles carrying only recombinant RNA are formed and are used to infect cells for analysis of protein expression. The first expression strategy is useful when studying the phenotypic expression of several mutant genes, in preliminary gene expression analyses, and when only a limited amount of expression studies are planned for one construct. The second strategy is more useful when many expression analyses are planned with the same construct and when large-scale production of the gene product is planned.

The first basic and alternate protocols employ the first strategy and differ only in transfection procedure (electroporation and liposome-mediated transfection, respectively). Accompanying support protocols provide methods for checking expression and transfection through β -galactosidase assays of transfected cells and cell lysates. The second basic protocol uses the second strategy and is accompanied by support protocols providing methods for titrating and purifying recombinant virus stocks. Although the protocols presented here are designed for use with BHK (baby hamster kidney) cells, the virus has a very broad host range and can be used with many different cell types (see Background Information).

STRATEGIC PLANNING: CHOICE OF SFV VECTOR

The available SFV vectors are all pGEM-based, confer ampicillin resistance, and carry the SFV replicase-encoding genes *nsP1-4* followed by a promoter for subgenomic transcription (Fig. 16.20.1). A unique *SpeI* restriction site is placed at the 3' end of the SFV-derived sequence to permit linearization of the plasmid prior to runoff transcription *in vitro*. Downstream from the subgenomic promoter (which overlaps with the 3' end of the *nsP4* gene) is a polylinker site (*Bam*HI-*Sma*I-*Xma*I) where the foreign DNA sequence is inserted. Following the polylinker are translational stop codons in all three reading frames (in case the inserted sequence lacks a stop codon).

The basic vector is pSFV1, which is used when the inserted DNA fragment contains an initiation codon (AUG) preceded by its own Kozak box (sequence specifying ribosome binding). pSFV3 contains a Kozak box and a start codon and is used when the inserted sequence lacks these elements; it provides proper translation as long as the inserted sequence is placed in frame with the initiating AUG of the vector. pSFV3-lacZ contains an added copy of the *E. coli* β -galactosidase gene and is used as a convenient control.

NOTE: Consult UNIT 4.1 for recommendations for minimizing contamination of RNA preparations by ribonucleases and Critical Parameters regarding precautions for working with SFV particles.

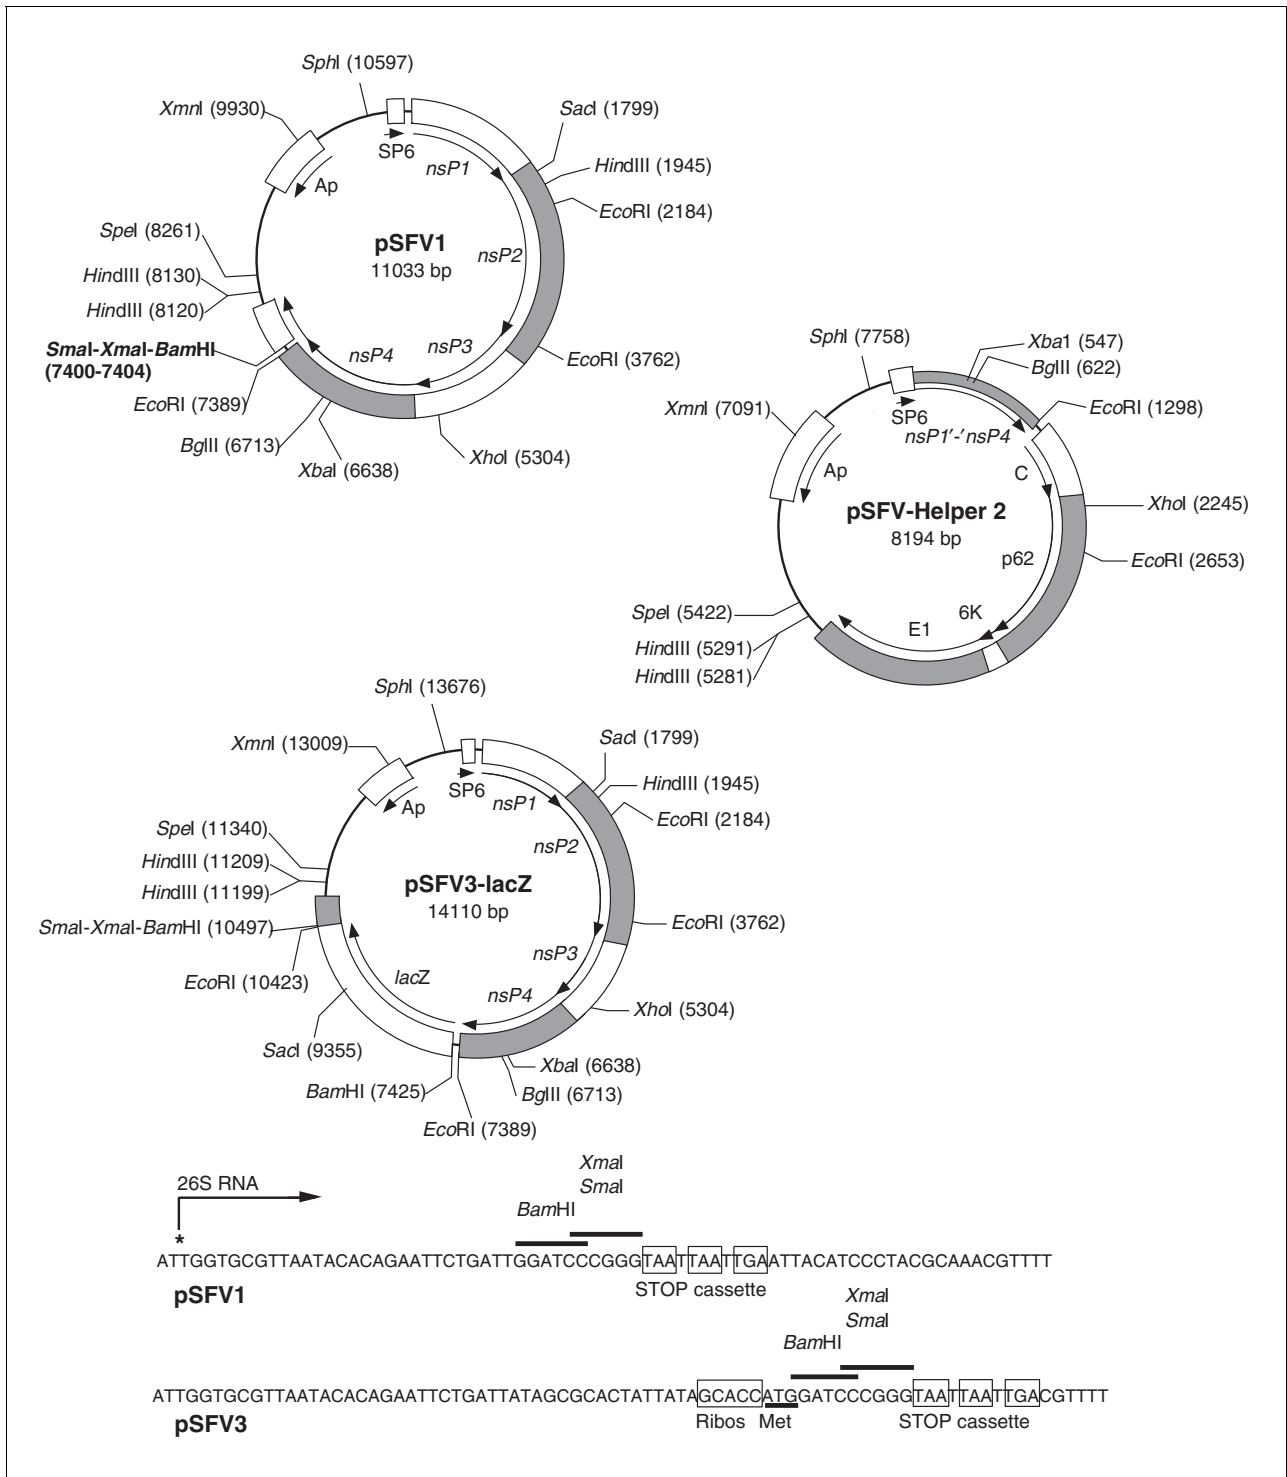

Figure 16.20.1 SFV expression vectors and their polylinker regions. pSFV1 and pSFV3 are almost identical in size and structure, differing only in their polylinker regions; pSFV3-lacZ is a variant of pSFV-3 containing an inserted copy of the *E. coli* β -galactosidase gene. These vectors carry the four genes encoding the SFV replicase (*nsP1-4*) but lack the structural genes of SFV (*C*, *p62*, *6K*, and *E1*). In contrast, the Helper plasmid lacks the *nsP* genes (the corresponding deletion flanking the remaining *nsP* sequences is indicated as *nsP1'-nsP4*, where the primes indicate the position of the deletion) but carries the structural genes. For all three plasmids, in vitro transcription is driven by the SP6 promoter. The unique *SpeI* site is used to linearize the plasmids prior to transcription. Sequences flanking the polylinker regions of pSFV1 and pSFV3 are shown below the plasmid maps. The first nucleotide transcribed from the subgenomic promoter, indicated above the pSFV1 sequence, is the same for all three plasmids. (Consult Liljeström and Garoff, 1991b; Liljeström et al., 1991; and Berglund et al., 1993 for further details).

16.20.2

EXPRESSION OF PROTEINS FROM RECOMBINANT SFV RNA USING ELECTROPORATIVE TRANSFECTION

BASIC PROTOCOL

SFV vector plasmids carrying heterologous sequences are used as templates for RNA synthesis *in vitro*. The RNA is transfected into BHK cells by electroporation, where the self-encoded RNA replicase amplifies the RNA molecules. In conjunction with efficient translational start signals resident on the RNA molecules, this ensures a high production rate for the heterologous protein. Production is easily monitored by metabolic labeling of transfected cells and analysis of the protein products by SDS-PAGE and autoradiography.

Materials

DNA fragment encoding protein of interest
pSFV1, pSFV3, or pSFV3-lacZ expression vector (GIBCO/BRL; see Fig. 16.20.1)
SpeI restriction endonuclease and buffer (UNIT 3.1)
10× SP6 RNA polymerase buffer
50 mM dithiothreitol (DTT)
10 mM ^{m7}G(5')ppp(5')G
rNTP mix
40 U/μl RNasin (Promega) or other RNase inhibitor
60 U/μl SP6 RNA polymerase (UNIT 3.8)
5× TD solution
λ DNA molecular weight markers (e.g., λ digested with *EcoRI* + *HindIII*; UNIT 2.5A)
BHK-21 cells (ATCC)
Complete BHK-21 medium
Phosphate-buffered saline (PBS; Reagents and Solutions), 37°C, room temperature, and ice cold
Trypsin/EDTA solution: 0.5 mg/ml trypsin/0.2 mg/ml EDTA in PBS
Starvation medium
15 mCi/ml [³⁵S]methionine (>1000 Ci/mmol)
Chase medium
NP-40 lysis buffer
75-cm² tissue culture flask
Electroporator (e.g., Bio-Rad)
0.2- or 0.4-cm electroporation cuvette
35-mm tissue culture plate

Additional reagents and equipment for subcloning (UNIT 3.16), preparation of plasmid DNA (UNIT 1.7), restriction endonuclease digestion (UNIT 3.1), phenol extraction and ethanol precipitation of DNA (UNIT 2.1), spectrophotometric quantitation of RNA and DNA (APPENDIX 3), agarose gel electrophoresis (UNIT 2.5A), SDS-PAGE for protein analysis (UNIT 10.2), and autoradiography (APPENDIX 3)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly. All incubations are performed in a humidified, 37°C, 5% CO₂ incubator unless otherwise specified.

Subclone fragment and prepare RNA by *in vitro* transcription

1. Subclone the DNA fragment of interest into an SFV expression vector. Grow up resulting plasmid and prepare purified DNA.
2. Linearize recombinant plasmid DNA by restriction digestion with *SpeI*. Phenol extract and ethanol precipitate the DNA. Determine DNA concentration and resuspend in water at 0.3 μg/μl.

Protein Expression

16.20.3

3. Set up *in vitro* transcription in a microcentrifuge tube by mixing the following:

- 5 μ l DNA (1.5 μ g)
- 5 μ l 10 \times SP6 buffer
- 5 μ l 50 mM DTT
- 5 μ l 10 mM m 7G(5')ppp(5')G
- 5 μ l rNTP mix
- 23 μ l H₂O
- 1.5 μ l 40 U/ μ l RNasin
- 0.5 μ l 60 U/ μ l SP6 RNA polymerase.

Because the spermidine in the SP6 buffer may precipitate DNA at 0°C, the reaction should be set up at room temperature. Under the conditions described (1.5 μ g of linear DNA and 30 U of SP6 RNA polymerase per reaction), the transcription mixture is saturated for DNA and should yield ~50 μ g of RNA. The yield can be increased by increasing the amount of SP6 RNA polymerase used.

4. Incubate 60 min in a 37°C water bath. Transfer a 1- μ l aliquot into 10 μ l water and add 3 μ l of 5 \times TD solution. Run sample on a 0.5% agarose gel, using digested λ DNA as a molecular weight marker. Freeze the remainder of the reaction in 10- μ l aliquots at -80°C.

Although the gel is nondenaturing and thus does not reflect the molecular weight of the RNA produced, it is nevertheless useful for checking RNA quality and quantity. The RNA band should be defined (no smearing) and relatively thick in comparison to DNA bands. If desired, RNA samples of known concentration can be run as a rough quantitative comparison.

Transfect BHK-21 cells by electroporation

5. Inoculate BHK-21 cells into 10 ml complete BHK-21 medium in a 75-cm² tissue culture flask and grow to late log phase (this will usually take 1 to 2 days).
6. Aspirate medium and wash cells once with room-temperature PBS.
7. Add 2 ml trypsin/EDTA solution, incubate until cells detach (~1 min), and briefly pipet cell solution back and forth, monitoring under a microscope, to obtain a single-cell suspension. Add 10 ml complete BHK-21 medium to stop trypsinization.
8. Centrifuge cells 5 min at 400 \times g, room temperature, in a tabletop centrifuge and remove supernatant. Resuspend cells in 10 to 20 ml PBS.
9. Centrifuge cells as in the previous step and resuspend in PBS at 10⁷ cells/ml.
10. Thaw an aliquot of the RNA to be transfected (transcription mixture from step 4), place 10 to 15 μ l in a microcentrifuge tube, and add 0.8 ml of cell suspension. Mix thoroughly by pipetting and transfer to a 0.2- or 0.4-cm electroporation cuvette.

Using 4 μ g RNA per 10⁷ cells will give a transfection frequency close to 100%. Thus, using 10 to 15 μ l transcription mixture (~5 to 7 μ g RNA) per 75-cm² flask works well.

11. Pulse twice at room temperature using a voltage of 850 V, a capacitor setting of 25 μ F, and a time constant after the pulse of 0.4.

If a large number of samples are being manipulated and cells start to sediment in the cuvettes before the pulse, cap each cuvette tightly and invert once before shocking.

The Bio-Rad gene pulser uses capacitor discharges to produce pulses, generating an exponential-decay waveform. For this electroporator the pulse-controller should be disconnected when using 0.4-cm cuvettes; in this case the set value of 850 V will represent the actual voltage given to cells in the cuvette (i.e., field strength = 2125 V/cm). When using 0.2-cm cuvettes, the pulse-controller must be connected to prevent

arc. In this case, however, the set *V* value will not represent what is given to the cells, so the actual *V* required to obtain the proper field strength should be determined by measuring the pulse directly in the cuvette (generally ~1700 V). If an electroporator other than the Bio-Rad model is used, settings may need to be modified; consult UNITS 9.3 & 9.9 for recommendations.

12. Dilute transfected cells 20-fold in complete BHK-21 medium, rinsing the cuvette with the medium to collect all cells, and transfer to a 35-mm tissue culture plate. Incubate 7 to 9 hr.

Cells will reattach in ~1 hr and metabolic labeling can be performed as early as 4 hr after transfection. However, for maximum labeling of the protein of interest and minimum labeling of host proteins, incubation for 7 to 9 hr after transfection is recommended.

Analyze heterologous protein by metabolic labeling of cells

13. Aspirate medium and wash cells twice with 3 ml prewarmed PBS. Overlay cells with 2 ml starvation medium and incubate plate 30 to 45 min.
14. Prepare 500 μ l of pulse medium: starvation medium containing 25 to 50 μ Ci [³⁵S]methionine. Aspirate medium from cells, replace with pulse medium, and incubate for the desired pulse time.

Consult UNIT 10.18 for a discussion of how to select appropriate pulse and chase times.

15. Remove pulse medium and wash cells once with 2 ml chase medium. Overlay cells with 2 ml chase medium and incubate for desired chase time.
16. Remove chase medium and wash cells with 3 ml ice-cold PBS.
17. Add 300 μ l NP-40 lysis buffer and incubate 10 min on ice.
18. Resuspend cells and transfer to a microcentrifuge tube. Microcentrifuge 5 min at 6000 rpm at 4°C or room temperature to pellet nuclei. Store supernatant (cytoplasmic proteins) or pellet (nuclear proteins) at -80°C.
19. Assay for protein expression by SDS-PAGE and autoradiography.

If pSFV3-lacZ was used, expression and transfection efficiencies can be checked using the β -galactosidase expression assays described in the first and second support protocols.

EXPRESSION OF PROTEINS FROM RECOMBINANT SFV RNA USING LIPOSOME-MEDIATED TRANSFECTION

ALTERNATE PROTOCOL

If a gene pulser is not available, liposome-mediated transfection can replace electroporation (steps 5 to 12 of the first basic protocol). With this method, the transcription mixture must be purified to remove the NTPs from the reaction mixture, either by gel filtration or by isopropanol precipitation of the RNA with a subsequent ethanol wash.

Additional Materials

- TE buffer, pH 7.5 (APPENDIX 2)
- 3 M sodium acetate, pH 4.8 (APPENDIX 2)
- Opti-MEM transfection medium (GIBCO/BRL)
- Isopropanol, -20°C
- 75% (v/v) ethanol
- Lipofectin (GIBCO/BRL)
- Nu-Clean R50 RNA spin columns (IBI)
- Centrifuge with swinging-bucket rotor

Protein Expression

16.20.5

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly. All incubations are performed in a humidified, 37°C, 5% CO₂ incubator unless otherwise specified.

1. Prepare RNA by in vitro transcription as described in steps 1 to 4 of the preceding basic protocol.

To purify RNA by gel filtration:

- 2a. Warm column to room temperature and invert several times to resuspend gel. Remove top and bottom caps and allow excess buffer to drain out of the column.
- 3a. Position the column on top of a 1.5-ml microcentrifuge tube placed within bucket of a swinging-bucket rotor and prespin 2 min at 1100 × *g*. Discard collection tube and replace with a fresh one.
- 4a. Thaw transcription mixture. If necessary, dilute with TE buffer to a final volume of 50 µl (volumes between 50 and 100 µl can be used). Add sample directly to top of column and spin again as in step 3a. Discard column. Aliquot 20 µl of the purified RNA sample (from collection tube) and freeze at −80°C.

To purify RNA by isopropanol precipitation:

- 2b. Thaw transcription reaction mixture and dilute with water to 100 µl. Add 20 µl of 3 M sodium acetate, pH 4.8.
- 3b. Add 72 µl of −20°C isopropanol, mix, and incubate 10 min at room temperature.
- 4b. Microcentrifuge 15 min at top speed, room temperature. Remove supernatant, rinse with 500 µl of 75% ethanol, respin, remove ethanol, and briefly dry. Resuspend pellet in 50 µl TE buffer, pH 7.5.

Only DNA or RNA >100 bp is precipitated by this method. However, it is important that the precipitation step be performed at room temperature.

5. Grow BHK-21 cells on 35-mm tissue culture plates to ~80% confluency.
6. Remove medium and replace with 2 ml Opti-MEM medium. Incubate 5 to 10 min.
7. While cells are incubating, mix 1 ml Opti-MEM with 9 µg Lipofectin (per plate of cells) and vortex mixture for 10 sec. Add 2.3 µg purified RNA (step 4a or 4b) and vortex again.
8. Remove the Opti-MEM covering the cells and replace with Opti-MEM/Lipofectin/RNA mixture. Incubate 2 hr, tilting the plate every 15 min.

Up to 90% transfection frequencies can be obtained using Lipofectin. However, it is imperative that the transfection mixture always cover the cells as evenly as possible. Frequent tilting of plates is recommended for consistent results.

9. Remove transfection mix and wash cells once with 2 ml complete BHK-21 medium. Add 2 to 3 ml complete BHK-21 medium and continue incubation 7 to 9 hr.
10. Analyze heterologous protein by metabolic labeling of cells as described in steps 13 to 19 of the first basic protocol.

SCREENING FOR GENE EXPRESSION USING β -GALACTOSIDASE

The pSFV3-lacZ vector can be used to check expression and transfection efficiencies. A quick, convenient method to screen cells for lacZ expression is by direct staining with Xgal. Alternatively, an infected cell lysate can be assayed for β -galactosidase activity.

Screening of Cells for β -Galactosidase Activity**Materials**

BHK-21 cells transfected with pSFV-lacZ vector (first basic protocol, step 12, or first alternate protocol, step 9)
Methanol, -20°C
Xgal stain solution
Stereomicroscope

1. Following infection or transfection to permit expression of β -galactosidase, incubate cells 7 hr to overnight.
2. Wash cells twice with PBS. Add 3 ml of -20°C methanol and incubate plate 5 min at -20°C to fix the cells.
3. Wash cells three times with PBS at room temperature and overlay with 1 ml Xgal stain solution. Monitor the ratio of positive (blue) to negative (white) cells using a stereomicroscope.

Staining is usually quite fast (beginning within minutes) and is complete after 2 to 4 hr at 37°C . Alternatively, plates can be left at room temperature overnight.

The ratio of blue to white cells serves as an indication of transfection efficiency.

Screening of Cell Lysates for β -Galactosidase Activity**Additional Materials**

Lysate of BHK-21 cells transfected with pSFV3-lacZ vector (first basic or alternate protocol)
Z buffer with and without 4 mg/ml *o*-nitrophenyl- β -D-galactopyranoside (ONPG)
Purified β -galactosidase
1 M sodium carbonate

1. Place 1 μl cell lysate (~200 to 300 cell equivalents) in a 1.5-ml microcentrifuge tube and add Z buffer to 400 μl . Incubate 5 min.
2. Add 100 μl of 4 mg/ml Z buffer ONPG, mix well by vortexing, and incubate until sample becomes yellow.
3. Stop reaction by adding 500 μl of 1 M sodium carbonate. Mix well. Measure A_{420} .

To permit determination of the actual amount of lacZ protein (β -galactosidase) produced in the cell lysate, a standard curve should be prepared using purified β -galactosidase (a series of concentrations ranging from 0.2 to 50 ng β -galactosidase is usually suitable). These samples will generally need to be incubated ~15 min. The exact quantitation will vary with the preparation, but is usually ~1 U/3 μg protein.

EXPRESSION OF PROTEIN FROM IN VIVO-PACKAGED RECOMBINANT SFV PARTICLES

Recombinant and helper RNAs are cotransfected into BHK cells. As a result of trans complementation, recombinant RNAs are packaged into SFV particles which are released into the growth medium (Fig. 16.20.2). The virus produced is used to infect cells in culture which are then assayed for expression of the cloned sequences.

Materials

- pSFV1, pSFV3, or pSFV3-lacZ vector (GIBCO/BRL; see Fig. 16.20.1)
- pSFV-Helper 2 DNA (GIBCO/BRL; see Fig. 16.20.1)
- BHK-21 cells (ATCC)
- Minimum essential medium (MEM), supplemented
- Phosphate-buffered saline (PBS; Reagents and Solutions)
- α -chymotrypsin solution
- 2 mg/ml aprotinin (Sigma)
- 35-mm tissue culture plate

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly. All incubations are performed in a humidified, 37°C, 5% CO₂ incubator unless otherwise specified.

Figure 16.20.2 Schematic presentation of in vivo packaging of recombinant RNA into SFV particles. Recombinant and helper RNAs are cotransfected into BHK cells, where the recombinant RNA-encoded replicase amplifies both RNA species. The capsid protein (C) packages only recombinant RNA molecules into nucleocapsids, as the helper RNAs lack a packaging signal (Ψ ; this resides in the *nsP1* gene). Assembly and budding of new recombinant SFV virions occurs at the cell surface through an interaction between cytoplasmically preformed nucleocapsids and the viral spike membrane proteins p62 and E1. Stippled boxes in the recombinant RNA represent packaging signals; black boxes represent replication sequences recognized by the SFV replicase; black circles at the 5' ends of the RNAs denote cap structures; and open boxes at the 3' ends of the RNAs denote poly-A stretches.

Package recombinant RNA into pSFV

1. Subclone DNA fragment of interest into pSFV plasmid. Prepare RNA by in vitro transcription from the recombinant pSFV plasmid and the pSFV-Helper 2 plasmid using the procedure described in steps 1 to 4 of the first basic protocol.
2. Mix the two RNAs in a 1:1 molar ratio. Transfect RNA mixture into BHK-21 cells as described in steps 5 to 12 of the first basic protocol or steps 5 to 9 of the alternate protocol. Incubate 24 hr.

In practice, equal amounts (usually 10 μ l each) of the two transcription mixtures or purified RNAs can be used, because the transcription mixture was set up to contain a saturated amount of DNA (and thus promoter copies). Deviations from a 1:1 ratio will lead to lower stock titers.

3. Collect the medium and clarify by centrifuging 15 min at $2000 \times g$ in a tabletop centrifuge at 4°C .
4. Aliquot and freeze 0.5-ml aliquots quickly on dry ice or in liquid nitrogen. Store at -80°C . Titrate one aliquot as described in the third support protocol.

At this stage virus can also be purified and/or concentrated (fourth support protocol).

Infect cells with SFV

5. Grow fresh BHK-21 cells to 80% to 100% confluency on a 35-mm tissue culture plate.
6. Aspirate medium and wash cells thoroughly with PBS.

Activate Helper 2-packaged recombinant virus

7. Add $\frac{1}{20}$ vol α -chymotrypsin solution to virus preparation and incubate 30 min at room temperature.
8. Inactivate α -chymotrypsin by adding 0.5 vol aprotinin.
9. Dilute activated virus preparation as appropriate in supplemented MEM using a multiplicity of infection of five. Transfer solution to ice.

Activation should be done just before infection, as the activated stock cannot be stored frozen or for longer periods of time on ice.

10. Add 500 μ l of the virus solution to the cells and incubate 45 min to 1 hr.
11. Remove virus solution, add 3 ml complete BHK-21 medium (or other suitable medium required for the experiment), and continue incubation as required.
12. Prepare cell lysates and analyze protein expression as described in steps 17 to 19 of the first basic protocol.

DETERMINATION OF RECOMBINANT VIRUS TITER

The recombinant virus can initiate only one round of intracellular replication. Therefore, the titer of the packaged stock cannot be determined by conventional plaque assay, but is done using indirect immunofluorescence. Different dilutions of the virus stock are used to infect cells and heterologous protein expression is detected by specific antibodies.

Materials

Recombinant virus stock (second basic protocol)
PBS-Eisen
Methanol, -20°C
Blocking buffer: 0.5% (w/v) gelatin/0.2% (w/v) BSA in PBS-Eisen

SUPPORT PROTOCOL

Protein Expression

16.20.9

Primary antibody in blocking buffer
Secondary antibody in blocking buffer
Moviol 4-88 solution containing 2.5% DABCO (1,4-diazobicyclo-[2.2.2]-octane)
Glass coverslips
Additional reagents and equipment for immunofluorescent labeling of monolayer cells (UNIT 14.6)

1. Grow BHK-21 cells on glass coverslips to ~70% confluency and count with a hemacytometer to determine number of cells plated.
2. Activate virus stock as in steps 7 to 10 of second basic protocol and prepare a series of dilutions in supplemented MEM. Infect the cells as described in the second basic protocol, steps 5 and 6. Incubate 7 to 15 hr to allow for expression of the protein of interest.

A good initial dilution series is 1:10, 1:100, and 1:1000 (Critical Parameters, UNIT 14.6).

3. Rinse each coverslip twice with PBS-Eisen to cover. Fix cells 5 min in -20°C methanol for 5 min.
4. Remove methanol and wash coverslip three times with PBS.
5. Add blocking buffer and incubate 30 min at room temperature to block nonspecific binding.
6. Replace blocking buffer with primary antibody solution. Incubate 30 min at room temperature.
7. Wash three times with PBS. Repeat step 6 using secondary antibody solution.
8. Wash three times with PBS and once with water. Drain and allow coverslip to air dry.
9. Mount coverslip on glass slide using 10 to 20 μl Moviol 4-88 solution containing 2.5% DABCO. Carry out immunofluorescent staining, count cells, and calculate the percentage of cells expressing the protein of interest.

For example, if 10^6 cells were plated, and 1% are observed expressing protein, then the viral titer is 10^4 per coverslip. This value should then be multiplied by the dilution factor to obtain the true titer.

DABCO reduces the fading of FITC.

SUPPORT PROTOCOL

PURIFICATION OF SFV PARTICLES

To concentrate or purify the recombinant virus from the medium, the particles are sedimented by ultracentrifugation onto a sucrose cushion.

Additional Materials

Transfected BHK-21 cells (first basic protocol, step 12)
20% (w/v) and 55% (w/v) sucrose in TNE buffer
TNE buffer
Beckman SW-40 or SW-41 centrifuge tubes and rotor, or equivalent

1. Centrifuge medium from transfected BHK-21 cells 15 min at $2000 \times g$ in a tabletop centrifuge at 4°C to separate growth medium from remaining cells and cell debris.
2. Set up a step gradient consisting of 1 ml of 55% sucrose and 3 ml of 20% sucrose in an SW-40 or SW-41 ultracentrifuge tube. Layer cleared medium on top of gradient (9 ml for a SW-40 tube or 8 ml for a SW-41 tube). Centrifuge 90 min at 30,000 rpm

(~160,000 × g) in a Beckman SW-40 or SW-41 rotor to sediment the virus onto the 55% cushion (see also *UNIT 5.3*).

3. Aspirate top fraction containing medium and remove (from above) 0.8 ml of the 55% sucrose from the bottom of the tube. Collect the virus band from the bottom of the tube in a total volume of 1 ml. Divide band into 50- to 100- μ l aliquots, diluting 1:2 or more with TNE buffer if desired. Quickly freeze on dry ice or in liquid nitrogen and store at -80°C .

Aliquoting is recommended because repeated freezing and thawing can markedly reduce the infectivity of the virus preparation.

REAGENTS AND SOLUTIONS

α -chymotrypsin solution

Prepare in PBS (see recipe):

10 mM MgCl_2

20 mM CaCl_2

10 mg/ml α -chymotrypsin

Store several months at -20°C

Chase medium

MEM (GIBCO/BRL)

2 mM glutamine

20 mM HEPES

150 $\mu\text{g/ml}$ methionine

Store ≤ 1 month at 4°C

Complete BHK-21 medium

G-MEM (GIBCO/BRL)

5% (v/v) fetal calf serum

10% (w/v) tryptose phosphate

20 mM HEPES

2 mM glutamine

0.1 U/ml penicillin (optional)

0.1 $\mu\text{g/ml}$ streptomycin (optional)

Store ≤ 1 month at 4°C

Minimum essential medium (MEM), supplemented

Prepare MEM (GIBCO/BRL) containing 0.2% (w/v) BSA, 2 mM glutamine, and 20 mM HEPES. Store ≤ 1 month at 4°C .

NP-40 lysis buffer

1% (v/v) Nonidet P-40 (NP-40; from 10% stock)

50 mM Tris-Cl, pH 7.6

150 mM NaCl

2 mM EDTA

Store several months at 4°C

PBS-Eisen

0.257 g NaH₂PO₄·H₂O
2.250 g Na₂HPO₄·2H₂O
8.767 g NaCl
H₂O to 1000 ml
Store indefinitely at 4°C

Phosphate-buffered saline (PBS)

2.68 mM KCl
1.47 mM KH₂PO₄
136.8 mM NaCl
8.0 mM Na₂HPO₄·7H₂O
Adjust pH to 7.0 to 7.2 with HCl
Autoclave 30 min
Store indefinitely at 4°C

PBS is also available commercially (GIBCO/BRL) and other formulations exist (e.g., see APPENDIX 2); however, not all can be successfully used for these protocols. PBS for these applications must be without MgCl₂ or CaCl₂.

rNTP mix

10 mM ATP
10 mM CTP
10 mM UTP
5 mM GTP
Aliquot and store indefinitely at -20°C

SP6 RNA polymerase buffer, 10×

400 mM HEPES·KOH, pH 7.4
60 mM magnesium acetate
20 mM spermidine·HCl
Store indefinitely at -20°C

Starvation medium

Methionine-free MEM (GIBCO/BRL)
2 mM glutamine
20 mM HEPES
Store ≤1 month at 4°C

TD solution, 5×

20% (w/v) Ficoll 400
25 mM EDTA, pH 8.0
0.05% (w/v) bromphenol blue
0.03% (w/v) xylene cyanol
Store several months at 4°C

TNE buffer

50 mM Tris·Cl, pH 7.4
100 mM NaCl
0.5 mM EDTA
Store indefinitely at room temperature

Xgal stain solution

Prepare in PBS:

5 mM $K_4Fe(CN)_6 \cdot 3H_2O$ (potassium ferrocyanide)

5 mM $K_3Fe(CN)_6$ (potassium ferricyanide)

2 mM $MgCl_2$

Store several months at 4°C

Just before use, add Xgal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside; dimethylformamide stock) to 1 mg/ml.

CAUTION: Avoid coming into contact with or inhaling cyanide and discard waste using appropriate precautions.

This recipe is based on Sanes et al. (1986); see also UNIT 9.11 for further discussion.

Z buffer

60 mM Na_2HPO_4

40 mM NaH_2PO_4

10 mM KCl

1 mM $MgSO_4$

40 mM 2-mercaptoethanol (2-ME)

Store \leq 1 month at 4°C

COMMENTARY

Background Information

Alphavirus replication. Alphaviruses such as Semliki Forest virus (SFV) are small-enveloped viruses with single-stranded RNA genomes of positive polarity that replicate in virtually all animal cells. Upon infection, the 5' end of the viral genome is used for translation of four nonstructural proteins (*nsP1-4*). These are responsible for the production of genome-length negative strands, which are subsequently used for production of new positive-strand genomes as well as a smaller subgenome species. The latter corresponds to the last one-third of the viral genome and is used as the mRNA for virus structural proteins—i.e., the capsid protein, C, and the two membrane proteins, p62 and E1 (Schlesinger and Schlesinger, 1990). The C protein complexes with new viral genomes to form cytoplasmic nucleocapsid structures, while the two membrane proteins are translocated into the endoplasmic reticulum to form heterodimers; these heterodimers are routed to the cell surface, where virus budding occurs. The membrane-protein spikes mediate virus binding and uptake into new host cells by receptor-mediated endocytosis. Inside the endosomes, the acidic milieu induces structural changes in the spike protein, thereby inducing fusion of the viral and endosomal membranes. This results in release of the nucleocapsid with the viral genome into the cell cytoplasm (Bron et al., 1992; Garoff et al., 1990; Liljeström and Garoff, 1991a; Lobigs and Garoff, 1990; Lo-

bigs et al., 1990a, b; Salminen et al., 1992; Suomalainen et al., 1992; Wahlberg and Garoff, 1992; Wahlberg et al., 1989, 1992).

Alphaviruses as expression vectors. Several different alphavirus genomes have recently been cloned as cDNAs and used to produce infectious RNA by in vitro transcription (Davis et al., 1989; Kuhn et al., 1991; Liljeström et al., 1991; Rice et al., 1987). The SFV and Sindbis cDNAs have been further developed into general expression systems for insertion of foreign DNA in place of the viral structural genes (Bredenbeek and Rice, 1992; Liljeström, 1993; Liljeström and Garoff, 1991b; Rice, 1992; Xiong et al., 1989). The basic difference between the two systems is the type of helper used. The Sindbis system uses a helper vector containing the sequence of a Sindbis DI (defective interfering) particle, and therefore contains an RNA packaging signal. When cotransfected with Sindbis recombinant RNA into host cells, the DI-helper RNA provides structural proteins for packaging of both the recombinant genome and the DI genome into virus particles. A mixed DI/recombinant virus stock is obtained after amplification through several passages. In contrast, the SFV system uses a helper construct which, although coding for the structural proteins, cannot itself be packaged due to the lack of a proper RNA packaging signal. Its use together with SFV recombinant RNA results in production of a virus stock that contains only recombinant virus genomes; therefore,

vector structural proteins are not produced when cells are infected by these particles. High-efficiency transfection conditions such as electroporation permit the generation of a high-titer recombinant SFV stock.

Advantages of the SFV expression system.

In comparison to those of other expression systems, the SFV replication cycle exhibits many features that are advantageous for the practical performance of the expression system. (1) Extremely high levels of production can be obtained because the heterologous gene is expressed using the viral RNA replication and translation signals. (2) Recombinant RNA molecules are expressed in the host cell cytoplasm. The virus *nsp* region encodes the machinery required for RNA replication as well as capping of the 5' ends, thereby circumventing many problems that may occur in nuclear gene expression (such as limitation of transcription factors and problems with RNA splicing or RNA transport). (3) The system is very fast and easy to use, employing standard plasmid subcloning techniques. A high-titer recombinant virus stock can be produced by a single passage in electroporated cells, without need for tedious amplification or selection procedures. (4) The recombinant virus stock does not include any helper virus, and thus there is no interference of coexpressed virus structural proteins with the heterologous gene product when the stock is used in expression studies. (5) SFV has a very wide natural host range. Consequently, virus particles produced by the SFV expression system are capable of delivering a heterologous gene into probably any higher eukaryotic tissue culture cell type used today. (6) Cell morphology is preserved. Although use of the SFV expression system eventually leads to cell death, there is a variable but considerable time lag before morphological changes begin to occur (10 to 20 hr depending on the host cell line). In particular, this expression system can be used in epithelial cell cultures (MDCK) and primary neuronal cells (rat ganglion cells) within these incubation time spans without loss of differentiated morphological features.

Critical Parameters

Transfection efficiency. The success of the SFV expression system is highly dependent on the RNA transfection efficiency. Practically all BHK cells can be transfected using the conditions described in the electroporation protocol. Similar results can probably be obtained in other cell types if transfection efficiency is optimized as function of voltage, capacitance,

time constant of electrical pulse, and number of pulses (see *UNITS 9.3 & 9.9*). Under optimal conditions, transfection with Lipofectin also gives good results. Although Lipofectin can be used with a wide variety of cells, the exact optimal conditions may vary slightly. Parameters to consider are final amounts of lipid and RNA, lipid:RNA ratio, and time of lipid-RNA administration (see *UNITS 9.4 & 9.9*, detailing liposome-mediated transfection with DNA, for further discussion of Lipofectin). For in vitro expression of the recombinant protein, an important consideration is the quality of the RNA preparation (see *Critical Parameters in UNIT 10.17*).

Virus particle formation. Another factor of importance is the ability of a given cell type to support virus particle formation. This can be checked using wild-type SFV. Recombinant virus stock should be aliquoted and stored at -80°C after quick freezing in dry ice or liquid nitrogen. Original culture supernatant or step gradient-purified virus can be stored in this fashion. Repeated freezing and thawing should be avoided, as it reduces virus infectivity; pelleting of the virus is not recommended, as it also may lead to considerable (10- to 100-fold) reduction in infectivity.

Safety considerations. When using the original pSFV-Helper 1 and recombinant RNA for virus stock preparation, recombination (strand-switching by the replicase) of the RNA species may occur (Geigenmüller-Gnirke et al., 1991; Weiss and Schlesinger, 1991). It is estimated that the frequency of recombinant particles found in one packaging mixture is $\sim 10^{-6}$ (i.e., $\leq 10^3$ spreading competent SFV particles). Although this would be of little importance for the outcome of an expression experiment involving, for instance, 10^6 cells infected with 5 infectious units (IU) per cell, the existence of such particles constitutes a potential biosafety risk. Therefore, a new vector, pSFV-Helper 2, was designed for use in producing conditionally infectious particles (Berglund et al., 1993). These particles must be activated by chymotrypsin treatment to become infectious. Due to the design of the new Helper system, no replication-proficient virus has been found. The new Helper has been approved by the NIH Recombinant DNA Advisory Committee for use at Biosafety Level-2 (BL-2).

Anticipated Results

In general, 10^7 BHK cells should yield $\sim 10^9$ to 10^{10} infectious recombinant particles when

cotransfected with recombinant and pSFV-Helper 2 RNA and incubated for 24 hr. In cells transfected with ~5 IU/cell, after ~4 hr of incubation the majority of newly synthesized polypeptide chains should represent heterologous protein products, meaning that the labeled heterologous protein should be seen as the major band on SDS gel analysis and autoradiography. After 20 to 25 hr of incubation the heterologous protein product should be the predominant protein in the cell, and Coomassie brilliant blue staining of the SDS gel should reveal the heterologous protein as a major band.

Time Considerations

Recombinant RNA can be used directly for phenotype analysis in cells after transfection. In this case phenotype analysis can be done after only a 4-hr incubation. Stock virus preparation requires 24-hr incubation of cotransfected cells. The supernatant can then be used directly for infection-mediated gene transduction into new hosts.

Overview of the HIV-1 Lentiviral Vector System

Replication-defective oncoretroviral vectors have been the most widely used vehicles for gene-transfer studies because of their capacity to efficiently introduce and stably express transgenes in mammalian cells (Hawley, 1996, 2001; *UNITS 9.9-9.14*). A limitation of oncoretroviral vectors, however, is that cell division is required for proviral integration into the host genome (Miller et al., 1990). By comparison, lentiviruses such as human immunodeficiency virus type 1 (HIV-1) have evolved a nuclear-import machinery that allows them to infect nondividing as well as dividing cells (Lewis et al., 1992; Lewis and Emerman, 1994). This unique property has led to the development of lentiviral vectors for gene delivery to a variety of nondividing or slowly dividing cells including neurons and glial cells of the central nervous system, cells of differentiated epithelial tissues, hepatocytes, muscle cells, retinal cells, and hematopoietic stem cells.

Since HIV-1 is a known human pathogen, the development of HIV-1-based lentiviral vectors has been especially challenging. Before they could be considered safe for general (BSL-2) laboratory use, lentiviral vector systems required numerous modifications to preclude the generation of wild-type or replication-competent retroviruses (RCR). The complex genome of HIV-1 was fully characterized to determine the minimal amount of viral sequences that could constitute a functional transfer vector. Production of replication-defective vectors is accomplished by providing only essential virion structural and enzymatic proteins *in trans*. The latest versions of HIV-1-based lentiviral vectors carry as little as 10% of the viral genomic RNA.

Lentiviral vectors based on HIV-2 (Poeschela et al., 1998), simian immunodeficiency virus (Kim et al., 2001), equine infectious anemia virus (Mitrophanous et al., 1999), feline immunodeficiency virus (Curran et al., 2000), and visna virus (Berkowitz et al., 2001) have also been developed. However, since HIV-1-based lentiviral vectors are the most advanced, they are the primary focus of this chapter. This unit is intended to provide an overview of HIV-1 molecular biology and an introduction to successive generations of HIV-1-based lentiviral vectors. In *UNIT 16.22*, detailed protocols outlining the methodology and techniques in-

involved in the construction and application of HIV-1-based lentiviral vector systems are presented. That unit also describes procedures that can be used to concentrate and purify high-titer recombinant lentiviral vector preparations, as well as protocols for transduction of adherent and suspension cells.

MOLECULAR BIOLOGY OF HIV-1

Like other members of the *Retroviridae* family of viruses, HIV-1 reverse transcribes its RNA genome into a double-stranded DNA form, hence the prefix “retro.” HIV-1 belongs to the subfamily *Lentivirinae*, which comprises primate and nonprimate retroviruses that cause slow, progressive diseases affecting the immune system. In humans, HIV-1 infection ultimately leads to the development of acquired immunodeficiency syndrome (AIDS). The molecular biology of HIV-1 has been reviewed extensively elsewhere (Frankel and Young, 1998). The salient features of the structure and life cycle of HIV-1 relevant to lentiviral vector-mediated gene transfer are summarized below.

HIV-1 Genes

The HIV-1 genome (Fig. 16.21.1) is an ~9.3-kb RNA that encodes nine open reading frames (ORFs). Three of these ORFs, *gag*, *pol*, and *env*, which are common to all retroviruses, specify the Gag, Pol, and Env polyproteins, respectively (Table 16.21.1). These polyproteins are subsequently cleaved into the following protein subunits: Gag is cleaved to form the structural proteins matrix (MA), capsid (CA), nucleocapsid (NC), P6, P2, and P1; Pol is cleaved into the replication enzymes protease (PR), reverse transcriptase (RT), and integrase (IN); and Env (or gp160) is cleaved to form the transmembrane (TM or gp41) and surface (SU or gp120) glycoproteins required for viral binding and entry into the cells. Of the remaining six genes, *tat* and *rev* code for the regulatory proteins transactivator of transcription (Tat) and regulator of expression of virion proteins (Rev). The other four genes *vif*, *vpr*, *vpu*, and *nef*, which are referred to as accessory genes since they are not essential for viral replication, encode the virion infectivity factor (Vif), the viral protein R (Vpr), the viral protein U (Vpu), and the negative factor (Nef), respectively. The accessory genes are also called the virulence factors,

Table 16.21.1 HIV-1 Genes, Gene Products, and Their Function

Gene	Size of mRNA	Encoded protein(s)	Function
Regulatory genes			
<i>tat</i>	1.7-2 kb	Tat (16 kDa)	<i>Trans</i> -activation of gene expression
<i>rev</i>	1.7-2 kb	Rev (19 kDa)	Nuclear export of late mRNAs; promotion of polysomal binding to RRE-containing RNAs
Accessory genes			
<i>vif</i>	5 kb	Vif (23 kDa)	Enhancement of virus transmission
<i>vpr</i>	4.5 kb	Vpr (10-15 kDa)	Nuclear transport of proviral DNA, induction of G ₂ arrest in dividing cells
<i>vpu</i>	4 kb	Vpu (15-20 kDa)	CD4 degradation; virus maturation and release
<i>nef</i>	1.7-2 kb	Nef (25-27 kDa)	CD4 and MHC-I down-regulation; enhancement of virus replication
Structural genes			
<i>gag</i>	9.3 kb	Pr55 ^{gag} : MA (p17), CA (p24), NC (p9), p6	Formation of viral particles, packaging of viral genomic RNA
<i>pol</i>	9.3 kb	Pr160 ^{gag-pol} : PR (p10), RT (p61/p52), IN (p31)	Reverse transcription, integration, and virion maturation
<i>env</i>	4 kb	gp160:SU (gp120), TM (gp41)	Binding and entry into the host cell

as they are associated with HIV-1 virulence and pathogenesis in vivo (Cullen, 1991).

HIV-1 Virion

The HIV-1 virion (Fig. 16.21.1B) has a diameter of ~110 nm and consists of a nucleocapsid core surrounded by a lipid membrane (Aloia et al., 1988). Inserted into the lipid membrane are the viral SU and TM glycoproteins which are noncovalently linked (Willey et al., 1988). Proteins within the inner shell of a mature virion are the cleavage products of the Gag (Pr55^{gag}) and Gag-Pol (Pr160^{gag-pol}) precursors (Mervis et al., 1988). The condensed inner core is formed by the capsid protein (CA), p24. In the space between the inner core and the lipid membrane is the N-terminal myristylated matrix protein (MA), p17, which remains associated with the lipid membrane. The virion core contains two copies of the single-stranded genomic RNA to which the NC protein is bound. Also packaged into the virions are host tRNA₃^{Lys}, RT, PR, IN, Vif (Liu et al., 1995), and Vpr (Cohen et al., 1990).

HIV-1 Life Cycle

A schematic representation of the HIV-1 life cycle is shown in Figure 16.21.2. The HIV-1 replication cycle can be divided into the following steps: (i) virus entry; (ii) reverse transcription; (iii) nuclear localization and integration; (iv) viral RNA transcription; (v) RNA processing and viral protein synthesis; and (vi) viral particle assembly, release and maturation.

Virus entry

HIV-1 infection is initiated by the binding of gp120 to the CD4 receptor which is found on the surface of T helper lymphocytes, macrophages, and glial cells (Dalglish et al., 1984; Maddon et al., 1986). Binding of gp120 to the CD4 receptor induces conformational changes that expose the N-terminal hydrophobic domain of gp41. This hydrophobic domain is then inserted into the cell membrane, initiating fusion in a pH-independent manner (Stein et al., 1987). Fusion of gp41 with the cell membrane has been shown to utilize a cellular coreceptor. The chemokine receptors CCR-5 (Alkhatib et al., 1996; Choe et al., 1996) and CXCR-4 (Feng et al., 1996) are the major coreceptors required for entry of macrophage-tropic and T cell-tropic strains of HIV-1, respectively.

Reverse transcription

Following entry, the outer lipid membrane of the virion is removed and its core is delivered into the cytoplasm. Within the core, genomic RNA is reverse transcribed by RT into double-stranded DNA using tRNA₃^{Lys} as a primer (Goff, 1990; Das et al., 1994). The tRNA₃^{Lys} primer allows first strand DNA synthesis by binding to the PBS (primer binding site) located near the 5' end of the HIV-1 genomic RNA. As the minus-strand DNA synthesis proceeds to the 5' end, RNase H degrades the template from the RNA/DNA hybrid allowing the minus-strand to undergo an intermolecular strand switch ("jump") to complementary sequences

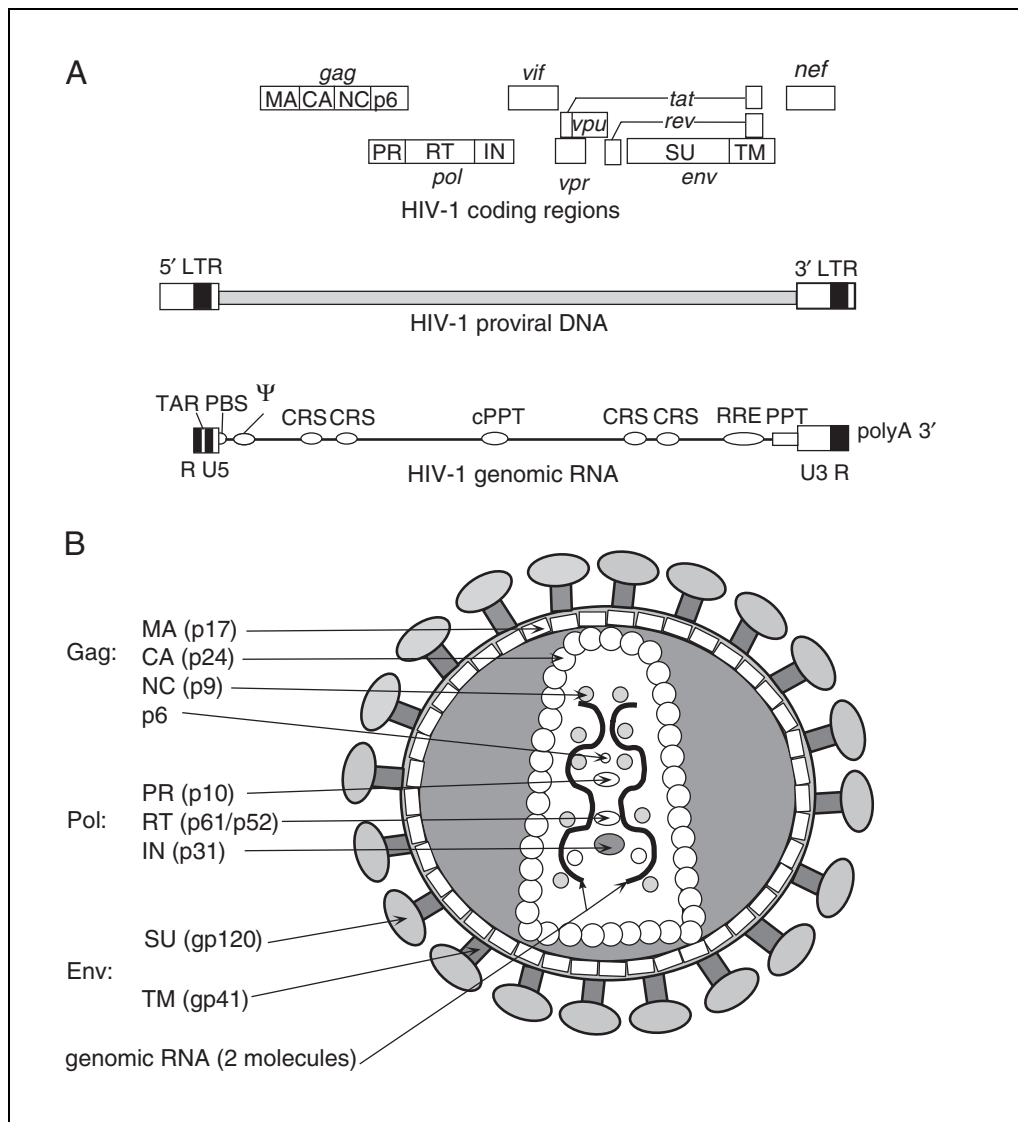

Figure 16.21.1 (A) Structural features of HIV-1 proviral DNA and genomic RNA. The proviral DNA is flanked by LTRs which control the expression of the viral genes. The relative positions of genes that encode the structural and enzymatic proteins (Gag, Pol and Env), the regulatory proteins (Tat and Rev), and the accessory proteins (Vif, Vpu, Vpr and Nef) are indicated. The various *cis*-acting responsive sequences (CRS) within the *gag*, *pol*, and *env* coding regions that negatively regulate HIV-1 gene expression are shown on the HIV-1 genomic RNA. (B) Schematic diagram of the HIV-1 virion. The mature virion contains an inner core surrounded by a host-cell derived lipid membrane. Inserted within the lipid membrane are the viral Env glycoproteins. The condensed inner core is made of the capsid protein. The space between the inner core and the lipid membrane contains the MA protein, which remains attached to the lipid membrane. The inner core encompasses two copies of the genomic RNA which are bound by NC proteins. Also packaged within the viral particles are the RT, PR, IN, Vif and Vpr proteins, as well as the primer tRNA₃^{Lys}, which is of the host origin.

at the 3' end of viral RNA (Panganiban and Fiore, 1988). RNase H activity also generates short template fragments at the 3' polypurine tract (PPT) located upstream of the unique 3' (U3) sequence and an internal PPT located at the 3' end of the *pol* gene (central PPT or cPPT) which serve as primers for plus-strand DNA synthesis (Charneau et al., 1992). A second jump (intramolecular) between the PBS se-

quences allows RT to extend to the ends of the templates, leading to complete synthesis of double-stranded HIV-1 DNA containing flanking long terminal repeats (LTRs).

Nuclear localization and integration

The newly synthesized linear double-stranded DNA is then translocated to the nucleus in the absence of mitosis while still part

Figure 16.21.2 Schematic diagram of the HIV-1 life cycle. Following entry into the cell, HIV-1 genomic RNA is reverse transcribed; the DNA intermediate, as part of a nucleoprotein complex, is then transported to the nucleus where it is inserted into the cellular genome. The full-length 9.3-kb viral RNA is differentially spliced to give rise to various HIV-1 mRNAs. Virus assembly takes place at the plasma membrane, where two copies of HIV-1 genomic RNA are incorporated into the budding viral particles. The steps indicated by numbers 1 to 6 are described in the text.

of the nucleoprotein complex, which contains the viral proteins Vpr, RT, MA and IN (Farnet and Haseltine, 1991; Bukrinsky et al., 1993). Nuclear translocation is mediated via interaction with the cellular nuclear import pathway (Trono, 1995). Interaction involves Vpr, MA and IN, all of which contain nuclear localization signals (Heinzinger et al., 1994). As described below, studies of lentiviral vectors identified a “central DNA flap” formed during reverse transcription as a result of the cPPT that facilitates nuclear translocation of the HIV-1 preintegration complex in both dividing and nondividing cells (Follenzi et al., 2000; Zenou et al., 2000).

Within the nucleus, the linear double-stranded DNA is integrated into the host chromosome by the action of viral IN to form the provirus. IN recognizes short inverted termini at the ends of the viral DNA and cleaves a dinucleotide from each 3' end (LaFemina et al., 1991). The chromosomal DNA is also cleaved by IN, which subsequently ligates the 5' ends of chromosomal DNA to the 3' ends of the

resulting proviral structure (Bushman and Craigie, 1991).

Transcription

Two identical direct 634-base pair (bp) repeats—the LTR sequences—flank the provirus at either end. The LTRs contain the enhancer and promoter elements for transcription of viral genes. Each LTR consists of the U3 region, the R (repeat) region and the unique 5' (U5) region. The U3 region contains binding sites for several cellular transcription factors including SP-1 and NF- κ B (Cullen, 1991). The R region of the LTR contains the 5' untranslated leader sequence, which provides the binding site for a number of factors involved in transcription. In particular, the 5' untranslated leader sequence contains the *trans*-activation response (TAR) element, which is a 59-nt-long region forming a stem-loop structure at the 5' noncoding region of all HIV-1 RNAs (Selby et al., 1989). Transcription of the HIV-1 provirus initiates at the 5' end of the R region within the 5' LTR (Cullen, 1991), with the site of polyadenylation deline-

ating the 3' end of the R region within the 3' LTR (Valsamakis et al., 1991).

High-level transcription from the HIV-1 provirus requires the viral Tat protein (Feng and Holland, 1988). Activation of HIV-1 transcription by Tat relies on the TAR RNA element. In the absence of Tat, early transcriptional events generate mostly short transcripts. Interaction of Tat with TAR enhances formation of RNA polymerase II complexes. As the Tat protein accumulates, the efficiency of transcriptional elongation is enhanced as it suppresses random terminations and increases the processivity of RNA polymerase II (Keen et al., 1996). In addition to enhancing the transcription of viral RNAs, Tat is also known to block the expression of major histocompatibility complex (MHC) class II genes in HIV-1-infected cells (Kanazawa et al., 2000).

RNA processing and viral protein synthesis

Newly transcribed HIV-1 viral RNA is doubly spliced by the cellular splicing machinery, producing 1.7- to 2.0-kb mRNAs which code for the Tat, Rev, and Nef proteins. The Rev protein regulates transport of HIV-1 transcripts from the nucleus to the cytoplasm by binding to the Rev response element (RRE) located in the *env* coding region (Daly et al., 1989). By binding to RRE, Rev allows the RRE-containing viral RNAs to access a pre-existing cellular-export pathway. The nuclear-export signal of the Rev protein (Fischer et al., 1995; Wen et al., 1995) recognizes and binds to the nuclear-export factor exportin 1 (Ullman et al., 1997). As Rev accumulates in the nucleus, viral RNA transport from the nucleus to the cytoplasm is enhanced. This in turn increases the probability that the viral RNA will escape the splicing machinery, resulting in nuclear export of 4- to 5-kb singly spliced and 9.3-kb unspliced viral RNAs.

The Nef protein is encoded by an open reading frame that overlaps the 3' LTR. Nef is a myristylated plasma membrane-associated protein that is expressed early during virus infection from several multiply spliced mRNAs (Robert-Guroff et al., 1990). Nef reduces the cell surface levels of CD4 (Aiken et al., 1994). This may permit increased incorporation of Env into virions, enhancing viral replication and pathogenesis (Aiken and Trono, 1995). Nef has also been shown to down-regulate cell surface expression of MHC class I molecules (Swann et al., 2001).

Once in the cytoplasm, the singly spliced viral mRNAs are translated to produce the Vif, Vpr, Vpu and Env proteins (Malim et al., 1989). The Vif protein is localized at the inner face of the cytoplasmic membrane of infected cells (Goncalves et al., 1994). It is also incorporated within viral particles in association with the nucleoprotein complex (Liu et al., 1995; Khan et al., 2001). Vif plays a critical role in the production of infectious virions by affecting viral particle assembly or maturation (Gabuzda et al., 1992; Kishi et al., 1992).

Both Vpu and Env proteins are expressed from a singly spliced bicistronic mRNA due to leaky ribosome scanning at the upstream Vpu initiation codon (Schwartz et al., 1992). The viral Env protein is translated as a gp160 precursor polyprotein. Gp160 is directed to the endoplasmic reticulum by its hydrophobic N-terminal signal peptide where it is extensively glycosylated (Robey et al., 1985). Subsequently, gp160 is cleaved within the endoplasmic reticulum–Golgi apparatus by cellular proteases (Stein and Engleman, 1990) into the SU (gp120) and TM (gp41) subunits (Freed et al., 1989), which are then inserted within the plasma membrane. Vpu is a hydrophobic membrane-associated protein, which mediates degradation of CD4 complexes in infected cells (Chen et al., 1996), crucial for maturation and release of fully infectious viral particles (Klimkait et al., 1990).

The unspliced HIV-1 viral RNA is translated into the Pr55^{gag} and Pr160^{gag-pol} polyprotein precursors. The *gag* and *pol* ORFs overlap by 241 nucleotides, with the *pol* ORF in the –1 translational reading frame with respect to the *gag* ORF. The translation of the *pol* ORF thus occurs as a consequence of ribosomal frameshifting, resulting in the synthesis of a Gag-Pol fusion protein, Pr160^{gag-pol} (Jacks et al., 1988). The N-termini of both Pr55^{gag} and Pr160^{gag-pol} polyprotein precursors are myristylated, which mediates their transport to the cellular membrane where they are packaged into the viral particles (Bryant and Ratner, 1990). Within the viral particles, the viral PR cleaves Pr55^{gag} to generate the mature virion structural proteins, MA, CA, and p15 (Peng et al., 1989). Subsequently, p15 is cleaved to produce the NC (p9) and p6 proteins (Sheng and Erickson-Viitanen, 1994). The Pr160^{gag-pol} polyprotein is also cleaved within the mature viral particles to produce PR, RT, and IN by the viral PR, which is itself derived from the Pr160^{gag-pol} precursor (Debouck, 1991).

Viral particle assembly, release, and maturation

HIV-1 virus assembly initiates with interactions between the Pr55^{gag} and Pr160^{gag-pol} polyproteins, producing an immature virion core. In addition to serving as mRNA for Pr55^{gag} and Pr160^{gag-pol} synthesis, the unspliced 9.3-kb RNA also serves as HIV-1 genomic RNA. For efficient incorporation of HIV-1 genomic RNA into viral particles, a ψ packaging signal located within the 5' untranslated region and the *gag* ORF plus a 1.1-kb RNA sequence within the *env* ORF are required (Lever et al., 1989). Dimerization of HIV-1 genomic RNAs is mediated by the annealing of palindromic sequences within the dimer linkage structure located at the 5' end of the RNA (Skripkin et al., 1994). Packaging of two copies of HIV-1 genomic RNA into viral particles then ensues, a process that involves an interaction between the NC domains of the Pr55^{gag} and Pr160^{gag-pol} protein precursors and stem-loop structures within the ψ packaging signal (Clever et al., 1995; Rice et al., 1995). The RT and NC domains of the Pr160^{gag-pol} polyprotein facilitate the incorporation of the cellular tRNA₃^{Lys} primer into the virions (Mak et al., 1994). PR is activated during the final stages of budding within the newly released immature particles, leading to proteolytic processing of the Pr55^{gag} and Pr160^{gag-pol} polyproteins (Peng et al., 1989) and viral particle maturation.

REPLICATION-DEFECTIVE HIV-1-BASED VECTORS

As with oncoretroviral vectors, generation of replication-defective lentiviral vectors requires segregation of *cis*-acting sequences necessary for the transfer of a functional viral genome to target cells and those sequences encoding essential viral structural and enzymatic proteins onto separate plasmids. The transfer vector consists of *cis*-acting sequences—the LTRs, the PBS, the packaging signal, the PPTs and the RRE—linked to a transgene of interest in the context of a transcriptional unit. Following cotransfection of the transfer vector together with packaging and envelope expression plasmids lacking most if not all of the *cis*-acting sequences into an appropriate “recipient” cell, viral proteins provided in *trans* assemble into virions encapsidating the replication-defective transfer vector RNA.

First-Generation HIV-1 Vector Systems

Although earlier HIV-1-derived vector configurations have been reported in the literature

(Page et al., 1990; Landau et al., 1991; Poznan-sky et al., 1991), only the more recent safety-modified versions of HIV-1 vector systems will be described here. An example of a “first generation” HIV-1 vector system comprising three expression plasmids—a transfer vector, a packaging construct, and an envelope gene—is depicted in Figure 16.21.3A (Naldini et al., 1996a). The transfer vector contains intact HIV-1 LTRs and the *cis*-acting sequences described above—including 350-bp of *gag* encompassing the ψ packaging signal and *env* sequences encompassing the RRE—with the exception of the cPPT. The transgene is expressed from an internal human cytomegalovirus (CMV) immediate early region enhancer-promoter. The packaging plasmid encodes all of the HIV-1 proteins except Vpu and Env. It consists of the HIV-1 genome with the following modifications: the 5' LTR was replaced with the CMV promoter to drive expression of the viral proteins required in *trans*; the ψ packaging signal, the *env* gene, and the ORF encoding the Vpu protein were deleted; and the 3' LTR was replaced at the end of the *nef* ORF with a polyadenylation [poly(A)] site from the insulin gene. In the envelope-encoding plasmid, the G glycoprotein gene of vesicular stomatitis virus (VSV-G) is transcribed from the CMV promoter. Transient cotransfection of human embryonic kidney 293T cells (DuBridge et al., 1987) with the three-plasmid combination generates replication-defective VSV-G-pseudotyped vector particles with titers on the order of 10⁵ transducing units (TU)/ml. The lentiviral particles efficiently transduced nondividing cells including human HeLa cells growth-arrested at G₁-S or G₂ phases of the cell cycle, 4-day contact-inhibited rat 208F fibroblasts, and terminally differentiated adult rat neurons.

Second-Generation HIV-1 Vector Systems

It was shown subsequently that none of the four HIV-1 accessory genes *vif*, *vpr*, *vpu*, or *nef* were required for HIV-1 replication in immortalized cell lines (Miller and Sarver, 1997) or for efficient generation of VSV-G-pseudotyped vector particles (Zufferey et al., 1997). This led to the development of a “second generation” of HIV-1 vector systems (Fig. 16.21.3B), which utilized a multiply attenuated packaging construct containing only the HIV-1 *gag*, *pol*, *rev*, and *tat* genes. Although elimination of all four accessory genes had no effect on the titers of VSV-G-pseudotyped vector particles produced in 293T cells, macrophage transduction effi-

Figure 16.21.3 Schematic representation of various HIV-1 vector systems. **(A)** A first-generation HIV-1 vector system expressing all of the HIV-1 proteins except Vpu and Env. The vector particles are pseudotyped with the VSV-G envelope glycoprotein expressed from a separate plasmid. **(B)** A second-generation HIV-1 vector system having all of the accessory genes removed. **(C)** A third-generation Tat-independent HIV-1 vector system. The SIN transfer vector illustrated contains the cPPT for efficient nuclear import and utilizes an internal MSCV LTR promoter (MU3) and the WPRE (W) for high-level transgene expression. The two packaging constructs encode only the HIV-1 Gag, Pol and Rev proteins.

iciencies were reduced by ~50%, which was apparently due to the lack of the Vpr protein (Zufferey et al., 1997). Efficient transduction of resting hepatocytes, skin fibroblasts, and lymphocytes has also been reported to require HIV-1 accessory proteins (Kafri et al., 1997; Gasmi et al., 1999; Chinnasamy et al., 2000), suggesting that some of these accessory proteins might be necessary for efficient gene transfer of certain cell types.

Third-Generation HIV-1 Vector Systems

The main concern regarding the use of any HIV-1 vector is the potential for generation of replication-competent retroviruses (RCRs). Numerous additional modifications have therefore been made to ensure the biosafety of current “third” generation HIV-1-based delivery systems (Dull et al., 1998; Kim et al., 1998; Miyoshi et al., 1998; Zufferey et al., 1998; also see Fig. 16.21.3C). Since the U3 region of the 3′ HIV-1 LTR serves as a template for the U3 regions of both LTRs in the resulting provirus, third-generation HIV-1 transfer vectors have been developed that contain a 400-bp deletion within this region. The consequence of this modification is that the 5′ LTR of the integrated

vector is almost completely inactivated (Miyoshi et al., 1998; Zufferey et al., 1998). Inability to efficiently transcribe full-length vector RNA by these so-called self-inactivating (SIN) HIV-1 vectors in transduced target cells considerably minimizes the possibility of RCR generation. The SIN configuration also reduces the possibility of oncogene activation by promoter insertional mutagenesis. By design, SIN vectors require an internal promoter for transgene expression. Fortunately, in contrast to what was observed previously for SIN oncoretroviral vectors, this modification does not result in a significant drop in vector titers.

To prevent reconstitution of U3 sequences within the deleted 3′ HIV-1 LTR by homologous recombination with the intact 5′ HIV-1 LTR during transient cotransfection of 293T cells, the U3 region of the 5′ LTR of third-generation transfer vectors has been replaced with the CMV or Rous sarcoma virus LTR promoters (Dull et al., 1998; Kim et al., 1998). Notably, titers as high as 10^7 TU/ml can be obtained from the chimeric LTRs irrespective of whether Tat is present, allowing deletion of the *tat* gene from the packaging construct. This finding permitted further refinement of the packaging system such that the *gag-pol* and *rev* genes can be

expressed from two separate nonoverlapping plasmids (Dull et al., 1998).

Efforts to eliminate the Rev dependence of HIV-1-based lentiviral vectors have generally involved replacing the RRE with autonomous RNA export signals termed constitutive RNA transport elements—typically from the simian type D retroviruses, Mason-Pfizer monkey virus, and the simian retroviruses type 1 and 2 (Bray et al., 1994; Ernst et al., 1997; Kim et al., 1998; Gasmi et al., 1999; Kotsopoulou et al., 2000; Mautino et al., 2000). Collectively, the studies have indicated that these elements can partially substitute for the Rev/RRE combination, although there is usually a reduction in vector titer when the Rev/RRE components are completely removed from the packaging system. For this reason, third-generation HIV-1 vectors generally retain the RRE sequence.

As noted above, after HIV-1 reverse transcription a 99 nucleotide-long overlap—the central DNA flap—is formed that is involved in normal import of the HIV-1 preintegration complex into the nucleus (Follenzi et al., 2000; Zennou et al., 2000). The sequences specifying the central DNA flap—a cPPT and a central termination sequence located within the *pol* ORF—were omitted from earlier generations of HIV-1 vectors. These sequences have been restored in more recent versions of third-generation HIV-1 vectors and shown to facilitate higher transduction efficiencies of several types of cells, both proliferating and growth-arrested.

For high-level transgene expression in a broad range of cell types *in vitro* and *in vivo*, a variety of viral and cellular promoters have been inserted into third generation HIV-1 vector backbones. In addition to the CMV promoter, other promoters that have been demonstrated to perform well include the murine stem cell virus (MSCV) vector LTR (Hawley et al., 1994), the gibbon ape leukemia virus LTR, the human elongation factor 1 α promoter, the CAG promoter (composed of the CMV immediate early enhancer linked to chicken β -actin promoter sequences) and the human X chromosome phosphoglycerate kinase 1 promoter (Ramezani et al., 2000).

Finally, other genetic elements have been identified that stimulate transgene expression post-transcriptionally. Chief among these is the woodchuck hepatitis virus post-transcriptional regulatory element (WPRE). This element has been postulated to exert a positive influence on transgene expression by augmenting 3'-end processing and polyadenylation (Loeb et al., 2000). Inclusion of the WPRE has been shown

to significantly enhance transgene expression levels from several types of promoters in both oncoretroviral and lentiviral vectors, and is thus routinely included in third-generation HIV-1-based gene delivery systems (Zufferey et al., 1999; Deglon et al., 2000; Ramezani et al., 2000).

Packaging Limit of HIV-1 Vectors

Another advantage of HIV-1-based vectors over oncoretroviral vectors is their greater packaging limit. The packaging limit is the length of vector RNA that can be encapsidated into viral particles. Although an HIV-1 vector greater than 12 kb in size has been reported to give reasonable titers (Uchida et al., 1998), a systematic determination of the packaging limit of lentiviral vectors demonstrated that the viral titers decrease semilogarithmically with increasing vector length (Kumar et al., 2001). In that study, VSV-G-pseudotyped HIV-1 vectors with a proviral length of 10.5 to 11 kb yielded titers comparable to that of a control vector 5.5 kb in size. The third-generation vector illustrated in Figure 16.21.3C contains ~1.9 kb of *cis*-acting HIV-1 sequences, an MSCV-based internal promoter (~0.3 kb) and the WPRE (~0.6 kb). It can therefore readily accommodate transgenes of ~8 kb.

HIV-1 Vector Packaging Cell Lines

HIV-1 lentiviral vectors with tropism limited to CD4⁺ cells have been produced from stable packaging cell lines, albeit at titers of only ~10⁴ TU/ml (Corbeau et al., 1996; Srinivasakumar et al., 1997). Because of the toxicity associated with the VSV-G envelope glycoprotein (Yang et al., 1995) as well as high-level constitutive expression of the HIV-1 PR (Kaplan and Swanstrom, 1991) and Vpr proteins (Planelles et al., 1995), the most common method of producing VSV-G-pseudotyped HIV-1 vectors has been by transient cotransfection. Titers in the range of 10⁶ to 10⁷ TU/ml can be obtained in this manner. Nonetheless, transient cotransfection of transfer, packaging, and VSV-G envelope plasmids can yield variable results and the process is labor-intensive when large amounts of vector stocks are required. Thus, although this method is satisfactory for most experimental applications, a stable producer cell line is highly desirable.

The requirement for a stable producer cell line has led to the development of inducible HIV-1-based packaging systems (Yu et al., 1996; Kaul et al., 1998; Kafri et al., 1999; Klages et al., 2000; Pacchia et al., 2001). Many

of these cell lines utilize a tetracycline-regulatable expression system to control protein synthesis from the packaging and VSV-G constructs (Fig. 16.21.4). Tetracycline-regulatable systems are based on the tetracycline resistance (*tet*) operon of *E. coli* (Gossen and Bujard, 1992). In one version of the system, commonly referred to as “tet-off” (Fig. 16.21.4A), the tetracycline repressor protein (TetR) is fused to the activation domain of the herpes simplex virus VP16 protein to generate a tetracycline-repressed transactivator (tTA). In the absence of tetracycline or tetracycline analogs such as doxycycline, tTA binds to and stimulates transcription from a minimal promoter sequence, usually derived from the human CMV immediate early region, linked to seven copies of the *tet* operon sequence (tetO). In the presence of low concentrations of tetracycline/doxycycline, tTA is prevented from binding to the promoter and transcription ceases. In the complementary “tet-on” system (Gossen et al., 1995), a “reverse” transactivator (rtTA) with the opposite properties of tTA binds to the minimal promoter and stimulates transcription only in the presence of doxycycline (Fig. 16.21.4B).

An example of a tTA-based HIV-1-packaging cell line that is capable of producing VSV-G pseudotyped vectors with titers on the order of 10^6 TU/ml for at least 3 to 4 days (Kafri et al., 1999) is illustrated in Figure 16.21.4C. The packaging cell line was generated by stable transfection of 293T cells with an expression plasmid that allows constitutive expression of tTA from the CMV promoter, a packaging construct containing all of the HIV-1 viral genes except the *env* gene under the control of a tetracycline-responsive promoter, and a VSV-G envelope plasmid also under tetracycline-responsive promoter control. More recently, a tTA-regulatable HIV-1 vector packaging cell line based on the third-generation split-genome, multiply attenuated packaging constructs has been developed (Klages et al., 2000). In this system, the HIV-1 proteins have been minimized to Gag, Pol and Rev. The Gag and Gag-Pol proteins are expressed from the CMV promoter. Advantage was taken of the fact that HIV-1 *gag/pol* transcripts are retained in the nucleus and rapidly degraded in the absence of Rev; consequently, Rev was placed under tetracycline-regulated control along with the VSV-G construct. Titers as high as 5×10^6 TU/ml can be obtained after 7 to 10 days following removal of doxycycline, and the cells can be maintained in culture for about another week.

Another group has utilized the ecdysone-inducible expression system to regulate expression of the HIV-1 Gag, Pol, and Rev proteins from a packaging construct and the VSV-G protein from a second plasmid (Pacchia et al., 2001). The system is based on the ability of the ecdysone analog, ponasterone A, to induce transcription in mammalian cells through a modified heterodimeric insect ecdysone receptor (No et al., 1996). In the presence of ponasterone A, the insect ecdysone receptor, modified by fusion to the herpes simplex virus VP16 transactivation domain, forms a heterodimer with the retinoid X receptor. The heterodimeric complex activates gene expression from a hybrid ecdysone response element linked to a minimal promoter. Compared to the tetracycline-regulatable system, the ecdysone-inducible system appears to have a lower basal level of expression and faster induction kinetics (No et al., 1996). Accordingly, the peak production of HIV-1 vector particles in this system was achieved in 3 to 5 days, although the maximum titers obtained were only 10^5 TU/ml.

TARGET CELLS OF HIV-1 VECTORS

An understanding of the molecular mechanisms mediating HIV-1 infection of nondividing cells has permitted HIV-1-derived lentiviral vectors to be designed to retain this property as well. As discussed previously, the nucleophilic properties mainly reside in the MA, IN, and Vpr proteins of the preintegration complex (Bukrinsky et al., 1993; Heinzinger et al., 1994; Gallay et al., 1997). Although the Vpr protein seems to be important for transduction of macrophages and hepatocytes (Naldini et al., 1996a; Kafri et al., 1997), it has been found to be dispensable for transduction of many other cell types (reviewed in Vigna and Naldini, 2000). Notably, however, while HIV-1 vectors do not require cell division, like HIV-1 they are unable to successfully transduce T lymphocytes that are in the G_0 stage of cell cycle. Inefficient transduction of metabolically inactive T cells is due to blocks at the levels of reverse transcription (Korin and Zack, 1998) and nuclear import (Sun et al., 1997). By comparison, T cells in the G_1/S or G_2 stages of cell cycle have permissive cytoplasmic conditions that allow HIV-1 and HIV-1-derived vectors to complete reverse transcription and nuclear localization.

As with oncoretroviral vector systems (Hawley, 1996, 2001), a major factor determining the host range and target cell type of HIV-1

Figure 16.21.4 Schematic representation of a tetracycline-regulatable HIV-1 packaging system. **(A)** Principle of the “tet-off” gene expression system. The tetracycline-controlled transactivator (tTA) was generated by fusion of the tetracycline repressor protein (TetR) to the activation domain of the herpes simplex virus VP16 protein. In the absence of tetracycline or doxycycline, tTA binds to the tetracycline-responsive promoter element (TRE) and stimulates transcription of the transgene. **(B)** Principle of the “tet-on” gene expression system. A mutant TetR (rTetR) was created by four amino acid changes in TetR and fused to the activation domain of the herpes simplex virus VP16 protein to generate a reverse tetracycline-controlled transactivator (rtTA). rtTA binds to the TRE in the presence of doxycycline and stimulates transcription. **(C)** An example of a tetracycline-regulated HIV-1 packaging system. The packaging cells constitutively express tTA which allows expression of the HIV-1 packaging construct and the VSV-G glycoprotein envelope gene in the absence of tetracycline. In order to monitor the induction process, a green fluorescent protein (GFP) reporter gene is coexpressed with the VSV-G envelope glycoprotein gene from a bidirectional tetracycline-responsive promoter.

vectors is the envelope protein. While the Env protein of wild-type HIV-1 limits target cell tropism to CD4⁺ lymphocytes, macrophages, and glial cells, VSV-G-pseudotyped HIV-1 vectors have a greatly expanded tropism, and, with the exceptions noted above, can transduce virtually all types of cells. The expanded tropism of VSV-G-pseudotyped HIV-1 vectors is due to the ability of the VSV-G protein to bind to a phosphatidyl serine component of the lipid bilayer present in the cell membrane of most eukaryotic cells (Schlegel et al., 1983). Thus VSV-G-pseudotyped HIV-1 vectors have been used to transduce and mediate transgene expression in differentiated cells and tissues as diverse as neurons, liver, muscle, and retina (Naldini et al., 1996a,b; Kafri et al., 1997; Miyoshi et al., 1997; Kordower et al., 1999) as well as undifferentiated stem cells and embryos (Hamaguchi et al., 2000; May et al., 2000; Hawley, 2001; Pawliuk et al., 2001; Wolfgang et al., 2001; Lois et al., 2002; Pfeifer et al., 2002).

Generation of HIV-1-Based Lentiviral Vector Particles

Generation of recombinant HIV-1 vector particles (see *UNIT 16.21* for overview) involves subcloning the gene of interest into an HIV-1 transfer vector backbone, cotransfection of the plasmid into a recipient cell line together with packaging and envelope plasmids (or directly into a stable packaging line), and collection of vector supernatants.

The transfer vector can be selected from currently available vector backbones (Ramezani et al., 2000; Vigna and Naldini, 2000) or custom-tailored for a particular application. Modification of an existing vector—e.g., changing the promoter or the marker gene and/or insertion of a new transgene—involves standard recombinant DNA techniques as described in other units of this book and elsewhere (Sambrook and Russell, 2001).

Once the transfer vector containing the transgene has been constructed and confirmed by restriction enzyme analysis and DNA sequencing, it can be used for the production of recombinant HIV-1 vector particles. Among the many techniques used for transient transfection of adherent mammalian cells, the CaPO₄ method of Graham and van der Eb (1973) remains one of the most cost-effective and reproducible. Because transient transfection of 293T cells is the primary method used to produce HIV-1 vector particles, the CaPO₄ method is used with this cell line in the procedure described below (see Basic Protocol 1) for the production of the vector particles. A protocol for production of vector particles from a stable producer cell line can be found in Klages et al. (2000). Basic Protocol 1 outlines small-scale vector preparation in 100-mm dishes and will yield ~5 ml of vector supernatant with titers of 10⁶ to 10⁷ TU/ml (depending on the vector). When larger volumes of vector supernatant are required, this method can be easily scaled up by using multiple 150-mm dishes. When 150-mm dishes are used, the quantities of all of the components must be tripled to account for the 3-fold increase in surface area compared to that of 100-mm dishes. By concentrating large volumes of vector supernatants obtained in this manner, titers as high as 10⁹ TU/ml can be achieved. A modification of this procedure using sodium butyrate to stimulate production of vector particles is also presented (see Basic Protocol 2).

In addition to the gene-transfer protocols routinely employed for production of recombinant vector supernatants (see Basic Protocols 1 and 2), this unit describes related techniques. When required, vector supernatants can be concentrated by centrifugation procedures (see Basic Protocol 3 and Alternate Protocol 1). Also provided are protocols for further purification and titration of vector particles (see Basic Protocols 4 and 5, and Alternate Protocol 2). Methods for transduction of both adherent and nonadherent cells are included (see Basic Protocol 7). Although the probability of de novo generation of a new infectious recombinant lentivirus (referred to as a replication-competent retrovirus or RCR; see *UNIT 16.21*) is extremely low due to the extensive modifications that have been made to the HIV-1 genome, it is important to stress that caution should still be exercised during the course of recombinant lentiviral vector particle production and application. It is therefore recommended that the RCR detection methods included in this unit (see Basic Protocol 6, and Alternate Protocols 3 and 4) be used regularly in order to definitively rule out the presence of RCR variants in any vector stocks.

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed.

NOTE: All culture incubations should be performed in a 37°C, 5% CO₂ incubator unless otherwise specified.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

**BASIC
PROTOCOL 1**

COTRANSFECTION OF 293T CELLS AND PRODUCTION OF LENTIVIRAL VECTOR SUPERNATANTS

VSV-G-pseudotyped HIV-1-based lentiviral vector particles are prepared by transiently transfecting the transfer vector plasmid, the packaging plasmid or plasmids (e.g., pCMVΔR8.91), and the VSV-G protein envelope plasmid (e.g., pMD.G) into subconfluent 293T cells by a modification of the calcium phosphate precipitation method (Hawley et al., 1989). Note that procedures for producing lentiviral supernatants are essentially the same as those used for producing oncoretroviral supernatants; the user is thus also directed to *UNIT 9.11* for additional details on culturing and transfecting 293T cells.

Materials

293T human embryonic kidney cell line (ATCC #CRL-11268)
293T cell growth medium (see recipe) with and without 10 mM HEPES [add HEPES from 100× (1 mM) stock (see recipe)]
Lentiviral vector plasmid DNA containing the gene of interest (see *UNIT 16.21*; Ramezani et al., 2000; Vigna and Naldini, 2000)
Lentiviral packaging construct DNA (e.g., pCMVΔR8.91; Zufferey et al., 1997)
VSV-G expressing plasmid DNA (e.g., pMD.G; Naldini et al., 1996)
2.5 M CaCl₂ (see recipe)
2× HEPES-buffered saline (HeBS; see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2*)
100-mm tissue culture dishes
Tabletop centrifuge
0.45-μm pore-size filter

Additional reagents and equipment for cell culture and counting cells (*APPENDIX 3F*)

1. Grow 293T cells in 293T cell growth medium.

*293T cells are split every 3 to 4 days between 1:4 to 1:8. A trypsin-EDTA solution (e.g., Life Technologies) is used to dissociate the cells. To trypsinize, remove medium and rinse the monolayer with PBS (without Ca²⁺ and Mg²⁺; see *APPENDIX 2*). Remove the PBS and add enough trypsin-EDTA solution to cover the monolayer. Incubate the cultures at room temperature until the cells round up and detach. Add an equal volume of fresh 293T cell growth medium containing 10% FBS to inactivate the trypsin. Collect the cells by low-speed centrifugation (3 min at 500 × g), resuspend in fresh culture medium, and plate. Do not allow the cells to grow above 80% confluence.*

*See *APPENDIX 3F* for general cell culture procedures.*

2. At a point 24 hr before transfection, count cells (*APPENDIX 3F*), and seed 293T cells into 100-mm tissue culture dishes, each containing 7 ml of 293T cell growth medium, at 4 × 10⁶ cells per dish.
3. For each plate to be used, prepare cotransfection precipitate as follows:
 - a. Mix 15 μg of the vector plasmid containing the gene of interest, 10 μg of the packaging plasmid pCMVΔR8.91, and 5 μg of the VSV-G protein envelope plasmid pMD.G.
 - b. Bring the volume up to 400 μl with sterile water.

- c. Add 100 μ l of 2.5 M CaCl_2 and mix.
- d. Add the DNA/ CaCl_2 solution dropwise to 500 μ l of 2 \times HeBS in a 15-ml conical tube. Use a battery-powered mechanical pipettor and a 2-ml pipet to bubble the 2 \times HeBS as the DNA/ CaCl_2 solution is added.

See Figure 9.1.1 for an illustration of the technique used.

- e. Vortex immediately for 5 sec and incubate at room temperature for 20 min.
4. Add the precipitate dropwise to the plates from step 2 so as to distribute it evenly over the cells and mix gently. Incubate the cells at 37°C overnight (16 hr).
5. The next day, remove medium from each dish, rinse cells with 5 ml PBS, and add 5 ml fresh 293T cell growth medium containing 10 mM HEPES.
6. Incubate an additional 48 hr, then collect the vector-containing supernatant medium. Centrifuge 10 min at 2000 \times g, 4°C, to remove cellular debris, then filter through a 0.45- μ m pore-size filter. Divide into 1- to 5-ml aliquots and freeze at -80°C, keeping a small amount for determination of vector titer (see Basic Protocol 5).

STIMULATION OF VECTOR PARTICLE PRODUCTION USING SODIUM BUTYRATE

**BASIC
PROTOCOL 2**

Sodium butyrate ($\text{CH}_3\text{CH}_2\text{CH}_2\text{COONa}$) is a short-chain fatty acid that has been demonstrated to inhibit histone deacetylase (McKnight et al., 1980). Hyperacetylation of nucleosomal histones results in a more open and accessible chromatin configuration within the promoter regions of genes, leading to higher transcriptional activity (Norton et al., 1989). Notably, expression of exogenous sequences introduced into mammalian cells is also enhanced by sodium butyrate treatment (Gorman and Howard, 1983; Laughlin et al., 1995). Inclusion of sodium butyrate at concentrations of 4 to 10 mM during transient production of lentiviral (and oncoretroviral) vector particles has been reported to result in 10- to 15-fold increases in titers (Soneoka et al., 1995; Gasmi et al., 1999).

Sodium butyrate treatment may be most effective for vectors that have low titers. Since sodium butyrate is toxic to the cells, it must be removed after the initial treatment and replaced with fresh medium if the supernatants are not going to be concentrated.

Materials

Cells containing calcium phosphate–DNA coprecipitate (see Basic Protocol 1, step 5)

500 mM sodium butyrate stock solution (see recipe)

293T cell growth medium (see recipe)

Phosphate-buffered saline (PBS; *APPENDIX 2*)

Additional reagents and equipment for cotransfection of 293T cells and preparation of lentiviral supernatants (see Basic Protocol 1)

1. After the overnight incubation of the cotransfected cells (see Basic Protocol 1, step 5):
 - a. Add sodium butyrate (from 500 mM stock) to 293T cell growth medium to a final concentration of 10 mM.
 - b. Remove the medium with the calcium phosphate–DNA coprecipitate from each dish and replace with an equal volume of the sodium butyrate–containing growth medium
 - c. Incubate the cells for 12 to 14 hr.

**Protein
Expression**

16.22.3

- d. Remove medium and wash with PBS to remove the sodium butyrate. Add 5 ml of fresh 293T cell growth medium.

If vector particles are to be concentrated (see Basic Protocol 3 and Alternate Protocol 1), this medium change is not necessary, as the sodium butyrate will be removed from the vector particle preparations during the subsequent concentration step.

2. Incubate an additional 24 hr, then collect the vector-containing supernatants.

See Basic Protocol 1, step 6, for treatment and storage of the vector-containing medium.

CONCENTRATION OF HIV-1 VECTOR PARTICLES BY ULTRACENTRIFUGATION

Lentiviral vector transduction efficiency depends to a large extent on the ratio of vector particles to target cells (multiplicity of infection, MOI). For example, when using VSV-G-pseudotyped lentiviral vectors, MOI values of 300 to 1000 have been used to achieve efficient gene delivery to hematopoietic progenitor cells (Miyoshi et al., 1999; Case et al., 1999). Achieving these MOI values requires highly concentrated vector particle preparations.

Several methods have been developed to concentrate lentiviral vector particles. The choice of concentration protocol depends on the envelope selected to pseudotype the particle and the quantities of particles to be produced. The stability of the VSV-G envelope protein allows generation of high-titer lentiviral vector stocks by ultracentrifugation, as described here. On the other hand, if the HIV-1 Env, the amphotropic envelope, or similar envelope glycoproteins are preferred, low-speed centrifugation methods should be used (see Alternate Protocol 1), since the TM and SU subunits of these envelope glycoproteins are not covalently linked and they tend to dissociate upon high-speed centrifugation.

Although convenient and efficient, the volume of the vector supernatant that can be concentrated by this ultracentrifugation is limited by the capacity of the ultra-high-speed rotors (six bottles, each containing 70 ml).

Materials

Vector-containing supernatants (see Basic Protocols 1 and 2)
Appropriate medium to resuspend concentrated vector particles
Ultracentrifuge and rotor
Polycarbonate 70-ml ultracentrifuge bottles and caps
Tabletop centrifuge

1. Ultracentrifuge vector supernatants 90 min at $50,000 \times g$, 4°C .

Small (~2- to 5-mm-diameter) pale-yellow pellets should be visible after centrifugation.

2. Remove supernatants and resuspend pellets in ~100 μl of medium appropriate for the downstream application by gentle pipetting. Vortex gently overnight at 4°C to allow complete resuspension.
3. Centrifuge 5 min at $10,000 \times g$, 4°C , in a tabletop centrifuge to bring down insoluble debris. Gently remove the supernatant containing the concentrated vector particles and freeze in 0.5-ml aliquots at -80°C , keeping a small amount for determination of vector titer (see Basic Protocol 5).

Vector particles are usually frozen as 0.5-ml aliquots. However, this volume could vary between 0.1 ml to 1.0 ml depending on the downstream application (i.e., the number of cells to be transduced). The volumes should be chosen so that repeated freezing and thawing of the vector particles is avoided, since this process leads to a reduction in vector titers.

If desired, the vector particles can be further concentrated by another round of ultracentrifugation. See Basic Protocol 4 for purifying the concentrated lentiviral vector particles by anion-exchange chromatography.

CONCENTRATION OF HIV-1 VECTOR PARTICLES BY POLY-L-LYSINE PRECIPITATION

**ALTERNATE
PROTOCOL 1**

Certain cationic molecules such as poly-L-lysine (PLL) have been used to concentrate lentiviral vectors (Zhang et al., 2001). The positive electrostatic charge of PLL binds to the vector particles and forms complexes that can be precipitated by low-speed centrifugation. This method is particularly suitable for concentrating large volumes of lentiviral vector supernatants—taking advantage of the capacity of the rotors (accommodating six bottles, each containing 250 ml) available for low-speed centrifugation—which is higher than the capacity of the ultracentrifuge rotors used in Basic Protocol 3. Furthermore, the relatively low centrifugation speed also prevents the precipitation of dyes such as the phenol red in the medium (Miller et al., 1996), marker gene products (Liu et al., 1996), or other small molecules that are often found to be toxic or cause the differentiation of primary cells.

Additional Materials (also see *Basic Protocol 3*)

100 mg/ml poly-L-lysine hydrobromide (PLL; mol. wt. based on viscosity, 27,400) in PBS (see *APPENDIX 2* for PBS), freshly prepared
Appropriate medium to resuspend concentrated vector particles
250-ml centrifuge bottles

1. Add the 100 mg/ml PLL solution to the vector supernatants (from Basic Protocol 1 or 2) to a final concentration of 0.005% (w/v), then incubate 30 min at 4°C.
2. Precipitate the vector particles by centrifuging 2 hr at $10,000 \times g$, 4°C.
3. After the centrifugation, gently remove the supernatant and resuspend each pellet in 100 μ l of medium appropriate for the downstream application. Gently mix the concentrated vector particles by vortexing overnight at 4°C to allow complete resuspension.
4. Centrifuge 5 min at $5000 \times g$, 4°C, to bring down the debris. Divide the supernatant containing the concentrated vector particles into aliquots and store at -80°C , keeping a small amount for determination of vector titer (see Basic Protocol 5).

PURIFICATION OF CONCENTRATED LENTIVIRAL VECTOR PARTICLES BY ANION-EXCHANGE CHROMATOGRAPHY

**BASIC
PROTOCOL 4**

The relatively low centrifugation speed used in PLL precipitation (see Alternate Protocol 1) to concentrate the lentiviral vector particles should generally preclude the coconcentration of low-molecular-weight toxic impurities. However, lentiviral vector particles concentrated by ultracentrifugation (see Basic Protocol 3) may contain contaminants that can be toxic to certain target cells and should be purified prior to use.

Contaminating toxic proteins can be removed from lentiviral vector preparations by anion-exchange chromatography either before or after the concentration step (Scherr et al., 2002). The yield of purified lentiviral vector particles obtained with this method ranges between 30% and 60%.

**Protein
Expression**

16.22.5

Materials

Vector particles concentrated by ultracentrifugation (see Basic Protocol 3), resuspended in PBS

Phosphate-buffered saline (PBS; *APPENDIX 2*) containing 1 M NaCl

80 × 6-mm anion-exchange column: Fractoflow 80-6 column (Merck) packed with 40- to 90- μ m mesh size resin according to manufacturer's instructions (also see *UNIT 10.10*)

Ultrafree-15 centrifugal filter devices (Millipore; 100,000 MWCO; also see *APPENDIX 3C*)

1. Add 1 to 10 ml of vector particles suspended in PBS to an anion-exchange column.
2. Elute the vector particles from the column by adding 30 ml PBS containing 1 M NaCl at a flow rate of 4 ml/min.
3. Desalt and concentrate the vector particles by centrifuging through a 100,000 MWCO Ultrafree-15 centrifugal filter device 15 min (or until vector supernatants are concentrated to the desired volume) at $2000 \times g$, 4°C (also see manufacturer's instructions).
4. Dilute the concentrated vector particles with the appropriate medium for transduction (Basic Protocol 7) and culture of the target cells. Divide into aliquots and store at -80°C, keeping a small amount for determination of vector titer (see Basic Protocol 5).

ALTERNATE PROTOCOL 2

PURIFICATION OF CONCENTRATED LENTIVIRAL VECTOR PARTICLES BY THE DUAL-FILTER METHOD

Dual-filter purification is a simple and efficient alternative that can be used to purify concentrated lentiviral vector particle preparations. This procedure is much less labor-intensive and time-consuming than anion-exchange chromatography (Basic Protocol 4), and has the advantages of being cost-effective and providing higher yields of vector particle recovery. The protocol is based on the size of the HIV-1 lentiviral vector particle, which is ~100 nm in diameter. The concentrated vector particles are first passed through a 0.22- μ m filter, commonly used to sterilize solutions. While the HIV-1 vector particles readily pass through this filter, large-molecular-weight cellular debris is trapped. The filtrate is then added to an Ultrafree-15 centrifugal filter with a 100-kDa molecular weight cut-off, which allows most small proteins, dyes, and empty vector particles (~50 nm in diameter) to be removed.

The dual-filter method reduces the processing time required to obtain purified vector particles to ~30 min, with a 50% and 70% recovery yield.

Materials

Vector supernatants concentrated by ultracentrifugation (see Basic Protocol 3)

Appropriate serum-free medium

10-ml syringes and 0.22- μ m syringe filters

Ultrafree-15 centrifugal filter devices (Millipore; 100,000 MWCO; also see *APPENDIX 3C*)

1. Add fresh serum-free medium to dilute the concentrated vector particles (from Basic Protocol 3, step 3) to 5 ml.
2. Using a 10-ml syringe, slowly pass the vector particle-containing medium through a 0.22- μ m filter into an Ultrafree-15 centrifugal filter device.

3. Centrifuge the Ultrafree-15 centrifugal filter device 15 min (or until vector supernatants are concentrated to desired volume) at $2000 \times g$, 4°C (also see manufacturer's instructions).
4. Collect the purified vector particles and freeze in aliquots at -80°C . Keep a small aliquot for determination of vector titers (see Basic Protocol 5).

TITRATION OF LENTIVIRAL VECTOR STOCKS

The HT1080 fibrosarcoma cell line (Rasheed et al., 1974) can be used to determine the titer of the lentiviral vector particle preparations.

Materials

HT1080 cell line (ATCC #CCL-121)
 293T cell growth medium (see recipe)
 Vector preparations (Basic Protocols 3 or 4 or Alternate Protocols 1 or 2)
 6 mg/ml (1000 \times) polybrene stock solution
 G418 (UNIT 9.5)
 0.3% (w/v) crystal violet in 70% (v/v) methanol
 6-well tissue culture plates

Additional reagents and equipment for flow cytometric analysis of EGFP expression (Rasko, 1999), Xgal staining for *lacZ* (β -galactosidase) expression (UNIT 9.10), or enumeration of *neo*-resistant cells (UNIT 9.5)

1. Grow HT1080 cells in 293T cell growth medium (same medium used in Basic Protocol 1). At a point 4 to 6 hr before the titration of the vector preparation, seed 2.5×10^5 HT1080 cells in each well of a 6-well plate.
2. At a time point 4 to 6 hr after cells have been seeded, prepare serial dilutions of an aliquot of each vector preparation (for unconcentrated vector supernatants, 10^0 , 10^{-1} , and 10^{-2} ; for concentrated supernatants, 10^{-2} , 10^{-3} , and 10^{-4}), using 293T cell growth medium, in a final volume of 1 ml. To each of the dilutions, add 1 μl of 6 mg/ml (1000 \times) polybrene for a final concentration of 6 $\mu\text{g/ml}$ polybrene. Add each serial dilution to the corresponding cell-containing well and return to the incubator for 4 hr.
Basic Protocol 7 contains additional information concerning stable transduction with recombinant lentiviral vectors.
3. After 4 hr of transduction, remove the vector-containing medium and replace with 2 ml fresh 293T cell growth medium. Continue incubating for 48 hr.
- 4a. *For vectors containing EGFP or lacZ marker:* After 48 hr, determine the relative end-point vector titers (in TU/ml) by flow cytometric analysis for EGFP expression (if the vector contains the EGFP gene; see, e.g., Rasko, 1999) or by Xgal staining (if the vector contains the *lacZ* gene; see UNIT 9.10). Use the following equation:

Vector titer = number of HT1080 cells \times % of EGFP⁺ or *lacZ*⁺ cells \times dilution factor.

- 4b. *For vectors carrying the neo drug-resistance gene:* After 48 hr, split cells 1:10 and seed into 100-mm dishes in medium containing 400 $\mu\text{g/ml}$ G418. Replace medium every 4 to 5 days. At a time point 2 weeks later, fix and stain cells with 0.3% crystal violet in 70% methanol and enumerate the G418-resistant colonies (see UNIT 9.5). Use the following equation to determine the vector titer:

Vector titer = number of G418-resistant colonies \times 10 \times dilution factor.

The factor of 10 must be used because of the 1:10 split.

**DETECTION OF REPLICATION-COMPETENT VIRUSES BY THE
REVERSE TRANSCRIPTASE ASSAY**

Absence of replication-competent HIV-1-derived virus in recombinant lentiviral vector stocks can be determined by the methods here and in Alternate Protocols 3 and 4. This assay measures the enzymatic activity of HIV-1 reverse transcriptase.

Materials

- HT1080 cell line (ATCC #CCL-121)
- Undiluted vector particle supernatant (Basic Protocol 3 or 4 or Alternate Protocol 1 or 2)
- 293T cell growth medium (see recipe)
- 35-, 100-, and 150-mm tissue culture dishes
- Tabletop centrifuge
- Ultracentrifuge and rotor
- Reverse transcriptase assay kit (e.g., Roche Diagnostics, cat. no. 1468120)
- Additional reagents and equipment for stable transduction of cells (see Basic Protocol 5, steps 1 and 2)

1. Prepare a culture supernatant from stably transduced HT1080 cells as follows:
 - a. Transduce 2.5×10^5 cells in a 35-mm tissue culture dish with 1 ml of undiluted vector particle supernatant (see Basic Protocol 5, steps 1 and 2).
 - b. Grow cells until confluent; transfer to a 100-mm tissue culture dish and then to a 150-mm tissue culture dish. Use 293T cell growth medium to split.
A confluent 150-mm dish should contain $1-2 \times 10^7$ cells.
 - c. Centrifuge 10 min at $2000 \times g$, 4°C , to remove cellular debris and collect the supernatant from these cells (~20 ml) for use in the assay.
2. Concentrate supernatants by ultracentrifuging 2 hr at $40,000 \times g$, 4°C , and resuspending the pellet in 40 μl of the lysis buffer provided with the reverse transcriptase assay kit.
3. Test the concentrated culture supernatants for HIV-1 reverse transcriptase activity using a commercial reverse transcriptase assay kit according to the manufacturer's instructions.

**DETECTION OF REPLICATION-COMPETENT VIRUSES BY THE
TAT-INDUCTION ASSAY**

This assay uses a reporter T cell line (CEM-GFP) which expresses the GFP gene driven by the HIV-1 LTR promoter to measure Tat activity. Infection of CEM-GFP cells with wild-type HIV-1 results in a 100-to 1000-fold increase in GFP fluorescence over 2 to 4 days compared with uninfected cells (Gervaix et al., 1997).

Additional Materials (also see Basic Protocol 6)

- CEM-GFP cell line (NIH AIDS Research and Reference Reagent Program)
- Growth medium for CEM-GFP cells: IMDM containing 10% FBS (see recipe for serum-containing growth media for transduction)
- 6 mg/ml polybrene stock solution
- HIV packaging plasmid DNA (e.g., pCMV Δ R8.91)
- Additional reagents and equipment for flow cytometric analysis of GFP expression (Rasko, 1999)

1. Prepare lentiviral supernatant (see Basic Protocol 6, step 1).
2. Culture and passage CM-GFP cells using IMDM containing 10% FBS according to the instructions provided by the NIH.

CM-GFP cells are suspension cells. They are cultured at 1×10^6 cells/ml and split every 3 days at a ratio of 1:3 with fresh medium.

3. Resuspend 5×10^5 CEM-GFP cells in a 1-ml aliquots of the supernatant from step 1 in a well of a 6-well plate, add polybrene to a concentration of 2 μ g/ml (from 6 mg/ml polybrene stock), and incubate overnight to achieve transduction. Transduce CEM-GFP cells with the pCMV Δ R8.91 packaging plasmid as a positive control.
4. Remove polybrene-containing medium and replace with 1 ml fresh medium. Return plates to incubator.

Maintain the cell density below 1×10^6 cells/ml by adjusting the volume of the medium as the cells proliferate.

5. Analyze GFP fluorescence 3 days post-incubation by flow cytometry (Rasko, 1999).

DETECTION OF REPLICATION-COMPETENT VIRUSES BY THE GAG TRANSFER ASSAY

**ALTERNATE
PROTOCOL 4**

The lentiviral vector stocks can be tested for the presence of replication-competent HIV-1-derived virus by serial transfer and performing an enzyme-linked immunosorbent assay (ELISA) to detect the HIV-1 p24 antigen. This assay measures the presence of HIV-1 p24 protein in the medium obtained from vector-transduced cells following several passages in culture (Naldini et al., 1996). Using this method, p24 concentrations as low as 1 pg/ml (~1 to 2 TU/ml) can be detected.

Additional Materials (also see Basic Protocol 6)

p24 ELISA assay kit (e.g., Alliance HIV-1 p24 ELISA kit from Perkin-Elmer Life Sciences; cat. no. NEK050001KT)

1. Prepare lentiviral supernatant from stably transduced cells (see Basic Protocol 6, step 1).
2. Test the culture supernatants for HIV-1 p24 by using a commercial p24 ELISA assay kit according to the manufacturer's instructions.

TRANSDUCTION OF TARGET CELLS

**BASIC
PROTOCOL 7**

Several protocols have been described for transducing target cells with lentiviral vector particles. In general, these are the same protocols that are used to transduce cells with oncoretroviral vector particles (UNIT 9.11). Although it has been reported that polycations such as polybrene or protamine sulfate, which reduce the electrostatic repulsive interactions between the negatively charged surfaces of the cell and the vector particles, do not improve transduction efficiencies with VSV-G-pseudotyped lentiviral vectors, these agents are routinely included in the transduction cocktails. Protamine sulfate is recommended for use when transducing primary cells since polybrene has been found to be somewhat more toxic to these cell types. Likewise, transduction efficiencies of nonadherent hematopoietic cells expressing the fibronectin receptors very late antigen 4 (VLA-4; CD49d) and very late antigen 5 (VLA-5; CD49e) with amphotropic envelope-containing oncoretroviral vector particles have been shown to be increased by incubating the cells on recombinant fibronectin fragments through simultaneous binding and colocalization of the vector particles and target cells (Moritz et al., 1994; Hanenberg et al.,

**Protein
Expression**

16.22.9

1997). While fibronectin does not seem to similarly facilitate transduction of these target cells by VSV-G-pseudotyped vectors, it has been demonstrated to have growth-supporting properties for hematopoietic progenitor cells (Dao et al., 1998; Yokota et al., 1998). It is thus frequently used during lentiviral gene delivery to these cells (Donahue et al., 2001).

Transduction of Adherent Cells

Although lentiviral vectors do not require cell division, optimal transduction efficiencies are obtained if the cells are actively dividing or have entered the G_{1b} phase of the cell cycle. A major limiting factor affecting the transduction efficiency is the local concentration of vector particles (Chuck et al., 1996; Haas et al., 2000). The transduction efficiency is therefore not increased under static incubation conditions by increasing the volume of the vector supernatant (Morgan et al., 1995).

Transduction of Nonadherent Cells

Nonadherent cells are transduced by incubating vector particles with the cells in presence of polybrene or protamine sulfate on CH-296 recombinant fibronectin fragment (Moritz et al., 1994; Donahue et al., 2001). In addition, transduction of nonadherent cells has been shown to be significantly enhanced by centrifugation, i.e., spinoculation (Kotani et al., 1994; Bahnson et al., 1995).

Materials

- Adherent *or* nonadherent target cells
- Appropriate serum-containing growth medium for transduction (see recipe)
- Vector preparation (Basic Protocols 3 or 4 or Alternate Protocols 1 or 2)
- 6 mg/ml (1000×) polybrene stock
- 4 mg/ml (1000×) protamine sulfate stock
- Recombinant fibronectin fragment CH-296 (RetroNectin; Takara Shuzo)
- 2% (w/v) bovine serum albumin (BSA) in phosphate-buffered saline (PBS; APPENDIX 2)
- 30-mm tissue culture dishes (for adherent cells), 35-mm suspension culture dishes (for nonadherent cells), or 6-well tissue culture plates (for transduction of nonadherent cells using recombinant fibronectin fragment)
- 14-ml round-bottom polypropylene centrifuge tubes
- Tabletop centrifuge
- Additional reagents and equipment for cell culture and counting cells (APPENDIX 3F)

To transduce adherent cells

- 1a. Culture the target cells in appropriate serum-containing growth medium (e.g., DMEM containing 10% heat-inactivated FBS).
See APPENDIX 3F for general cell culture procedures.
- 2a. Split cells 8 hr prior to transduction and seed 2.5×10^5 cells in a 35-mm tissue culture dish.
- 3a. Remove supernatant and add vector particles in the presence of 6 µg/ml polybrene (added from 1000× polybrene stock). Incubate for 4 hr.
- 4a. Add 3 ml fresh medium to the cells. Allow 24 to 48 hr before measuring transduction efficiencies.

For most cell types the polybrene-containing medium does not need to be removed, as the addition of the fresh medium dilutes out the polybrene. However, if one is working with a cell type that is very sensitive to polybrene, the polybrene-containing medium can be removed before adding the fresh medium.

To transduce nonadherent cells by spinoculation

- 1b. Culture the target cells in appropriate serum-containing growth medium (e.g., IMDM containing 10% heat-inactivated FBS).
- 2b. Resuspend 5×10^5 cells in 1 ml of lentiviral vector particles in the presence of 6 $\mu\text{g/ml}$ polybrene or 4 $\mu\text{g/ml}$ protamine sulfate (added from corresponding 1000 \times stock) in a 14-ml round-bottom polypropylene centrifuge tube.
- 3b. Centrifuge 2 hr at $2000 \times g$, room temperature, to perform spinoculation. Resuspend the cell pellet in 1 ml of fresh medium and incubate overnight.
- 4b. Repeat the spinoculation (steps 2b and 3b) once a day for 2 days.

To transduce nonadherent cells using recombinant fibronectin fragment

- 1c. Prepare a stock of 9.6 mg/ml recombinant fibronectin fragment in sterile deionized, distilled water. Dilute the stock to final concentration of 9.6 $\mu\text{g/ml}$ with PBS.
- 2c. Place 1 ml of the diluted solution of recombinant fibronectin fragment in each well of a 6-well tissue culture plate and incubate for 2 hr at room temperature.
- 3c. Remove the fibronectin solution and add 1 ml of 2% BSA in PBS. Incubate for 30 min at room temperature to block. Remove the BSA solution and rinse with PBS once.

The blocking step prevents nonspecific binding.

- 4c. Add $0.5\text{--}1 \times 10^6$ cells per well. Allow at least 2 hr for the cells to attach, carefully remove the supernatant, and then add 1 ml of growth medium containing the vector particles (to completely cover the cells). Incubate overnight.

Spinoculation and overnight transduction on fibronectin can be combined to maximize transduction efficiency. Cells can be transduced by spinoculation followed by overnight culture in fresh vector-containing medium on fibronectin-coated plates, and the combined process can be repeated if necessary.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

293T cell growth medium

Dulbecco's modified Eagle's medium (DMEM) supplemented with:

10% heat-inactivated fetal bovine serum (FBS)

2 mM L-glutamine

50 U/ml penicillin

50 $\mu\text{g/ml}$ streptomycin

Store up to 1 month at 4°C

CaCl₂, 2.5 M

Dissolve 183.7 g CaCl₂ dihydrate (tissue culture grade) in deionized, distilled water and make volume up to 500 ml. Filter sterilize through a 0.22- μm nitrocellulose filter and store indefinitely at -20°C in 50-ml aliquots (can be frozen and thawed repeatedly).

HEPES-buffered saline (HeBS) (2 \times)

16.4 g NaCl (0.283 M final)

11.9 g HEPES acid (0.023 M final)

continued

**Protein
Expression**

16.22.11

0.21 g Na₂HPO₄ (1.5 mM final)
H₂O to 1 liter
Titrate to pH 7.05 with 5 M NaOH
Filter sterilize and store indefinitely at –20°C

HEPES stock solution, 1 M (100×)

Weigh 238.3 g HEPES and add water to 1 liter. Filter sterilize and store up to 6 months at 4°C.

Sodium butyrate stock solution, 500 mM

Prepare 500 mM sodium butyrate. Adjust pH to 7.0 with 10 N NaOH. Sterilize the solution by 0.22-μm filtration and store up to 6 months at 4°C.

Serum-containing growth media for transduction (Basic Protocol 7 and Alternate Protocol 3)

Dulbecco's modified Eagle medium (DMEM; for adherent cells) or Iscove's modified Dulbecco's medium (IMDM; for nonadherent cells), supplemented with:

10% (v/v) heat-inactivated FBS

2 mM L-glutamine

50 U/ml penicillin

50 μg/ml streptomycin

Store up to 1 month at 4°C

These media are given as examples; depending upon the cell type other serum-containing media may be appropriate.

COMMENTARY

Background Information

Although stable lentiviral producer cell lines have been developed, transient transfection of human 293T cells is the most widely used strategy to generate lentiviral vector particles. The 293T cell line is a derivative of 293 cells, human embryonic kidney cells transformed by the early region of adenovirus type 5 (Graham et al., 1977), into which the gene for a temperature-sensitive version of the simian virus 40 (SV-40) large T tumor antigen has been inserted (DuBridge et al., 1987). SV40 T antigen stimulates replication of plasmids containing the SV40 origin of replication. The facile transfectability of 293T cells coupled with SV40 T antigen-mediated extrachromosomal amplification of HIV-1 vector plasmids makes these cells particularly well suited for transient production of HIV-1-based lentiviral vector particles. In addition to obviating toxicity problems associated with high-level stable expression of HIV-1 proteins, this transient means of producing VSV-G-pseudotyped lentiviral vectors also circumvents difficulties associated with constitutive expression of the VSV-G envelope glycoprotein, which is fusogenic and causes syncytium formation.

As discussed in *UNIT 16.23*, most current-generation HIV-1-based vectors contain a strong constitutive internal promoter to drive transgene expression. For certain applications, it may be desirable to substitute tissue-specific or regulatable promoter sequences. In addition, a selectable marker gene is frequently incorporated into the transfer vector. Inclusion of a selectable marker gene as a reporter allows identification and/or selection of stably transduced cells. Among the commonly used selectable marker genes are the neomycin-resistance (*neo*) gene, the β-galactosidase (*lacZ*) gene, and the enhanced green fluorescent protein (EGFP) gene (Hawley et al., 2001a). Recently, a red fluorescent protein gene (drFP583) was isolated from a nonbioluminescent reef coral (Matz et al., 1999). The subsequent development of rapidly maturing versions of the drFP583 gene (Bevis and Glick, 2002) and flow cytometry protocols to simultaneously analyze up to four fluorescent proteins (Hawley et al., 2001b) provides the opportunity for facile comparative analysis of multiple constructs or other experimental variables. To express a selectable marker gene in conjunction with a gene of interest, internal ribosome entry site (IRES)

sequences are frequently utilized to generate bicistronic transcripts. The IRES sequence, which is inserted between the two genes, confers cap (m7pppGN)-independent translational initiation of the second gene through formation of a stem-loop structure and a stretch of pyrimidine-rich sequences near the internal AUG codon (Jang and Wimmer, 1990). The most commonly used IRES sequences are those derived from the picornaviruses encephalomyocarditis virus and poliovirus (Adam et al., 1991; Ghattas et al., 1991).

Critical Parameters

During transient transfection, vector particle production peaks on days 2 and 3 post-transfection and drops significantly after day 4. If the vector particles are to be used without further concentration, the optimal time to collect the supernatant is 48 hr post-transfection. If vector particles are to be concentrated by the ultracentrifugation method, the supernatants should be collected on two consecutive days. The supernatants collected on day 1 should be stored at 4°C until they are pooled with the day 2 supernatants for concentration.

When using EGFP as a reporter gene, allow ~72 hr before determining the transduction efficiencies by flow cytometry to ensure that all transduced cells are expressing EGFP at detectable levels. Analysis at this time point also minimizes the contribution of false positive signals due to pseudotransduction, which is the direct transfer of EGFP protein present in the vector supernatants or incorporated into the vector particles to the target cells (Liu et al., 1996). When determining lentiviral vector titers with reporter genes, it is also important to be aware of the fact that transgenes can be transiently expressed from unintegrated lentiviral vectors for 8 to 10 days, although generally at lower levels than from integrated vectors (Haas et al., 2000).

Troubleshooting

Low vector titers are often caused by inefficient transfection of 293T cells. Transfection efficiency can vary significantly and depends on several factors including the following. (1) When the 293T cells are plated for transfection, they must be trypsinized well to prevent clumping and allow formation of a uniform monolayer. Cells should be 50% to 70% confluent at the time of transfection. (2) Plasmid DNA of high purity and quality is crucial to achieve high-efficiency transfection. DNA concentra-

tion and quality should be determined by spectrophotometric analysis and gel electrophoresis. Commercially available plasmid DNA extraction kits can be used to obtain highly purified supercoiled plasmid DNA. Prior to transfection, the DNA should be sterilized by ethanol precipitation. The air-dried pellet is then resuspended in sterile deionized, distilled water. (3) The pH of the 2× HeBS solution is particularly critical and should be exactly 7.05. It is important to bubble the 2× HeBS solution with air as the DNA/CaCl₂ solution is added dropwise. Once added to the cells, a fine precipitate should develop that is readily visible under the microscope.

Vector titers are also influenced by the stability of the vector particles, which is affected by factors such as temperature, pH, freeze-and-thaw frequency, and incubation conditions. VSV-G-pseudotyped HIV-1 vector particles have a half-life of 10.4 ± 1.2 hr at 37°C, 1 to 2 days at room temperature, and ~1 week at 4°C (Higashikawa and Chang, 2001). Changes in pH can dramatically affect vector stability. Although VSV-G-pseudotyped HIV-1 vectors are stable at pH 7.0, their half-life at pH 6.0 or 8.0 is <10 min (Higashikawa and Chang, 2001). In order to prevent pH changes in vector supernatants, add HEPES buffer to the 293T medium at a final concentration of 10 mM.

Anticipated Results

Transfection efficiencies of 293T cells should be in the range of 60% to 80%. A typical vector carrying a 3- to 4-kb transgene should produce a titer of $\sim 10^6$ to 10^7 TU/ml following transient transfection of 293T cells. Titers can be routinely increased to 10^9 TU/ml by concentrating the vector supernatants. Expect a 50% to 75% recovery following vector concentration. Titers will generally be lower with inserts greater than 5 kb. A titer of 10^8 TU/ml should allow efficient transduction of most cell types.

Time Considerations

Although developing and testing new lentiviral vectors can be considerably time-consuming, it should not take more than a few hours a day over a period of less than a week to subclone a DNA fragment into an existing lentiviral vector backbone. Generation of vector particles by transient transfection requires 4 to 5 consecutive days. Concentrating and purifying the vector particles requires 2 to 4 days, titering takes 3 to 10 days, and testing for RCR entails a couple of weeks.

The ability to select for integration of plasmid DNA into the host chromosome allows the generation of stably transfected cell lines. With transfection of a selectable marker linked to a nonselectable target gene (or by cotransfection of the two unlinked genes), high-level expression of the desired gene is obtained by selecting for amplification of the selectable marker.

This unit presents two systems for gene amplification and expression. The first (see Basic Protocol 1) describes the dihydrofolate reductase (DHFR) selection system while the second (see Basic Protocol 2) is based on selection of the glutamine synthetase (GS) gene. The DHFR system is probably more widely used, and results in very high levels of amplification (up to 1000 copies per cell in some cases) and expression; however, the DHFR amplification process is lengthy and may require several months to isolate and characterize a stable, amplified line. In contrast, the GS system typically requires only a single round of selection for amplification to achieve maximal expression levels. In this system the length of time necessary to isolate stably amplified clones from the primary transfectants is dramatically reduced to 2 months or less.

AMPLIFICATION USING DIHYDROFOLATE REDUCTASE

The pED series of dicistronic vectors (Fig. 16.23.1) can be used to obtain high-level expression of a targeted gene in stably transfected cells. These vectors carry a cloning sequence for insertion of the target gene followed by the selectable and amplifiable marker gene, dihydrofolate reductase (DHFR). Alternatively, a plasmid expressing the gene of interest and a plasmid expressing DHFR can be cotransfected. DHFR-deficient CHO cells transformed with the appropriate vector(s) are selected by ability to grow in nucleoside-free medium. Subsequent selective cycling in the presence of increasing concentrations of methotrexate (MTX)—a potent inhibitor of DHFR function—results in amplification of the integrated DNA and increased expression of the desired gene product.

Materials

pED (Kaufman et al., 1991) expressing appropriate cDNA; *or* pCVSVEII-DHFR or pAd26SV(A) (Kingston et al., 1984; Kaufman and Sharp, 1982a) and a separate vector expressing appropriate cDNA

CHO DXB11 or CHO DG44 cell lines (available from Lawrence Chasin, Columbia University) or CHO GRA (available from Randal Kaufman, University of Michigan)

Complete ADT medium (see recipe)

10% glycerol

Dialyzed fetal bovine serum (FBS; see recipe)

Complete α^- medium (Life Technologies) with 10% dialyzed FBS

Sterile vacuum grease

0.05% trypsin/0.6 mM EDTA in PBS (see APPENDIX 2 for PBS), 37°C

2% methylene blue in 50% ethanol (optional)

5 mM methotrexate (see recipe)

Cloning cylinders (see recipe)

Additional reagents and equipment for subcloning (UNIT 3.16), and either CaPO₄-mediated transfection (UNIT 9.1), electroporation (UNIT 9.3), or liposome-mediated transfection (UNIT 9.4)

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise indicated.

BASIC PROTOCOL 1

Protein Expression

16.23.1

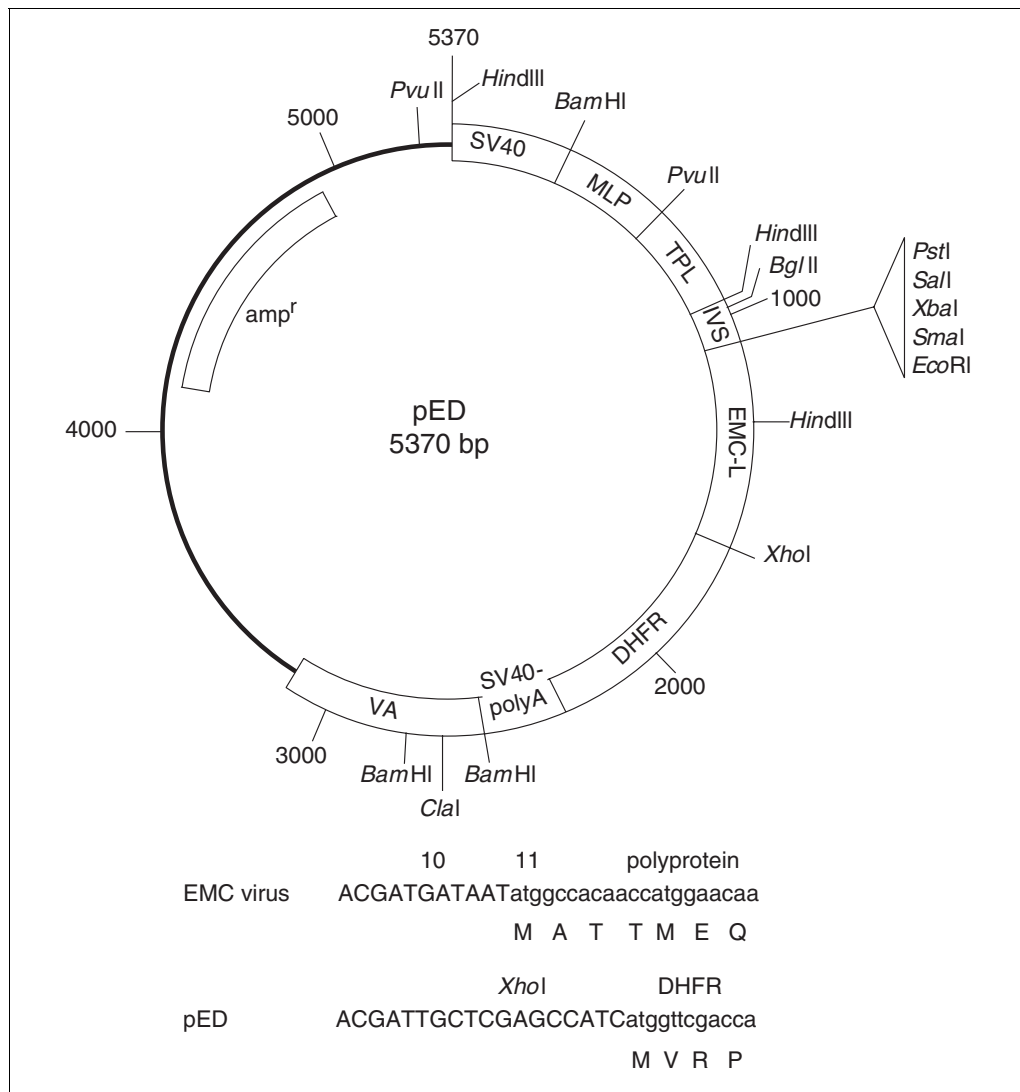

Figure 16.23.1 Map of dicistronic mRNA expression vector pED. The components of the 5360-bp pED expression vector in the pUC18 background are indicated as follows: SV40, *HindIII*-*PvuII* fragment containing the SV40 origin of replication and enhancer element; MLP, adenovirus major late promoter from the *XhoI* site (15.83 map units, m.u.) to the 5' cap site (16.55 m.u.); TPL, 180 bp of the first two and $\frac{2}{3}$ of the third leaders from adenovirus major late mRNAs; IVS, a hybrid intron composed of the 5' splice site from the first leader of adenovirus major late mRNAs and a 3' splice site from an immunoglobulin gene; *PstI* and *EcoRI* unique cloning sites; EMC-L, the 5' untranslated leader from EMC virus (nucleotides 260-827); DHFR, a murine DHFR coding region; SV40-polyA, the SV40 early polyadenylation signal; VA, the adenovirus VAI RNA gene from the *HpaI* (28.02 m.u.) to the *BalI* (29.62 m.u.); and β -lactamase, a selectable gene for propagation in *E. coli*. Below is indicated the sequence junction of the EMC-L and DHFR as compared to the context of the AUG 11 which is initiation codon for the EMC virus polyprotein. A unique *XhoI* restriction site is available for insertion of other coding regions to be translated from the EMC virus leader. Adapted with permission from IRL Press.

Transfect CHO cells

1. The day before transfection, split a confluent dish of CHO cells 1:15 in complete ADT medium.
2. Transfect the cells with 5 to 10 μg plasmid DNA (per dish) from step 1, using either electroporation (UNIT 9.3), the calcium phosphate technique (UNIT 9.1), or liposome-mediated transfection (UNIT 9.4).

The calcium phosphate treatment followed by glycerol shock works well for CHO DXB11 cells. A 3-min shock with 10% glycerol should be performed 4 to 6 hr after the DNA precipitate is placed on the cells. The gene can then be introduced into pED that also contains a DHFR gene. Alternatively, if a pED vector is unavailable, it is possible to introduce the desired gene by cotransfection using two separate plasmids. In this latter case, transfected DNA should contain the plasmid whose amplification is desired and a plasmid expressing the DHFR gene from a strong promoter [e.g., pCVSVEII-DHFR or pAdd26SV(A)]. Use a 5:1 molar ratio of the gene of interest to the DHFR gene.

It is not necessary to physically link the DHFR gene to the gene whose amplification is desired. The two genes will integrate in the same region of the chromosome and will coamplify (Kaufman and Sharp, 1982b). Using one-fifth the molar amount of the DHFR gene makes it likely that most of the selected cell lines will contain the gene of interest in an intact form as well as the DHFR gene.

- 3a. *For cells transfected by electroporation or calcium phosphate:* Allow the cells to reach confluence after transfection (this should occur after 2 to 3 doublings in 2 days.) Split each dish 1:15 into α^- medium containing 10% dialyzed FBS (complete α^- medium).
- 3b. *For cells transfected using liposomes:* Add 5 ml complete α^- medium and incubate overnight. Remove medium, wash twice with 37°C PBS, add 5 ml complete α^- medium, and incubate 2 days. Dilute cells 1:10 or 1:15 into complete α^- medium without ADT.

Complete α^- medium (containing no added nucleosides) is a selective medium, as cells need DHFR to synthesize necessary nucleosides. Use of dialyzed serum is necessary to avoid addition of nucleosides present in normal FBS. Note that methotrexate is not needed for selection.

4. Incubate cells 10 to 12 days if proceeding from step 3a or 14 days if proceeding from step 3b. Move the dishes as infrequently as possible during this time to prevent formation of sibling colonies.

Cells can float away from their original colonies, land elsewhere on the dish, and produce a colony of their own. This should be minimized, as picking and analyzing two such sibling colonies is inefficient (they presumably are identical).

Pick stable colonies

5. At a time point 10 to 14 days after placing the cells in selective medium, check the dishes for colonies by holding the dish above one's head at an angle with respect to the overhead lights and looking for opaque patches. Circle such patches with a laboratory marker so that they can easily be located and examined in the phase-contrast microscope.

In order to determine how well the transfection worked, one of the transfected dishes can be stained with methylene blue. To stain, first aspirate off the medium, then place ~2 ml of a 2% methylene blue solution (made up in 50% ethanol) on each dish. Wait 2 min, then pour the dye solution off and wash off the residual methylene blue by dipping the dish in a bucket of cold water. In order to have good success picking colonies for stable lines, each dish should have several heavily staining colonies as well as 10 more smaller colonies.

6. Select the colonies to be picked. Circle the chosen colonies with a laboratory marker to determine where to place the cloning cylinders.

Choose only large, healthy colonies. Colonies should have ~500 cells, and the cells should appear to be compact and polygonal. Colonies with many flat and spread-out cells should be avoided, as this morphology indicates that they are not making very much DHFR. Pick ~20 colonies so that in the end there will be many stably transfected cell lines available for amplification. Keep track of which dish a colony comes from, as colonies from the same dish may be siblings. This is most easily done by numbering the dishes and using that number in the name of the colony that has been picked.

It is also possible at this point to pool large numbers of transformants that have integrated the vector into different sites. Because different integration sites have quite different potentials for amplification, one can use sequential increases in MTX resistance to select cells rapidly that have amplified the gene to high copy number.

7. Coat one end of a cloning cylinder with sterile vacuum grease by touching the cylinder to grease that has been autoclaved in a glass petri dish. Gently place the cylinder around the colony to be picked (Fig. 16.23.2).

Make certain that there is not too much grease on the end of the cloning cylinder—use a sufficient amount of grease to form a thin film between the cloning cylinder and the tissue culture dish, but do not allow the grease to cover any of the colony. The cloning cylinder is most easily positioned using bent forceps sterilized by flaming in ethanol immediately prior to use.

8. Using a sterile Pasteur pipet, rinse the colony with 37°C 0.05% trypsin/0.6 mM EDTA by filling and emptying the cloning cylinder (Fig. 16.23.2).

Care must be taken to avoid knocking the cylinder over, and also to avoid scraping cells off the colony with the end of the Pasteur pipet. Hold the Pasteur pipet as close to vertically as possible in order to avoid knocking over the cloning cylinder. A little trypsin can be left in the well after rinsing.

9. Add 3 drops of 37°C trypsin/EDTA to the cloning cylinder. Wait 1 min. Fill the cloning cylinder with medium and repeatedly run the contents of the cylinder in and out through a Pasteur pipet in order to remove the trypsinized cells from the dish and disperse them. Plate the cells in a 40-mm dish.

Figure 16.23.2 Placement of cloning cylinder around CHO colony.

10. As the cells grow out, split them frequently (every 4 to 5 days or so) so that they do not form large colonies.

The central cells in large colonies do not fare well.

Amplify stable transfectant

Amplification is a long process. Before amplifying a stable transfectant, one should be sure that the gene of interest has indeed been integrated into the cell in a functional form. This can be done by examining the cellular DNA by Southern analysis (UNIT 2.9), by examining the cellular RNA (Chapter 4), or most easily in many cases by using a functional assay for the introduced protein. Some cell lines amplify more readily than others (chromosome location of the introduced DNA appears to play a role), and the gene of interest can rearrange or mutate during the process. These considerations make it prudent to amplify six or more stable transfectants or pools of cells containing the gene of interest at the same time.

11. Split a confluent dish of cells growing in complete α^- medium 1:6 into two dishes complete α^- medium supplemented with 0.005 μM methotrexate (added from 5mM methotrexate stock).

CAUTION: *Use gloves when handling methotrexate as it is carcinogenic.*

The addition of methotrexate to the medium increases the level of selection, as methotrexate is a potent inhibitor of DHFR. Empirically, 0.005 μM methotrexate requires ~4-fold more DHFR to be made in the cell than does complete α^- medium with no methotrexate. By splitting the cells into this medium, one is selecting for cells making elevated levels of DHFR. This is generally accomplished by increasing the copy number of the transfected DHFR gene.

12. The cells should grow to confluence fairly readily. When they do, split them 1:6 again.

The cells will probably grow more slowly and take on a flat, spread-out morphology. This indicates that they are starved for DHFR.

Cells grow well immediately after splitting into a higher level of methotrexate because they have an endogenous reserve of nucleosides that needs to be depleted before the selection takes place.

13. Keep splitting the cells 1:6 into complete α^- medium supplemented with 0.005 μM methotrexate. When their rate of growth increases and when they begin to take on a more normal morphology, increase the degree of the split to 1:8, then 1:10, then 1:15. When the cells grow to confluence in 3 days from a 1:15 split and have regained a polygonal morphology, perform the next amplification step.

It is possible that cells will immediately grow well in 0.005 μM methotrexate, indicating that they are already making enough DHFR to survive at this level of selection. If so, switch immediately to 0.02 μM methotrexate. Many researchers start out by placing the DHFR-containing cell line in 0.005, 0.02, and 0.05 μM methotrexate (at step 11) to see at what level the initial recombinant lines can survive.

14. Repeat the above process (steps 12 and 13) using complete α^- medium supplemented with 0.02 μM methotrexate.

15. Continue amplifying by increasing the level of methotrexate in the medium by 4-fold increments. Continue until the cells are growing in 20 to 80 μM methotrexate (the cells should now contain 500 to 2000 copies of the transfected gene).

Be sure to freeze samples of the cells at each amplification step to avoid having to go back to the beginning in the event of contamination. Each amplification step should take 3 to 4 weeks. Use of methotrexate levels above 80 μM does not result in much further amplification, as the ability of the cell to transport the drug becomes limiting.

AMPLIFICATION BY CLONING AT EACH SELECTIVE STEP

The above procedure is straightforward and does not require very much hands-on time. It does not, however, necessarily result in a clonal cell line at the end of each passage. The protocol requires a long time (9 to 12 months) to generate an amplified line. One may clone lines from the final amplified line to see whether some clones express more of a desired protein than others. Alternatively, one may amplify by cloning cells at every step and selecting for those that retain high levels of production of the protein of interest. This is a particularly attractive approach if the desired protein is secreted and easily assayed from the medium. This second approach may result in an overproducing line more rapidly, but it requires substantially more effort. If this approach is desired, substitute the following for steps 11 to 14 of Basic Protocol 1.

- 11a. Split a confluent dish of cells growing in complete α^- medium 1:15 into complete α^- supplemented with 0.02 μM methotrexate (8 dishes) and into complete α^- medium supplemented with 0.08 μM methotrexate (7 dishes). Feed every 4 days with the appropriate selective medium.

The goal of this step is to find individual cells that have amplified the DHFR gene enough to grow in a significantly higher level of methotrexate. These cells will expand into colonies during the 10- to 12-day incubation. As described in step 4, sibling colonies must be avoided, so dishes should be disturbed as little as possible.

- 12a. Check the dishes for colonies after 10 to 12 days and pick healthy colonies, as in steps 5 to 10 of the basic protocol.

- 13a. Expand the colonies and check for the level of expression of the desired product. Choose a colony that is producing good levels of the desired product, and repeat steps 11a and 12a using levels of methotrexate 16- and 64-fold higher than the level of methotrexate in which the colony is growing.

Each of these rounds will take ~1 month, and after three to four rounds, the cells should be growing in 80 μM methotrexate and contain highly amplified sequences.

AMPLIFICATION USING GLUTAMINE SYNTHETASE

In the glutamine synthetase (GS) gene amplification system, a cDNA or genomic coding sequence is inserted into the multilinker cloning site of the plasmid pEE14 (Fig. 16.23.3) such that it is expressed from the powerful hCMV promoter-enhancer. pEE14 also contains a glutamine synthetase gene that can be used as a dominant selectable marker in a variety of cell lines including CHO K1. The GS gene expressed from the plasmid confers resistance to a low level of the GS inhibitor methionine sulfoximine (MSX). CHO cells transformed with the vector are selected for lines containing increased numbers of copies of the vector using increased levels of MSX in a single round of amplification.

Materials

- Plasmid vector pEE14 (Celltech)
- Complete Glasgow modified Eagle medium containing 10% dialyzed FBS (complete GMEM-10; see recipe)
- CHO K1 cell line (ATCC #CCL61)
- 100 mM L-methionine sulfoximine (MSX; Sigma) prepared in PBS (see APPENDIX 2 for PBS; filter sterilize MSX solution and store in aliquots at -20°C ; handle carefully)

Figure 16.23.3 Map of pEE14 GS expression vector. pEE14 (~9.4 kb in length) contains a GS minigene as the selectable marker which has a single intron and GS polyadenylation signals and is driven from an SV40 late promoter. The hCMV-MIE promoter-enhancer and 5' untranslated region are used to express the gene of interest and the remainder of the plasmid contains an ampicillin-resistance gene and replication origin for replication in *E. coli*. The plasmid was constructed as follows. A 900-bp *EcoRI* fragment from the cDNA clone λ gs1.1 (Hayward et al., 1986) was assembled with a 3.4-kb *EcoRI*-*SacI* hamster GS genomic fragment from pGS1 (Sanders and Wilson, 1984), which provides the 3' end of the minigene. (The *SacI* site was converted to a *BamHI* site to facilitate vector construction.) The *EcoRI* site within the GS coding sequence was destroyed by site-directed mutagenesis without altering the amino acid sequence and a *HindIII* site in GS 3'-flanking DNA was destroyed by digestion with *HindIII*, filling in the single-stranded ends, and religation. A 340-bp SV40 late promoter (Cockett et al., 1990) was added to the 5' end as a *BamHI*-*EcoRI* fragment and the *EcoRI* site between the promoter and the GS sequences was destroyed by filling in. The resulting 4.5-kb *BamHI* fragment was inserted into pEE6hCMV (Stephens and Cockett, 1989) at a single *BglII* site upstream of the hCMV enhancer (hence destroying the *BglII* and *BamHI* sites) to form pEE14. The resulting SV40-GS minigene in pEE14 is functionally equivalent to that in pSVLGS.1 (Bebbington and Hentschel, 1987) but has been deleted of *EcoRI* and *HindIII* sites. Polylinker sequence of pEE14 is shown below.

Additional reagents and equipment for subcloning (UNIT 3.16), CaPO_4 -mediated transfection and glycerol shock (UNIT 9.1), and cloning by limiting dilution (UNIT 11.8)

NOTE: All tissue culture incubations are performed in a humidified, 37°C, 5% CO_2 incubator unless otherwise indicated.

1. Subclone the target gene into the appropriate site within the polylinker of plasmid pEE14 (Fig. 16.23.3).
2. Maintain CHO K1 cells growing exponentially in complete GMEM-10. The day

before transfection, trypsinize the cells and seed several 9-cm petri dishes at 10^6 cells per dish.

3. Introduce 10 μg circular plasmid DNA (per dish) from step 1 into the cells using calcium phosphate-mediated transfection followed by glycerol shock. “Mock”-transfect several plates without added DNA.
4. After 24 hr, replace the medium with fresh complete GMEM-10 containing MSX at a final concentration of 25 μM (selective medium).

CAUTION: MSX is toxic and should be handled carefully.

5. After 4 to 5 days, refeed the plates with fresh selective medium and wait for MSX-resistant colonies to appear, typically two weeks after infection.
6. Score the number of MSX-resistant colonies on transfected and “mock”-transfected plates.

There should be 20 to 30 colonies per plate on transfected dishes and <5 colonies per “mock”-transfected plate.

7. Isolate several independent transfected cell lines producing significant amounts of the desired product (see Basic Protocol 1, steps 6 to 11) for amplification using DHFR. Plate out each cell line on several petri dishes at a density of $\sim 10^6$ cells per dish in complete GMEM-10. Incubate 24 hr.

Whenever trypsinizing GS-selected cells, leave the cells for 24 hr to recover before reapplying MSX. In our experience, independent transfectants amplify more efficiently than pools of transfectants.

8. Replace the medium with fresh selective medium containing various concentrations of MSX, ranging between 100 μM and 1 mM.
9. Incubate the dishes 10 to 14 days, changing the medium once during this time.

After this time considerable cell death should have occurred and colonies resistant to the higher levels of MSX should have appeared. The maximum concentration of MSX at which colonies survive will depend on the particular initial transfectant, but is typically between 250 μM and 500 μM .

10. Isolate the colonies at the highest MSX concentration yielding several discrete colonies. The colonies can either be picked and assayed individually or all colonies from one initial cell line can be pooled and assayed together.

The increased production rate can be up to 10-fold in this first round of amplification. It is not normally appropriate to select for subsequent rounds of amplification because the production rate does not usually increase significantly at higher levels of MSX.

11. Clone the amplified cells with high production rates by limiting-dilution cloning.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Cloning cylinders

Glass or metal cloning cylinders can be purchased (e.g., stainless steel Penicylinders, Fisher). Place clean cylinders well rinsed in distilled water in 95% ethanol. Sterilize by flaming immediately prior to use. Alternatively, disposable cloning cylinders can be prepared by cutting off the fat end of a 200- μl pipettor tip ~ 1 cm from the large opening with a razor blade. Sterilize by autoclaving.

Complete ADT medium

α^- medium (Life Technologies) supplemented with:

- 10 μ g/ml adenosine (Sigma)
- 10 μ g/ml deoxyadenosine (Sigma)
- 10 μ g/ml thymidine (Sigma)
- 10% FBS

It is convenient to prepare stocks of the nucleosides for addition to the medium. Adenosine (1 mg/ml), deoxyadenosine (1 mg/ml), and thymidine (4 mg/ml) stocks are prepared using distilled water, and are filter sterilized.

Complete GMEM-10

Add the following in order given, using aseptic technique:

- 500 ml Glasgow modified Eagle medium (GMEM) without tryptose phosphate broth (Life Technologies, but made *without* glutamine; must be made to order as it is not a stock item)
- 5 ml 100 \times nonessential amino acids (Life Technologies)
- 5 ml G+A (see recipe)
- 5 ml 100 mM sodium pyruvate (Life Technologies)
- 10 ml 50 \times nucleoside mix (see recipe)
- 50 ml dialyzed FBS (see recipe)
- 5 ml of 5000 U/ml penicillin/streptomycin (Life Technologies)

It is essential to use dialyzed FBS when performing GS selection because serum contains significant amounts of glutamine.

Dialyzed fetal bovine serum (FBS)

Purchase dialyzed FBS from commercial supplier (e.g., Life Technologies or J.R.H. Biosciences) or prepare as follows:

1. Heat inactivate FBS at 56°C for 60 min.
2. Soak Spectrapor dialysis tubing (MWCO 6000 to 8000) in PBS (*APPENDIX 2*). Remove, rinse tubing, clip one end closed, and fill with the heat-inactivated FBS.
3. Dialyze (also see *APPENDIX 3C*) 6 to 8 hr in cold room against PBS. Change dialysis solution at least once.
4. Filter sterilize using a 0.02-mm filter and store frozen (–20°C) in 50-ml aliquots.

Glutamate + asparagine (G+A)

- 600 mg L-glutamic acid (Sigma)
- 600 mg L-asparagine (Sigma)
- H₂O to 100 ml
- Filter sterilize using a 2- μ m filter and store at 4°C

Methotrexate, 5 mM stock

Dissolve methotrexate to 5 mM in α^- medium (Life Technologies) and filter sterilize. Store at –20°C in a foil-wrapped container.

It is important to make a large 5 mM stock solution before starting amplification, then dilute that stock solution in α^- medium for the various levels of selective media. The potency of methotrexate can vary somewhat from lot to lot, making it desirable to use one stock throughout the amplification process.

CAUTION: *Methotrexate is a carcinogen and should be handled only with gloves and in a fume hood.*

Nucleoside mix, 50×

35 mg adenosine (Sigma)

35 mg guanosine (Sigma)

35 mg cytidine (Sigma)

35 mg uridine (Sigma)

35 mg thymidine (Sigma)

H₂O to 100 ml

Filter sterilize and store at -20° in 10-ml aliquots

COMMENTARY

Background Information

Gene amplification

When mammalian cells are placed in an environment that requires an increase in a normally constitutive gene product, cells that survive in many cases do so because of an increase in copy number of the gene. This process has been termed gene amplification and involves large regions of the chromosome, so that not only the selected gene becomes amplified, but the surrounding regions as well. Amplification was first detected when cells were treated with increasing concentrations of methotrexate, and the copy number of the resident DHFR gene was analyzed in the surviving cells (Alt et al., 1978). This observation, combined with the observation that cotransfected segments of DNA tend to integrate in the same chromosomal location (Wigler et al., 1978), has resulted in the ability to amplify any desired gene. Notable among the many reports of amplified genes in mammalian cells are *E. coli* XGPRT (Ringold et al., 1981), hepatitis B surface antigen (Christman et al., 1982), mouse *c-myc* (Wurm et al., 1986), tissue inhibitor of metalloproteinases using glutamine synthetase (GS) selection (Cockett et al., 1990), CD4 T lymphocyte glycoprotein (Davis et al., 1990), and human initiation factor 2 α using DHFR selection (eIF-2 α ; Kaufman et al., 1991).

Until recently, gene amplification was achieved by cotransfection of a vector carrying a selectable marker gene with another vector carrying the nonselectable gene of interest. In this process, called cotransformation, separate DNA molecules become ligated and cointegrate as a unit by nonhomologous recombination into the host chromosome (Wigler et al., 1978). Amplification of the region of DNA containing the selectable gene and the target gene is accomplished by incubating the cells in increasing amounts of a specific inhibitory drug. However, varying DNA transfection methods and cell lines can yield dramatically

different frequencies of cotransformation with different plasmids. Consequently, expression vectors have been developed that contain both the selectable gene and a transcription unit for the inserted target gene linked on the same plasmid. Various approaches in constructing these plasmids have been used to ensure adequate expression of both the selectable and nonselectable marker.

CHO cells

Many amplifiable selection markers are now available for use in mammalian cells (see Table 16.23.1; Kaufman, 1989, 1990). Although various cell lines (including monkey COS-1 and NIH 3T3) can be used for gene amplification, many protocols rely upon the use of Chinese hamster ovary (CHO) cells. The advantages of CHO cells for heterologous gene expression are (1) amplified genes that are integrated into host chromosome may be stably maintained, even in the absence of continued drug selection; (2) a variety of proteins have been expressed at high levels (Ringold et al., 1981; Cockett et al., 1990; Davis et al., 1990; Kaufman et al., 1991); and (3) volumes of CHO cells have been scaled up to >5000 liters. Two of the most successful strategies employing CHO cells—the dihydrofolate reductase (DHFR) and glutamine synthetase (GS) gene amplification systems—are described below.

Amplification using dihydrofolate reductase vectors

DHFR catalyzes the conversion of folate to tetrahydrofolate, which is required for purine, amino acid, and nucleoside biosynthesis. The folic acid analog methotrexate (MTX) binds and inhibits DHFR, causing cell death. Surviving populations of cells exposed to sequentially increasing concentrations of MTX contain increased levels of DHFR that result from gene amplification. The pED (DHFR) vector produces a transcript containing the target gene in the 5' position and the selectable marker in the

Table 16.23.1 Amplifiable Markers for Mammalian Cells^a

Selection	Gene
Adenosine, alanosine, and 2'-deoxycoformycin	Adenosine deaminase
Adenine, azaserine, and coformycin	Adenylate deaminase
β-aspartyl hydroxamate or albizzin	Asparagine synthetase
PALA	Aspartate transcarbamoylase
Methotrexate	Dihydrofolate reductase
Methionine sulfoximine	Glutamine synthetase
Cadmium	Metallothionein
α-difluoromethylornithine	Ornithine decarboxylase
Multiple drugs	P-glycoprotein 170
6-azauridine or pyrazofuran	UMP synthetase
Mycophenolic acid	Xanthine-guanine phosphoribosyltransferase

^aAdapted with permission from Academic Press.

3' position of the transcript. This vector has been optimized for translation of the selectable gene in the 3' position by use of specific sequences from the encephalomyocarditis (EMC) virus that promote internal ribosome binding and translation initiation (Kaufman et al., 1991). The development of CHO cell lines (e.g., CHO DG44) that are deleted for the endogenous DHFR genes greatly increases the ease of amplification using DHFR (Urlaub and Chasin, 1980; Urlaub et al., 1983). Amplification of exogenous genes has been accomplished either by using cells and vectors that express a normal DHFR gene (Ringold et al., 1981; Kaufman and Sharp, 1982a; Kaufman et al., 1991), or by using vectors that encode a DHFR gene partially resistant to methotrexate and normal CHO cells (Christman et al., 1982; Kaufman et al., 1991).

Amplification using glutamine synthetase vectors

GS provides the only pathway for synthesis of glutamine in mammalian cells (using glutamate and ammonia as substrates); thus, in a glutamine-free medium, GS is an essential enzyme. CHO cells contain endogenous GS enzyme, but concentrations of methionine sulfoximine (MSX) in excess of 20 to 25 μM are sufficient not only to inhibit wild-type levels of GS but also to prevent the growth of the majority of natural variants that arise by amplification of the endogenous GS genes. Hence, essentially all nontransfected cells are killed when grown in media containing MSX at these levels. The

GS vector pEE14 carries both the selectable GS marker and the nonselectable target gene, each transcribed from a separate promoter. The target gene is cloned into the multilinker cloning site with transcription initiating from the powerful human cytomegalovirus (hCMV-MIE) promoter-enhancer sequence, while transcription of the GS gene is driven from an SV40 late promoter (Cockett et al., 1989). The GS “minigene” in pEE14 permits sufficient GS expression to allow transformants to survive at low levels of MSX, and increased levels of MSX select cells that have undergone amplification of vector sequences integrated into the cell genome. The appropriate choice of MSX concentration for initial selection together with the use of a weakly expressed GS gene typically selects cell lines containing multiple copies of the vector. The combination of the hCMV promoter to drive the gene of interest and the GS-selection system usually provides relatively high levels of expression after only a single round of selection following gene amplification.

Critical Parameters

For this approach to be successful, the gene of interest must be integrated in a functional form in the original cell line. It is also crucial that the gene of interest not rearrange during amplification. These two criteria may be difficult to achieve if the expressed gene is cytotoxic when overproduced. This problem can be circumvented by expressing the gene of interest from an inducible promoter and thus amplify-

ing the gene in an "off" state (Wurm et al., 1986).

The key to obtaining high-level expression in primary transfectants is to screen as many as possible (typically ~100 lines) since the site of integration of the vector in the host cell genome has a profound influence on expression levels. To get good results on amplification, it is also important to screen a number of lines (e.g., 5 to 10 high producers), as again the integration site influences the frequency of amplification. Once high-producing lines have been isolated, it is often useful to reclone these to ensure a homogeneous population of cells, in order to increase the likelihood that the productivity will be maintained over long periods of culture. The selective agent should be present throughout these procedures and only when frozen stocks of recloned amplified cells have been secured may selection be relaxed, if it is important to choose lines that are stable without selective agent. Finally, it may again be necessary to screen a number of lines to identify ones that are stable without selective agent.

Anticipated Results

Dihydrofolate reductase. Cell lines containing >100 copies of an exogenous gene can be produced. The levels of mRNA and protein obtained depend upon the target gene to be expressed, but can constitute up to 5% of total protein synthesis (Kaufman, 1991).

Glutamine synthetase. Introduction of pEE14-based vectors using the CaPO₄-mediated transfection usually leads to multiple copies of the vector becoming integrated in the genome (up to 200 copies). The copy number can increase up to 30-fold in one round of selection for amplification (Cockett et al., 1989). The amount of product made depends both on the individual transfectant and on the protein being expressed, but can be up to 10 µg protein/10⁶ cells per 24-hr period from primary transfectants for some proteins. On amplification, protein expression can parallel the increase in copy number but is likely to reach a plateau, usually after a single round of amplification for many secreted proteins, probably because the secretion apparatus is saturated. Final yields of secreted proteins from overgrown cultures have been 180 mg/liter for tissue inhibitor of metalloproteinases (TIMP), and up to 120 mg/liter for secreted variants of the rat CD4 protein (Davis et al., 1990). pEE14 has also been used successfully to express an integral membrane protein (Harfst et al., 1992).

Time Considerations

DHFR. Transfection and detection of stably transformed colonies takes 2 weeks. It will take ~2 additional weeks to expand the colonies and analyze them to ensure that they contain the gene of interest. Amplification of the resultant stable lines may take up to 6 months by the standard protocol. If cells are cloned at every step, as described in the alternate protocol, the amplification process can take as little as 3 months.

GS. Transfection and analysis of initial cell lines takes ~4 weeks (as for DHFR selection). Selection for vector amplification and screening of resultant cell lines typically takes an additional 4 to 6 weeks; there is usually no advantage in undergoing further rounds of selection.

Helper-Dependent Adenoviral Vectors

UNIT 16.24

Helper-dependent adenoviral vectors (HDAds) have improved the safety profile and greatly prolonged transgene expression compared with early-generation adenoviral vectors (Ads). HDAds contain only Ad *cis* elements necessary for vector genome replication and packaging into the capsid. Other factors are supplied in *trans* by a helper virus. In its preparation, it is important to ensure that the HDAd is free of contamination by helper virus, a first-generation Ad.

A summary of the HDAd strategy is shown in Figure 16.24.1. The first step is to subclone the expression cassette of the gene of interest into a shuttle vector (e.g., p Δ 21, p Δ 28, pC4HSU), which contains stuffer DNA in order to keep vector genome within a size that allows for efficient packaging (27 to 38 kb; Sandig et al., 2000; Kim et al., 2001; Oka et al., 2001). The second step is to rescue the HDAd by transfecting a linearized shuttle vector into a packaging cell line expressing a sequence-specific recombinase (i.e., Cre or FLP). Infection with a helper virus follows, to supply the necessary components for HDAd genome packaging into the capsid. The most commonly used protocols depend on the popular Cre-*loxP* recombinase system to minimize packaging of the helper. The third step is serial vector amplification. The final step is the large-scale vector production followed by purification.

Basic Protocol 1 provides detailed instructions for generating recombinant HDAds using the Cre-*loxP* system. Basic Protocol 2 describes large-scale production and purification of HDAd. Support Protocol 1 describes monitoring of vector amplification by Southern blot analysis. Support Protocol 2 provides a DNA-based method for determining HDAd titer, as HDAds do not form plaques upon infection of 293 cells. Helper virus contamination severely compromises the advantages of HDAds, and can be monitored by a real-time PCR-based method described in Support Protocol 3.

The components of a standard Cre-*loxP* based HDAd production system include: HDAd shuttle vector, pC4HSU, a helper virus H14, 293Cre4 packaging cell line. These components, and 293 and 293N3S cells are available for academic researchers through Microbix (<http://www.microbix.com/>). The 293 cells can also be obtained from ATCC.

293, 293N3S, PERC6, or N52.E6 cells are used only for helper virus amplification or plaque purification. They are not used to produce HDAd vectors. 293Cre66 cells can be used throughout HDAd vector production (transfection, serial passage, and large-scale production). 293Cre66S (suspension) cells are used only in large-scale production. 116 cells can be used throughout vector production.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO₂ to maintain pH 7.4.

BIOSAFETY

According to the National Institutes of Health biosafety guidelines based on risk assessment, manipulations on human adenoviruses should be performed in a laboratory operating at Biosafety Level 2 (BL-2) as approved by the user's Institutional Biosafety

Committee. The requirements include the use of laminar flow hoods, the establishment of proper procedures for decontamination and disposal of liquid and solid waste, and the disinfection of contaminated surfaces and equipment.

STRATEGIC PLANNING

Vector Design

The size of the transgene insert of HDAd must be between 27 and 38 kb for efficient packaging. Smaller inserts can be packaged as head-to-tail and tail-to-tail concatamers within this size limit (Parks and Graham, 1997). If necessary, stuffer DNA is inserted into the vector construct to bring the insert size to the packageable range (Fig. 16.24.1). The nature of stuffer DNA influences efficiency of transgene expression. Fully characterized DNA of mammalian origin that does not contain any genes or repetitive sequences should be used, in order to avoid rearrangement during serial passages and to prevent any possible effects on transgene expression. The presence of matrix attachment sites in the HDAd enhanced transgene expression in one study (Schiedner et al., 2002), but not in another study (Ehrhardt and Kay, 2002). Since HDAd contain no viral coding sequence, transgene expression is largely independent of the orientation and only marginally influenced by the location of the transgene cassette within the vector genome (Schiedner et al., 2002). HDAd containing natural genes appear to have more sustained transgene expression than those containing cDNAs driven by heterologous promoters (Kim et al., 2001; Schiedner et al., 2002). However, long-term transgene expression (>1 year) has been reported in constructs using a heterologous promoter (Soudais et al., 2003; Nomura et al., 2004). Factors that regulate duration of expression are complex and poorly understood. Target-tissue-specific promoters are preferable to ubiquitous promoters for sustained transgene expression, and the use of promoters active in antigen-presenting cells should be avoided to minimize the generation of antibodies against transgene products. The inclusion of the first 400 bp from the right end containing the E4 promoter without any coding sequence into an HDAd vector has been reported to increase vector production efficiency either by enhancing replication or packaging of the vector DNA (Sandig et al., 2000). The authors of this unit have found that inclusion of the element gives inconsistent results, though its presence does not negatively impact viral production, and they usually include it in the standard vector design. Another popular element to increase transgene expression is the

Figure 16.24.1 (at left) Strategy for the construction of helper-dependent adenoviral vector (HDAd) using a helper virus. A simple strategy starts with the subcloning of expression cassette of a gene of interest into an intermediate cloning vector (e.g., pLPBL1), which contains the multiple cloning site (MSC) flanked by *Ascl* sites (Oka et al., 2001). The expression cassette should contain either promoter, cDNA, and polyadenylation signal, or the entire gene. The second step is to subclone the resulting expression cassette into HDAd shuttle vector (e.g., p Δ 28, p Δ 21, and pC4HSU; Sandig et al., 2000; Kim et al., 2001; Oka et al., 2001). It is important to maintain the size of HDAd shuttle vector between 27 and 38 kb (excluding the 3-kb plasmid backbone) for efficient packaging. In addition, the nature of stuffer DNA influences the degree and duration of transgene expression, as well as vector rearrangement during serial passages (Parks and Graham, 1997; Sandig et al., 2000). The HDAd shuttle vector containing the expression cassette is linearized with *PmeI* to release the plasmid backbone, and transfected into 293 or an equivalent E1-complementing cell line expressing Cre recombinase (293 Cre cells). After transfection, 293Cre cells are infected with helper virus, a first-generation E1-deleted Ad vector containing the packaging signal flanked by *loxP* sequences. Infection of 293Cre cells with the helper virus results in excision of its packaging signal. Although the helper virus genome continues to provide all of the components necessary for replication and packaging, the helper virus genome cannot be packaged. Instead, the genome of HDAd vector containing essential *cis*-acting elements (viral packaging signal and inverted terminal repeats) introduced into cells by transfection is replicated and packaged into Ad particles. Abbreviations: RITR, right inverted terminal repeat; Ψ , packaging signal; LITR, left inverted terminal repeat; HPRT, intron region of human genomic HPRT stuffer sequence; C346, cosmid C346 human genomic stuffer sequence.

woodchuck hepatitis virus post-transcriptional regulatory element (WPRE), a *cis*-acting element that increases the amount of unspliced RNA in both the nuclear and cytoplasmic compartments (Donello et al., 1998). The insertion of WPRE in the 3' untranslated region upstream to the polyadenylation signal is a useful strategy to increase transgene expression without affecting promoter specificity. However, the authors of this unit have obtained inconsistent results with this strategy.

Cloning Genes of Interest into Shuttle Vectors

The transgene construct containing the appropriate promoter is cloned into an HDAd shuttle vector. HDAd shuttle vectors contain several unique cloning sites. A simple method to clone the gene into a shuttle vector is by using an additional cloning vector (e.g., pLPBL-1; Oka et al., 2001) in which the expression cassette is constructed and excised using compatible unique restriction enzyme sites (e.g., *AscI* or *SwaI* for p Δ 28; *AscI* for p Δ 21; and *AscI*, *SwaI*, or *NotI* for pC4HSU). In this approach, the expression cassette should not have an internal *AscI*, *SwaI*, *NotI* or *PmeI* site. *PmeI* is used to linearize the shuttle vector prior to transfection.

If one cannot apply such an approach, the cloning can be done by employing partial digestions, blunt-end ligation, or recombination in *E. coli* (Toietta et al., 2002). HDAds can be rescued without linearizing the shuttle vectors. However, the efficiency is very low. Although the plasmid shuttle vector construct is relatively large (30 to 41 kb), subcloning is usually straightforward in experienced molecular biology laboratories. The preferred bacterial strain is DH5 α . Some constructs may require incubation at 30°C to increase DNA stability during vector propagation.

GENERATION OF RECOMBINANT HELPER-DEPENDENT ADENOVIRAL VECTORS USING Cre-*loxP* SYSTEM

To generate recombinant HDAd vectors, linearized shuttle vector DNA is transfected into a Cre-expressing packaging cell line followed by infection with a helper virus. It is important to liberate both ends of the shuttle vector for efficient vector rescue.

The following basic protocol is based on the use of 293Cre66 cells (Schiedner et al., 2002), AdLC8cluc helper virus, and pC4HSU shuttle vector. It is also generally applicable to other cell lines with appropriate modifications.

293Cre66 cells can be transfected by one of two methods: calcium phosphate precipitation or liposome-mediated transfection. The calcium phosphate precipitation method is slightly more effective than liposome-mediated transfection; however, the latter method requires less DNA and appears to be more reproducible. Only the latter method is described below. It is recommended that a shuttle vector containing a reporter gene be included for the first time to easily monitor vector amplification and to ensure a properly functioning system.

A schematic diagram of this protocol is shown in Figure 16.24.2.

Materials

Expression cassette: gene of interest with promoter active in the target tissue and poly(A) signal

Restriction endonucleases *AscI* and *PmeI*

Calf intestinal phosphatase (UNITS 3.10 & 3.16)

Shuttle vector: pC4HSU (available from Microbix), p Δ 21, p Δ 28, pSTK129 or other similar shuttle vectors, with stuffer DNA of mammalian DNA origin; Sandig et al., 2000; Kim et al., 2001; Oka et al., 2001; Schiedner et al., 2002)

Figure 16.24.2 Schematic overview of helper-dependent adenoviral vector (HDAd) production using Cre-loxP system. The packaging cell line expressing Cre (293Cre66) is transfected with a linearized HDAd shuttle vector (e.g., pC4HSU containing a transgene cassette) and then infected with a helper virus (HV) at 500 vector particles (VP)/cell. Abbreviations: ITR, inverted terminal repeat; ψ , packaging signal. Since the packaging signal of a helper virus is flanked by loxP sequences, it is excised in 293Cre66 cells leaving a helper virus unpackageable. Only HDAd vector is packaged. The titer of HDAd vector is increased by serial passages. The 293Cre66 cells in a 6-well plate are coinfecting with HDAd vector and a helper virus (100 VP/cell) in passage 1. Coinfection is repeated in a 10-cm dish for passage 2, and in a TripleFlask (TF) for passage 3. The vector titer is determined before large-scale production. There are two ways to produce HDAd vectors on a large-scale (see Basic Protocol 2): adherent cell culture system using multiple TFs and suspension cell culture system. In the TF system, typically twelve TFs are infected. For suspension system, 3 liters of suspension cells are infected. After passage 4, HDAd vector is purified by CsCl density gradient centrifugation. The typical yield of HDAd vector is $3\text{--}5 \times 10^{12}$ VP by the adherent cell protocol and $5\text{--}10 \times 10^{12}$ VP by the suspension system. If necessary, the purified HDAd vector is used as a seed stock to produce more vectors.

70% and 100% ethanol

Transfection-grade H₂O

E1-function-complementing cell lines expressing Cre recombinase, e.g., 293Cre4 (Parks et al., 1996; available from Microbix), 293Cre66 and suspension 293Cre66S (Schiedner et al., manuscript in preparation), or 116 (293N3S based suspension cell line; Palmer and Ng, 2003)

E1-function-complementing cell lines (for amplification of helper virus) such as 293 (ATCC, Microbix), 293N3S (suspension cells, Microbix), PERC6, or N52.E6

Complete medium: α -MEM supplemented with 10% heat-inactivated FBS and 1 \times antibiotic-antimycotic (ingredients available from Invitrogen)

Minimal essential medium alpha (α -MEM; Invitrogen) without FBS or antibiotic-antimycotic

0.25% trypsin-EDTA (Invitrogen)

SuperFect transfection reagent (Qiagen)

Helper virus (see recipe)

Maintenance medium for adherent cells: α -MEM supplemented with 5% heat inactivated horse serum and 1 \times antibiotic-antimycotic (ingredients available from Invitrogen)

40% (w/v) sucrose (tissue culture grade) in H₂O, autoclave and filter through 0.22- μm filter; store at room temperature

15-ml and 50-ml conical tubes

37°C orbital shaker

6-well tissue culture plates

10-cm tissue culture plates

Cryotubes

TripleFlask (TF, Nunc) or 15-cm tissue culture dishes

Additional reagents and equipment for restriction endonuclease digestion (UNIT 3.1) and subcloning of DNA (UNIT 3.16), transformation (UNIT 1.8) and growth (UNITS 1.2 & 1.3) of *E. coli*, alkaline lysis miniprep of plasmid DNA (UNIT 1.6), agarose gel electrophoresis (UNIT 2.5A), extraction and precipitation of DNA (UNIT 2.1A), mammalian cell culture (APPENDIX 3F), and Southern blotting (UNIT 2.9A)

Clone gene into HDAd shuttle vector

1. Linearize shuttle vector using restriction endonuclease *Asc*I (UNIT 3.1) and treat with calf intestinal phosphatase (UNIT 3.16), then subclone expression cassettes of interest directly into the shuttle vector (UNIT 3.16), taking into consideration the issues described above (see Strategic Planning). Perform the ligation in a total volume of 10 μl , using 100 to 200 ng of calf intestinal phosphatase-treated shuttle vector.

Confirm the final plasmid construct by diagnostic restriction endonuclease digestions (see Strategic Planning) before transfection.

2. Transform $>2 \mu\text{l}$ of ligation mixture into $50 \mu\text{l}$ of competent *E. coli* cells (UNIT 1.8) with heat shock at 42°C for 30 sec. Spread all of the competent cells directly (without prior amplification in LB medium) onto a 10-cm LB/ampicillin/IPTG/Xgal plate and incubate 15 to 18 hr.
3. Pick smaller white bacterial colonies (four to six “candidate clones”), streak on a 10-cm LB/ampicillin/IPTG/X-gal master plate, and then inoculate them into 4 ml of LB/ampicillin liquid medium in separate 15-ml conical tubes.

Colonies are individually (i.e., separately) streaked in different grids on a master plate first, and then inoculated into LB medium.

4. Incubate the master plate in a 37°C bacterial incubator, and at the same time grow the corresponding candidate clones that were inoculated into the LB/ampicillin liquid medium overnight (15 to 18 hr) at 37°C with agitation on an orbital shaker.

Some constructs require 30°C incubation to avoid vector recombination.

5. Collect the cells from the candidate clones growing in the liquid medium and purify plasmid DNA using a commercial miniprep kit or the alkaline lysis procedure (UNIT 1.6).

The version of miniprep kit using a spin column (Qiagen) is most useful. The amount of DNA obtained from the miniprep may be low due to the size of the plasmid, but should be sufficient for screening.

6. Digest the DNA with diagnostic restriction enzyme *AscI* (UNIT 3.1) and perform agarose gel electrophoresis (UNIT 2.5A).

*The goal of diagnostic enzyme digestion is to confirm the presence and orientation of the expression cassette in an HDAd shuttle vector. *AscI* digestion is used to verify recombinant plasmid with two DNA bands corresponding to the expression cassette insert and the shuttle vector backbone. Additional digestion with an appropriate diagnostic enzyme that cuts into both the expression cassette insert and a site in the shuttle vector is needed to determine the orientation of the insert. It is also important to completely map the final construct to ensure that only a single copy of the cassette is included in the vector.*

7. Pick one correct clone from the master plate (i.e., one whose corresponding cells grown in the liquid medium have shown the correct structure) and grow in 100 ml LB/ampicillin overnight at 37°C with agitation on an orbital shaker.

8. Purify DNA using a commercial midiprep kit.

*A yield of 50 to 100 μg of DNA can be obtained from 100 ml culture. If the yield is poor, it is recommended that the plasmid be retransformed into *E. coli* DH5 α and that a well isolated single colony be picked directly into the 100-ml (or larger volume) culture and grown overnight.*

9. Digest 20 to 40 μg of DNA with *PmeI* (UNIT 3.1) to release the plasmid backbone in a total volume of 100 μl .
10. Confirm the digestion by running 1 to 2 μl of reaction mixture on a 1% agarose minigel (UNIT 2.5A).
11. Extract DNA (UNIT 2.1A) once with 100 μl of 25:24:1 phenol/chloroform/isoamyl alcohol. Precipitate DNA in a 1.5-ml microcentrifuge tube with 10 μl of 3 M sodium acetate, pH 5.2, and 220 μl of 100% ethanol.

- Microcentrifuge 3 min at 12,000 rpm and remove the supernatant. Rinse the DNA pellet with 500 μ l of 70% ethanol, microcentrifuge again for 3 min at 12,000 rpm, then remove the supernatant under the tissue culture hood.

DNA should be kept sterile from this step forward.

- Briefly air dry DNA and resuspend DNA in 20 μ l of transfection-grade water.

Transfect and rescue helper-dependent adenoviral vector

- Trypsinize and seed 293Cre66 cells (or other E1-function-complementing cells expressing Cre recombinase) with complete medium into a 6-well plate to reach 50% to 60% confluency on the day of transfection.

APPENDIX 3F provides basic cell culture protocols. 293Cre66 cells should not be rinsed with PBS before adding trypsin since this cell line is loosely attached to the flask and tends to become detached by doing so.

To obtain the level of confluency specified above, ~80% confluent 293Cre66 cells are split 1:4 (based on surface area). It then takes ~2 days to reach 50% to 60% confluency.

- For each well to be transfected, dissolve 2.5 μ g of the *PmeI*-linearized shuttle vector (from step 13) in 75 μ l plain α -MEM (no FBS or other additives).

If possible, it is recommended that the transfection be performed in duplicate. Proceed to passage 3, below, in duplicate, then pick the CVL (crude viral lysate) containing the higher titer for subsequent large-scale vector production.

- Add 12.5 μ l per well to be transfected of SuperFect (liposome-based) transfection reagent to the DNA solution and mix gently by pipetting up and down several times. Incubate for 5 to 10 min at room temperature. During incubation, wash the cells once with 2 ml of plain α -MEM (no additives) prewarmed to 37°C.

- Add 0.25 ml per well to be transfected of plain α -MEM to DNA solution, mix by pipetting up and down. Remove medium from cells. Overlay 337.5 μ l of the DNA/liposome/ α -MEM mixture per well, on top of cells.

- Incubate cells for 2 to 3 hr, swirling every 30 min, then add 1 ml of complete medium.

- The next day, wash the cells once with 2 ml of plain α -MEM. Remove medium and infect with 0.25 ml of plain α -MEM containing 5×10^8 vector particles (VP) of helper virus (500 VP/cell).

The amount of helper virus is based on the ratio of infectious particles to vector particles being between 1:20 and 1:100. The exact amount of helper virus should be optimized for each helper virus preparation based on the infectious titer. However, the amount described in the protocol is applicable in most cases without modification.

- Incubate cells for 1 hr, swirling every 10 to 15 min. Add 1 ml of maintenance medium for adherent cells.

- Incubate until >90% cells show cytopathic effect (CPE; cells are rounded and detached from the plate), which should occur between 48 to 72 hr post-infection.

- Transfer cells and medium (crude viral lysate, CVL) to a cryotube. Add 0.1 vol of 40% sucrose.

The resulting CVL in 4% sucrose can be stored up to 1 year or more at -80°C.

Perform passage 1

- Seed 293Cre66 cells in a 6-well plate for 80% to 90% confluence on day of infection.

24. On day of infection, thaw CVL (from step 22) in a 37°C water bath. Remove medium and incubate cells with 0.5 ml of CVL together with helper virus at 100 VP/cell (1×10^8 VP). Continue infection for 1 hr, swirling every 15 min.
25. Add 1 ml maintenance medium for adherent cells. Incubate until >90% of cells show CPE.

If cells do not show CPE after 72 hr, helper virus is insufficient. Thus, more helper virus must be added.
26. Transfer CVL (see step 22) to a cryotube. Add 0.1 vol of 40% sucrose and store at -80°C.

Perform passage 2

27. Seed 293Cre66 cells in a 10-cm dish for 80% to 90% confluence on day of transfection.
28. On day of infection, thaw CVL (from step 26) in a 37°C water bath. Remove medium and incubate cells with 1 ml of CVL supplemented with 7×10^8 VP of helper virus. Incubate 1 hr.
29. Add 5 ml maintenance medium for adherent cells, then continue incubating until >90% of cells show CPE (usually 2 to 3 days).
30. Retain a 0.2-ml of CVL for vector DNA analysis (see Support Protocol 1). Transfer the remaining CVL to a 15-ml conical tube, add 0.1 vol of 40% sucrose, and store at -80°C.

Perform passage 3

31. Seed 293Cre66 cells in a Nunc TripleFlask or in three 15-cm tissue culture dishes. Thaw CVL (from step 30) in a 37°C water bath.
32. Dilute CVL with plain α -MEM to 10 ml. Add 5×10^9 VP of helper virus to CVL and incubate 1 hr to infect cells.
33. Add 20 ml maintenance medium for adherent cells. Incubate until >90% of cells show CPE (2 to 3 days).
34. Transfer 0.2 ml of CVL to a 1.5 ml tube for DNA extraction. Transfer the remaining CVL into a 50-ml tube. Add 0.1 vol of 40% sucrose and store at -80°C.
35. Before proceeding to large-scale vector production, analyze vector DNA for vector amplification as described in Support Protocol 1, since an appropriate vector titer is necessary for a large-scale infection. If no clear vector amplification is detected at passage 3, repeat one or two more serial passages in TripleFlasks using the steps described under passage 3, and analyze vector amplification again as described in Support Protocol 1.

With efficient vector amplification, the intensity of the band corresponding to the left arm of HDAd vector is comparable to that of helper virus lacking the packaging signal at passage 3 ($\sim 6.5 \times 10^{10}$ VP/ml). If no HDAd vector is detected after additional passages, it is likely due to inefficient transfection, and repeating the transfection is recommended. The authors have found that one or two more serial passages increase the titer without detectable vector rearrangement. However, unnecessary amplification should be avoided since it increases the chance of vector rearrangement. The efficiency of vector amplification can be influenced by vector structures. If the vector contains a transgene that is cytotoxic and that is expressed during vector production, it will be poorly amplified. If such a poor amplification is anticipated, use packaging cell lines in which the transgene promoter is silent, or consider the use of a regulatable expression system.

**LARGE-SCALE HELPER-DEPENDENT ADENOVIRAL VECTOR
PRODUCTION**

There are two methods for producing HDAd vectors at a large scale. The first method is vector amplification using multiple flasks of adherent cells, as described in Basic Protocol 1 for passage 3 (see Basic Protocol 1, steps 31 to 34). The alternate steps utilize a suspension culture system. Because of ease of handling and scale-up, this is the preferred method for large-scale Ad vector production. Each laboratory should choose the method that best suits its needs. For example, a suspension system is preferred for large animal experiments with a small number of vectors. However, adherent cell culture is more economical if small animal experiments are performed with many vectors.

The following protocol is based on the use of 293Cre66S, 293Cre66 cells adapted for suspension *in vitro* (G. Shiedner et al., manuscript in preparation). The growth medium can be either MEM- α or Joklik MEM supplemented with 10% FBS. This cell line can be maintained in suspension as well as in adherent culture. It grows as adherent after several passages in a culture dish. 293N3SCre8 cells are available free for academic institutions through Merck Research Laboratories. Alternatively, contact Frank Graham at graham@mcmaster.ca. For 293Cre66 and 293Cre66S, contact Stefan Kochenek at Stefan.kochenek@medizin.uni-ulm.de. For 116 cells, contact Philip Ng at png@bcm.tmc.edu.

The protocol includes cell disruption by deoxycholate and CsCl gradient centrifugation using the NVT rotor. The advantage of using the NVT rotor is that the running time is short and purification can be completed in a day.

Materials

- Adherent 293Cre66 or 293Cre4 cells
- Minimal essential medium alpha (α -MEM; Invitrogen)
- CVL from passage 3 or additional passage (see Basic Protocol 1)
- Helper virus (see recipe)
- Maintenance medium for adherent cells: α -MEM supplemented with 5% heat inactivated horse serum and 1 \times antibiotic-antimycotic (ingredients available from Invitrogen)
- 100 mM Tris-Cl, pH 8.0 (APPENDIX 2)
- 40% (w/v) sucrose (tissue culture grade) in H₂O: autoclave and filter through 0.22- μ m filter; store at room temperature
- Cre-expressing, E1-complementing cell lines adapted for suspension: e.g., 293N3SCre8, 293Cre66S (Schiedner et al., manuscript in preparation), or 116 cells
- Growth medium for suspension cells (see recipe)
- Maintenance medium for suspension cells (see recipe)
- 5% sodium deoxycholate, filter-sterilized
- 2 M MgCl₂
- DNase I solution (see recipe)
- RNase A solution (see recipe)
- CsCl density gradient solutions (density = 1.25, 1.35, and 1.41 g/ml; see recipe)
- PBS⁺⁺ : PBS (APPENDIX 2) containing 0.68 mM CaCl₂ and 0.5 mM MgCl₂
- Dialysis buffer (see recipe)
- TripleFlasks (Nunc)
- 250-ml centrifuge tubes (Corning)
- 15-cm culture dishes
- Low-speed centrifuge (e.g., Sorvall RC5C)

250- and 3000-ml spinner culture flasks and spinner culture base (Bellco or Corning)
Refrigerated centrifuge (e.g., Sorvall centrifuge with SS-34 rotor)
NVT 65 ultracentrifuge tubes (Beckman)
2- and 5-ml pipets
Beckman LE-80K ultracentrifuge (or equivalent ultracentrifuge with swinging-bucket rotor)
1- or 3-ml syringes and 21-G needles
Dialysis cassette (Pierce)
Additional reagents and equipment for mammalian cell culture and counting cells
(APPENDIX 3F)

Expand virus

For adherent cells

- 1a. Seed adherent 293Cre66 (see materials for Basic Protocol 1) cells in 12 Nunc Triple-Flasks. Incubate to 80% to 90% confluence (~3 days) in growth medium for adherent cells.

See APPENDIX 3F for basic cell culture techniques.

- 2a. Thaw the CVL in 50-ml tube from passage 3 or additional passage in a 37°C water bath. Bring volume to 36 ml with plain α -MEM in each 50-ml tube. Add helper virus (6×10^{10} VP), and mix by inverting the tube several times.
- 3a. Remove the medium from the TripleFlasks and add 7 ml of plain α -MEM to each TripleFlask. Add 3 ml of CVL containing a helper virus (from step 2a) to each TripleFlask. Continue incubating 1 hr with occasional mixing to infect the cells.
- 4a. Add 20 ml of maintenance medium for adherent cells (see materials for Basic Protocol 1) and continue the incubation. Check the cells every 12 to 24 hr and collect CVL in 250-ml centrifuge tubes when CPE is nearly complete (i.e., when 90% of cells show CPE, 48 to 72 hr post-infection).
- 5a. Centrifuge 10 min at $800 \times g$, 15°C. Discard the supernatant.
- 6a. Resuspend the cells with 100 mM Tris·Cl, pH 8.0, in a total volume of 20 ml. Add 0.1 vol of 40% sucrose, and proceed to purification (step 7). Alternatively, divide into two aliquots in 15-ml tubes, and store at -80°C.

For suspension cells

- 1b. Split suspension-adapted 293Cre66S cells from one ~80% confluent 162-cm² flask into four 15-cm dishes. Culture for 3 days in a 37°C incubator using growth medium for suspension cells.
- 2b. Transfer all cells into a 3000-ml spinner flask and make up the volume to 1000 ml with growth medium for suspension cells (day 0). Culture cells in a 37°C incubator with stirring at 60 rpm. Check the cell density (APPENDIX 3F) the next day (day 1).
Cell density should be $\sim 2 \times 10^5$ cells/ml.
- 3b. Add 1000 ml of growth medium on day 2. Add an additional 1000 ml of growth medium for suspension cells on day 3. Check the cell density (APPENDIX 3F) on day 4.
Cell density should be $\sim 3-4 \times 10^5$ cells/ml.
- 4b. Collect cells by centrifuging 5 min at $800 \times g$. Save 500 ml of the supernatant (conditioned medium). Resuspend cells with 50 ml of conditioned medium, transfer to a 250-ml culture flask and bring the final volume to 100 ml.

- 5b. Thaw the CVL in a 50-ml tube from passage 3 or additional passage in a 37°C water bath. Add helper virus (100 VP/cell × total number of cells from step 3b) to the CVL. Add the above CVL/helper virus mixture to the 250-ml culture flask containing cells. Incubate for 2 hr in a 37°C incubator while stirring at 60 rpm.
- 6b. Transfer into a 3000-ml flask and make up the total volume to 500 ml with the conditioned medium. Add 1500 ml of fresh maintenance medium for suspension cells and continue incubation. Harvest the cells on day 7 (3 days after infection) by centrifuging at 10 min at 800 × g. Store as described in step 6a.

Purify and characterize virus

7. If cells were frozen, thaw by incubation in a 37°C water bath. Add 2 ml of 5% sodium deoxycholate to the lysate, and incubate for 30 min at room temperature while mixing occasionally.

The solution becomes gelatinous.

This step calls for deoxycholate disruption of the cell membranes. Although this requires more hands-on time, the yield of HDAd released from the cells is higher than if several rounds of freezing/thawing (freezing in a dry ice/methanol bath and thawing at 37°C) are used to release the viruses from the cells.

8. Add 0.2 ml of 2 M MgCl₂, 0.15 ml of DNase I solution, and 0.15 ml of RNase A solution to the lysate. Mix well and incubate at 37°C for 1 hr while mixing occasionally.
9. Centrifuge 10 min at 5000 × g (6500 rpm in Sorvall SS-34 rotor), 4°C for 10 min. Recover the clear supernatant.

First ultracentrifugation

10. For each viral preparation to be purified, sterilize six NVT 65 ultracentrifuge tubes either by autoclaving, irradiation under UV light for several hours, or soaking in 100% ethanol followed by washing with sterile water and air drying in the hood (six tubes are required for purification of each viral preparation).
11. In each of the ultracentrifuge tubes, place 3 ml of low-density CsCl gradient solution (1.25 g/ml), then underlay 3 ml of high-density CsCl density gradient solution (1.41 g/ml) using a 2-ml pipet.
12. Carefully overlay 5 ml of clear supernatant collected at step 9 using a 5-ml pipet.
13. Fill the tubes to the neck (using a 2-ml or Pasteur pipet) with either the clear supernatant or PBS⁺⁺, and cap the tubes.

The tubes do not need to be weighed.

14. Ultracentrifuge 30 min at 200,000 × g (50,000 rpm in Beckman LE-80K), 20°C, with the brake on.

Any swinging-bucket rotors can be used, but may require different centrifugation time and/or rpm. Check for the appropriate speed and centrifugation time at <http://www.beckman.com/resourcecenter/labresources/centrifuges/rotorcalc.asp>.

15. Remove caps from the tubes. Collect the lower opalescent band with a 1- or 3-ml syringe and 21-G needle by side puncture (clean the area for needle puncture with 70% ethanol prior to collection).

It is useful to remove the empty capsid band (upper opalescent band) before collecting the infectious virus band, since the two bands are physically close together and are difficult to isolate one from the other.

Second centrifugation

16. Place 8 ml of 1.35 g/ml CsCl density gradient solution in each of a series of new NVT 65 ultracentrifuge tubes prepared as in step 10. Overlay the bands recovered from first centrifugation in the respective tubes, then fill in the tubes to the neck with 1.35 g/ml CsCl density gradient solution.
17. Ultracentrifuge as in step 14, except for 3.5 hr. Recover the opalescent (virus) band with a syringe as in step 15.
18. Transfer the virus into a dialysis cassette. Dialyze against 3 liters of DB without sucrose once for 1 hr at 4°C, and then against 3 liters of DB at 4°C overnight.
19. Characterize the vector.

Routine vector characterization includes, determination of infectious titer (see Support Protocol 2); detection of helper virus contamination (see Support Protocol 3); verification of vector structure (see Support Protocol 4) and determination of vector concentration (VP/ml) using optical density. To read OD, add 20 μ l virus or 20 μ l blank solution and 380 μ l TE buffer (APPENDIX 2)/0.1% SDS, vortex 30 sec, centrifuge 5 min, and measure OD₂₆₀. One OD unit contains $\sim 10^{12}$ viral particles/ml (particles:infectious particles = $\sim 20:1$). However, the OD₂₆₀ calculation is based on an estimate of viral DNA content and does not imply either competent viral packaging or transgene expression. Therefore, it is advisable to combine this estimate with the other approaches noted above.

Efficient HDAd vector amplification results in less than 1% helper virus contamination without purification. The approximate yield and helper virus contamination of HDAd vectors can be determined before CsCl purification by retaining a 0.2-ml aliquot of cell suspension at the time of harvest and extracting DNA for Southern blot analysis as described in Support Protocol 1. The typical yield of HDAd vector on pC4HSU backbone at passage 4 with adherent cells is $3\text{--}5 \times 10^{12}$ VP with $<0.1\%$ helper virus contamination, and the ratio of infectious particles to vector particles is 1:20. With suspension cells, the yield is $\sim 0.5\text{--}1 \times 10^{13}$ VP. For future vector amplification, the purified virus is used as a seed stock.

MONITORING VECTOR AMPLIFICATION

The efficiency of HDAd vector amplification is somewhat variable and often limiting. It is therefore important to monitor vector amplification during serial passages. Southern blot analysis is a dependable method for analyzing vector amplification. By this analysis, vector amplification can be monitored and at the same time DNA rearrangement can be detected. In general, significant vector amplification is detected after passage 2. Southern blotting also allows determination of Cre-mediated excision of the helper virus packaging signal.

Additional Materials (also see Basic Protocol 1)

Aliquots of CVL from serial passages of the virus (see Basic Protocol 1)

Proteinase K reaction mixture (see recipe)

TE buffer, pH 8.0 (APPENDIX 2)

*Hind*III restriction endonuclease (or other appropriate restriction enzyme; see UNIT 3.1)

QIAamp DNA purification kit (Qiagen)

6 \times gel loading buffer (see recipe)

1.2% agarose gel (UNIT 2.5A)

1 kbPlus DNA marker (Invitrogen)

400-bp fragment containing the left ITR plus the packaging signal (contact Dr. K. Oka at kazuhiro@bcm.tmc.edu) as probe for Southern blotting, labeled with ³²P using a random priming DNA labeling kit

Additional reagents and equipment for Southern blotting (UNIT 2.9A) and autoradiography or phosphor imaging (APPENDIX 3A)

SUPPORT PROTOCOL 1

Protein
Expression

16.24.13

1. Thaw the 0.2-ml aliquots of CVL collected from serial passages in a 37°C water bath.
2. Add 0.2 ml proteinase K reaction mixture to each aliquot. Incubate ≥ 1 hr at 56°C.
Not more than 0.2 ml of CVL should be used for extraction of DNA, as excess cellular debris causes poor phase separation for subsequent phenol/chloroform/isoamyl alcohol extraction.
3. Add 400 μ l of 25:24:1 phenol/chloroform/isoamyl alcohol and vortex vigorously.
4. Microcentrifuge 2 min at maximum speed. Transfer the supernatant to a new 1.5-ml microcentrifuge tube.
5. Precipitate DNA by adding 40 μ l of 3 M sodium acetate buffer, pH 5.2, and 880 μ l of 100% ethanol.
A DNA clump should be visible soon after adding ethanol due to the presence of chromosomal DNA. See UNIT 2.1A for additional details on DNA precipitation.
6. Incubate at room temperature for 10 to 20 min to prevent salt precipitation, then microcentrifuge at 3 min at 12,000 rpm. Discard supernatant.
7. Rinse DNA pellet with 500 μ l of 70% ethanol. Briefly air dry pellet, then reconstitute in 30 μ l TE buffer, pH 8.0.
It is important not to excessively dry DNA, since dried DNA is difficult to dissolve.
8. Purify helper virus DNA using QIAamp DNA purification kit. Linearize shuttle vector using restriction endonuclease *PmeI* as in Basic Protocol 1, step 1.
9. Digest 6 μ l of the vector DNA from step 7 with an appropriate enzyme (the authors routinely use *HindIII*; UNIT 3.1) in a total volume of 20 μ l for 1 hr at 37°C. In separate tubes, digest 0.1 μ g (corresponding to 2.58×10^9 VP) of purified helper virus DNA and 0.1 μ g of linearized shuttle vector with the same enzyme used to digest the vector DNA.
10. To each tube, add 4 μ l of 6 \times gel loading buffer, then vortex and microcentrifuge briefly to collect solution at the bottom of the tube. Load contents of tubes in separate lanes of a 1.2% agarose gel (24 μ l/well). Also load 4 μ l of 1kbPlus DNA marker diluted to 50 ng/ μ l in 1 \times loading buffer as a molecular size standard. Perform agarose gel electrophoresis (UNIT 2.5A).
11. Perform Southern blot analysis according to standard protocols (UNIT 2.9A), using [³²P-labeled] 400-bp fragment containing the left ITR plus the packaging signal as the probe. Perform a final wash with 0.1 \times SSC/0.1% SDS at 65°C.
12. Expose the membrane to either a film or a phosphor imager (APPENDIX 3A) to detect the radioactive bands.

The 400-bp fragment containing the left ITR plus the packaging signal is used as a probe, since it differentiates the left and right arms of the HDAd vector. The size for intact helper virus left arm is 3.3 kb; left arm of helper virus lacking the packaging signal, 3.1 kb; the right arm of helper virus, 1 kb; the left arm of pC4HSU based HDAd, 2.4 kb; the right arm of pC4HSU based HDAd, 0.4 kb. When the amplification of HDAd is efficient, the band intensity of HDAd vectors becomes more prominent than that of helper virus.

DETERMINATION OF INFECTIOUS TITER

The infectious titer of a first-generation Ad vector is determined by plaque assay, which relies on vector replication and subsequent viral gene expression in E1-complementing cells. HDAds do not contain any viral coding sequences, and therefore do not form plaques. Hence, it is necessary to perform an assay based on internalization of vector DNA. This assay (based on the method described by Kreppel et al., 2002) can be used to titer early-generation Ads as well.

Additional Materials (also see *Basic Protocol 1*)

293 cells (ATCC)

Helper-dependent adenoviral vector (HDAd; see *Basic Protocol 1*)

HDAd vector containing a reporter gene (e.g., *lacZ*, green fluorescence protein) whose infectious titer is determined independently based on the reporter gene expression on 293 cells

PBS⁺⁺:PBS (*APPENDIX 2*) containing 0.68 mM CaCl₂ and 0.5 mM MgCl₂

10× citric-saline (see recipe)

0.8 M NaOH

ITR or packaging signal (contact Dr. K. Oka at kazuhiro@bcm.tmc.edu) as probe for slot blotting, labeled with ³²P using a random priming DNA labeling kit

24-well tissue culture plates

Additional reagents and equipment for slot blotting (*UNIT 2.9B*) and phosphor imaging (*APPENDIX 3A*)

1. Seed 293 cells in a 24-well plate with complete medium for adherent cells and incubate until cells become 80% to 90% confluent.
2. Dilute HDAd vectors and reference HDAd vector containing a reporter gene to 5 × 10⁹ VP/ml with plain α-MEM.

The infectious titer of the reference vector is determined by counting plaques for each dilution, averaging the duplicate wells (foci expressing the reporter gene are identified and counted by microscopy). The average will determine the titer of adenoviral stock as expressed in blue-forming units per milliliter (bfu/ml) for lacZ reporter gene or green fluorescence-forming units per milliliter (gfu/ml) for GFP reporter gene.

3. Remove medium from each well and replace with 0.2 ml of plain α-MEM.
4. Add the following volumes of diluted HDAd vector to duplicate wells: 0, 2, 4, 8, 16, and 32 μl. Add the same volumes of the reference vector to separate duplicate wells. Incubate 1 hr to infect.
5. Add 0.3 ml of maintenance medium for adherent cells (see materials for *Basic Protocol 1*), and incubate the plate overnight.
6. Wash the cells twice, each time with 1 ml of PBS⁺⁺, then add 0.2 ml of 1× citric saline to each well. Incubate at room temperature for ~20 min or until cells start to round up and detach from the well.
7. Transfer the cell suspension to a 1.5 ml microcentrifuge tube by pipetting up and down. Add 0.2 ml of 0.8 M NaOH, vortex vigorously, and incubate at room temperature for 15 min.
8. Assemble the slot blot apparatus and load 200 μl of the above cell suspension to each slot. Proceed to slot-blot hybridization (*UNIT 2.9B*), using the ³²P-labeled ITR or packaging signal as a probe.

9. Quantify the radioactive bands with a phosphor imager. Calculate the infectious titer of HDAd vector is calculated from the standard curve obtained by HDAd containing the reporter gene.

An alternative method, based on competition of an HDAd vector with a reference Ad vector for infection of 293 cells, has been reported by Palmer and Ng (2004). This method is potentially simple and accurate; however, the authors of this unit have not established a working protocol.

REAL-TIME PCR TO DETECT HELPER VIRUS CONTAMINATION

Helper virus contamination can be determined by semiquantitative Southern blot analysis using known amounts of helper virus DNA as a standard. The radioactive bands corresponding to the left arm are quantified by a phosphor imager and the amount of helper virus present in HDAd vector is calculated from the standard. Real-time PCR is a more accurate way to quantify helper virus contamination. Although TaqMan PCR, originally developed for this purpose, may have greater precision, the following protocol using SYBR Green I as a detection dye also works quite well and is simple and economical. For this analysis, DNA should be purified by a QIAamp DNA kit or an equivalent method.

Additional Materials (also see Basic Protocol 1)

Helper-dependent adenoviral vectors (HDAds) to be analyzed (see Basic Protocol 1)

2× SYBR Green QPCR master mix (Stratagene, Bio-Rad, or equivalent)

10 pmol/μl PCR primers (see recipe)

96-well reaction plates

Real time QPCR platform (Stratagene Mx3000 or equivalent)

1. Purify HDAd vector to be analyzed using QIAamp DNA purification kit.
2. Linearize shuttle vector using restriction endonuclease *PmeI* (UNIT 3.1). Make seven serial dilutions of helper virus and *PmeI*-linearized pC4HSU shuttle vector DNA by 10-fold increments starting at 0.1 ng/μl and ending at 10⁻⁷ ng/μl, with water.
3. Make four serial dilutions of HDAd vectors to be analyzed by 10-fold increments starting at 0.1 ng/μl and ending at 10⁻⁴ ng/μl with water.
4. Prepare PCR-primer mix for helper virus. For 24 wells, mix:

25 × 26 μl (24 wells + 2 extra wells) of 2× SYBR Green QPCR master mix

26 μl of 10 pmol/μl primer 1

26 μl of 10 pmol/μl primer 2

13 × 26 μl of H₂O.

Mix gently by pipetting up and down. Minimize exposure to light since SYBR Green is light sensitive.

5. Prepare PCR-primer mix for HDAd vector by repeat the procedure in step 3 with primers 3 and 4 or primers 5 and 6.
6. Dispense 40 μl of PCR primer mix to duplicate wells of a 24-well reaction plate.
7. Add 10 μl of DNA solution (steps 1 and 2) to each well in duplicate. Add 10 μl of water to separate duplicate wells as a no-template control (NTC).

Therefore, two rows include NTC, standards (seven dilutions), and HDAd vector to be assayed (four dilutions) in duplicate.

8. Perform real-time PCR according to the manufacturer's instruction for the Stratagen Mx3000 using the following cycling programs.

1 cycle:	10 min 95°C	(initial denaturation)
40 cycles:	30 sec 95°C	(denaturation)
	30 sec 55°C	(annealing)
	60 sec 72°C	(extension).

9. Calculate helper virus contamination in percent:

$$\% \text{ contamination} = (\text{ng of helper virus}/\text{ng of HDAd vector})/(\text{ng of shuttle vector DNA}/\text{ng of HDAd vector}) \times 100 \times \text{size correction factor}$$

The size correction factor is equal to $[31 \times (\text{size of pC4HSU based HDAd vector in kb})]/[35 \times (\text{size of AdLC8cluc in kb})]$.

VERIFICATION OF VECTOR STRUCTURES

HDAdS are produced in serial passages by coinfection with helper virus. The existence of overlapping sequences between HDAd and helper virus could result in recombination between the two viruses. Such vector recombination can be detected by Southern blot analysis, in which the vector undergoing recombination appears as extra bands of varying sizes other than HDAd vector or helper virus. Therefore, it is important to routinely compare the structures of HDAd and shuttle vector plasmid by Southern blot analysis. The protocol for doing this is described in Support Protocol 1, except that in this case it utilizes a probe corresponding to the plasmid shuttle vector without the plasmid backbone.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Citric-saline, 10×

1.35 M KCl

0.15 M sodium citrate

Autoclave and store up to 3 months at room temperature

CsCl density gradient solutions

For each density gradient solution to be prepared, pour 350 ml of 1× Tris density buffer (see recipe for 10×) into a beaker. Add the following quantities of CsCl to prepare the gradient solutions of the respective density:

135 g CsCl for $d = 1.25$

160 g CsCl for $d = 1.33$

180 g CsCl for $d = 1.41$.

Mix with a stir bar, and equilibrate to room temperature. Place exactly 1 ml of the CsCl solution in a small weighing boat using a 1-ml pipet calibrated such that 1 ml of water is exactly equal to 1.00 g, obtain an accurate weight, and return the 1-ml aliquot to the beaker. If the density is higher than desired, add more 1× Tris density buffer to the respective beaker; if it is lower, add more CsCl powder. Repeat this process until the exact density concentration is reached. Sterilize the density gradient solutions using a 0.22- μm filter. Store up to 6 months at room temperature.

SUPPORT PROTOCOL 4

Protein
Expression

16.24.17

Dialysis buffer

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)
2 mM MgCl₂
4% (w/v) sucrose
Store up to 2 weeks at 4°C

DNase I solution

10 mg/ml bovine pancreatic deoxyribonuclease I
20 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
50 mM NaCl
1 mM dithiothreitol
0.1 mg/ml BSA
50% (v/v) glycerol
Store up to 1 year in aliquots at –20°C

Gel loading buffer, 6×

1× TAE buffer (*APPENDIX 2*) containing:
0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol
30% (v/v) glycerol
Store up to 1 year at 4°C

Growth medium for suspension cells

Joklik MEM or S-MEM containing:
10% FBS
1% Pluronic F-68
1× penicillin/streptomycin
1× L-glutamine
80 µg/ml G418
Store up to 2 months at 4°C

The above ingredients are available from Invitrogen.

Helper virus

Helper virus with the packaging signal flanked by *loxP* sites—e.g., AdLC8cluc (Parks et al., 1996; available free to academic institutions through Merck Research Laboratories) or H14 (Sandig et al., 2000; available commercially from Microbix)—is required. Helper virus should be plaque purified prior to large-scale production on 293 cells or other E1-function-complementing cell lines and its structure verified before its use. This is essential since any variant (e.g., helper virus without *loxP* sequences) can outgrow HDAd during serial passages. Purified helper virus is stored at –80°C in small aliquots in 10 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)/2 mM MgCl₂/4% (w/v) sucrose at concentrations of 1–3 × 10¹² viral particle (VP)/ml. Freezing/thawing several times does not affect the function of helper virus.

See Critical Parameters and Troubleshooting for more information.

LB/ampicillin/IPTG/Xgal plates

LB plates (*APPENDIX 2*) containing:
100 µg/ml ampicillin
0.4 mM isopropylthio-β-galactoside (IPTG)
0.004% (w/v) 5-bromo-4-chloro-3-indolyl-β-D-galactoside (Xgal)
Store up to 2 weeks at 4°C

Maintenance medium for suspension cells

Joklik MEM (Invitrogen) containing:
5% FBS
1% Pluronic F-68
1× penicillin/streptomycin
1× L-glutamine
Store up to 2 months at 4°C

PCR primers, 10 pmol/μl

The PCR primer sequences to detect helper virus and HDAd vector genome (see Support Protocol 3) are as follows. Dilute to 10 pmol/μl using sterile water.

Helper virus (AdLC8cluc):

Primer 1: 5′-CCTACACCAACACAACAACCTC-3′

Primer 2: 5′-ATCCACCTCAAAAGTCATGTC-3′

268-bp PCR product

HDAd on pC4HSU backbone:

Primer 3: 5′-CCATCAGCATAACATACGCAG-3′

Primer 4: 5′-CCAGTCAGTCACAGTCAAGAG-3′

260-bp PCR product

HDAd on pΔ21 or pΔ28 backbone:

Primer 5: 5′-CCCATCTCCTTCATCACATCTC-3′

Primer 6: 5′-TCACAGTTCCTCCAGCCTC-3′

273-bp PCR product

See UNIT 2.11 for oligonucleotide synthesis. HPLC-purified oligonucleotides are preferred, but not essential.

Proteinase K reaction mixture

Prepare a 10 mg/ml proteinase K stock solution and store in small aliquots up to 1 year at −20°C. Just before use, mix the following at room temperature to prepare the reaction mixture:

176 μl H₂O

20 μl 10% (w/v) SDS

4 μl 10 mg/ml proteinase K stock solution

RNase A solution

10 mg/ml RNase A

10 mM Tris·Cl, pH 7.4 (APPENDIX 2)

15 mM NaCl

Store up to 1 year in small aliquots at −20°C

Tris density buffer, 10×

80.0 g NaCl

3.8 g KCl

30.0 g Tris base

1.87 g Na₂HPO₄·7H₂O

Add H₂O to 1000 ml

Adjust pH to between 7.4 and 7.5 with 5 M NaOH

Filter sterilize and store up to 6 months at room temperature

COMMENTARY

Background Information

Early-generation adenoviral (Ad) vectors retain many viral genes. In vivo toxicity and immune response to transduced cells associated with these Ad vectors are caused in part by leaky viral-gene expression. These problems are partially solved in HDAds by removing all viral sequences from the Ad except the essential *cis* elements. This approach also increased the cloning capacity to the packaging limit (~38 kb); see review by Kochanek (1999). This most recently developed Ad vector has been referred to as “helper-dependent,” “high-capacity,” “gutless,” or “guttled” Ad vectors. All the necessary functions and proteins for replication and packaging are supplied in *trans* by a helper virus. The term “helper-dependent” reflects the current production method described herein. To take full advantage of this system, the helper virus, a first-generation Ad, must be separated from HDAd vectors. The most popular method utilizes the Cre-*loxP* (Parks et al., 1996) or FLP-*frt* (Ng et al., 2001; Umana et al., 2001) sequence-specific recombinase systems to remove the packaging signal of a helper virus during vector production. HDAd vectors have been reported to exhibit superior performance over early-generation Ads in many in vivo applications, due to their low toxicity and long-term transgene expression (Morral et al., 1999; Kim et al., 2001; Soudais et al., 2003; Nomura et al., 2004). Ad vectors are essentially a nonintegrating viral vector system. Transgenes delivered by Ad vectors are eventually eliminated from the host by cell division or cell turnover. HDAd vector is no exception. Readministration of the same vector is not effective because the Ad vectors are neutralized by antibodies against capsid proteins. However, neutralizing antibodies are serotype-specific, which permits the readministration of the same HDAd vector of different serotype (Parks et al., 1999; Kim et al., 2001). A major advantage of this strategy using HDAd vector is that HDAd vectors with various serotypes can be readily produced by coinfection of the same vector backbone and a helper virus of the alternate serotypes during the large-scale production phase of the vector (serotype switch). Another strategy to overcome the transient nature of transgene expression is to incorporate elements that permit stable integration of the vector into the host chromosome. Taking advantage of the cloning capacity and broad tropism of HDAd vectors

and the capability of DNA integration of other systems, many laboratories have developed HDAd hybrid viral vectors (Recchia et al., 1999, 2004; Goncalves et al., 2001; Soifer et al., 2001, 2002; Yant et al., 2002). In most of the hybrid HDAd vectors, the transgene is integrated at random sites, except for HDAd/AAV hybrid viruses that coexpress Rep78 gene (Recchia et al., 1999, 2004). However, many of these systems require coexpression of necessary components for vector integration, in addition to therapeutic genes. Such components may have adverse effects on the host, though the use of regulatable systems to express such proteins could minimize such effects. Optimization of such integrating systems could produce even more powerful HDAd variants in the future.

Critical Parameters and Troubleshooting

The critical requirements for a good HDAd preparation are a helper virus with the correct structure, a packaging cell line with high Cre expression, and shuttle vectors of appropriate structure. High-titer helper virus is prepared using plaque-purified helper virus. It is important to have enough helper virus stock for vector production; also, the structure of the helper virus must be fully characterized. Pick four to six well isolated plaques and propagate to obtain high-titer virus seed stock, which allows for viral DNA extraction and subsequent diagnostic enzyme digestions. Large-scale helper virus preparation is carried out using the fully characterized seed stock. Helper virus passages should not exceed 5 for working helper virus. Helper virus contamination in HDAd vector preparation is determined by the efficiency of Cre-mediated excision of the packaging signal of helper virus. The efficiency of excision is determined by Southern blot analysis, as described in Support Protocol 1. The band corresponding to the left arm of intact helper virus should not be detectable in CVL. Helper virus contamination <0.2% is desirable, though for some experiments, levels <1% may be acceptable. The overall structures of HDAd vectors influence the efficiency of vector amplification as well as propensity for vector DNA rearrangement. In the authors' experience, vectors 31 to 35 kb in size are efficiently amplified. Vectors containing genomic fragments tend to be amplified more efficiently, and they may also be more stable during vector production. Thus, it is desirable

Table 16.24.1 Troubleshooting Guide for Production of Helper-Dependent Adenoviral Vectors

Problems	Possible causes(s)	Solution(s)
Low number or no colonies after transformation in DH5 α	Transformation efficiency is too low	Use commercial Subcloning Efficiency DH5 α (Invitrogen)
	Ligation did not work.	Run 1-2 μ l of ligation mixture on a 1% agarose gel to make sure that the banding patterns are different before and after the ligation. If not, use more T4 DNA ligase.
Too many blue colonies after transformation	The DNA insert to be subcloned contains plasmid backbone.	Purify the insert twice and run on an agarose gel to make sure the band corresponding to the plasmid backbone is not detectable. Qiagen spin column gel extraction kit works well.
Too many colonies of the intact shuttle vector	Alkaline phosphatase reaction is insufficient	Treat linearized shuttle vector with 1 U of calf intestinal alkaline phosphatase for 30 min at 37°C, and extract with phenol/chloroform twice.
The structure of recombinant DNA does not match either the shuttle vector or the plasmid containing expression cassette	Most likely, recombination occurred during bacterial culture at 37°C	Incubate bacterial culture at 30°C
CPE occurs too early or too late	Amount of helper virus is inappropriate	Adjust helper virus to obtain 90% CPE 2-3 days after infection
No HDAd vector is detected by Southern blot analysis after passage 3	Transfection efficiency is low	Check the transfection efficiency using the reporter gene construct. One day after the transfection, at least 20%-30% cells should be positive for the reporter gene expression.
	HDAd vector is not amplified efficiently	Perform one or more passages in 6- or 10-cm dish to determine the presence of HDAd vector. If the vector is not detectable, repeat transfection.
	Helper virus does not provide the necessary functions	Perform comprehensive restriction analysis of the helper virus. If the structure differs, plaque purify the original helper virus.
HDAd vector amplification is poor	Transgene product is toxic and is expressed during vector production	Use a promoter not active in the packaging cell line, or use a regulatable system
	Vector genome size is close or out of the size of limit	Change the vector genome size for efficient packaging (31-35 kb)
In Southern blot analysis, extra band(s) in addition to the 4 expected bands from a helper virus and HDAd vector are detected	Recombination between the helper virus and the HDAd vector, or within the HDAd vector occurred	It is possible to obtain HDAd vector with the correct structure by repeating the transfection. The authors have obtained a few HDAd vectors with the correct structure after 30 transfections.
		Change the vector design or the shuttle vector. HDAd vector with pC4HSU-based backbone is less prone to recombination.

*continued***Protein
Expression****16.24.21**

Table 16.24.1 Troubleshooting Guide for Production of Helper-Dependent Adenoviral Vectors, *continued*

Problems	Possible causes(s)	Solution(s)
After infection of packaging cell line with a helper virus, the band corresponding to the left arm of an intact helper virus is detected by Southern blot analysis	Cre expression is not optimum for the amount of helper virus used	Use less helper virus or change to another Cre-expressing packaging cell line
Multiple bands other than empty capsids or helper virus after CsCl density gradient ultracentrifugation	Potential difference of HDAd vector genome conformation	Collect each band separately and characterize for DNA structures, and transgene expression. They are likely the same.
No transgene expression detected	The integrity of transgene expression cassette is not maintained	Make sure the transgene cassettes intact by restriction enzyme analysis
	Transgene is not efficiently expressed	Include a Kozak sequence at the translation initiation site, or WPRE after the termination codon but before the polyadenylation signal. Alternatively, use a more potent promoter.
	Infectious titer is too low	Determine infectious titer by slot blot analysis described in Support Protocol 2. Harvest virus within 3 days after infection and use sodium deoxycholate method to release virus during purification.

to use genomic DNA containing all the necessary elements for gene expression, if possible.

Table 16.24.1 lists potential problems associated with HDAd vector production and their possible causes and solutions.

Anticipated Results

HDAd technology is still in its infancy. Despite an increasing number of publications on the use of HDAd vectors, large-scale production of HDAd vectors free from helper virus contamination has been technically demanding. The protocols described herein work well for pC4HSU-derived HDAds. A key step may be transfection efficiency. If transfection efficiency is low, HDAd amplification is poor and more passages are required to achieve enough titer for large-scale vector production. This increases the chance of vector DNA rearrangement. The typical yield of HDAd vectors on pC4HSU backbone is 10,000 to 20,000 VP/cell with 293Cre66 adherent cells, and 3000 to 8000 VP/cell with 293Cre66S suspension cells.

Time Considerations

Each serial passage takes 2 to 3 days. If every step works well and there is enough titer after passage 3, one can expect to get the pu-

rified HDAd vector from the first large-scale vector production in 2 to 3 weeks. Cloning the desired expression cassette into a shuttle vector requires some experience with large plasmid vectors, but should be straightforward for experienced molecular biology laboratories. Therefore, the total time commitment needed for each experiment is determined largely by the efficiency of transfection and subsequent vector amplification.

CHAPTER 17

Preparation and Analysis of Glycoconjugates

INTRODUCTION

OVERVIEW

The modern revolution in molecular biology has been driven to a large extent by advances in methods for analysis and manipulation of DNA, RNA, and proteins. Although oligosaccharides (sugar chains) are also major macromolecules of the typical cell, they did not initially share in this molecular revolution. The reasons for this are, to a large extent, technical. Whereas DNA, RNA, and proteins are linear polymers that can usually be directly sequenced, oligosaccharides show substantially more complexity, having branching and anomeric configurations (α and β linkages). Thus, while three amino acids or nucleotides can be combined into six possible sequences, three hexose monosaccharides can theoretically generate 1056 possible oligosaccharides. Also, the synthesis of DNA, RNA, and proteins are template-driven, and the sequence of one can generally be predicted from that of another. In contrast, the biosynthesis of oligosaccharides, termed glycosylation, is extremely complex, is not template-driven, varies among different cell types, and cannot be easily predicted from simple rules.

It is clear that oligosaccharides have important, albeit varied, effects upon the biosynthesis, folding, solubility, stability, subcellular trafficking, turnover, and half-life of the molecules to which they are attached. These are matters of great importance to the cell biologist, protein chemist, biotechnologist, and pharmacologist. On the other hand, the successful growth of several glycosylation mutants as permanent tissue culture cell lines indicates that the precise structure of many oligosaccharides is not critical for the growth and viability of a single cell in the protected environment of the culture dish. Thus, until recently, it was possible for many molecular biologists working with in vitro single-cell systems to ignore the existence of oligosaccharides. However, with the increasing emphasis on studying cell-cell interactions in normal development, tissue morphogenesis, immune reactions, and pathological conditions such as cancer and inflammation, the study of

oligosaccharide structure and biosynthesis has become very important.

The term “glycobiology” has found widespread acceptance for denoting studies of the biology of glycoconjugates in both simple and complex systems. Many technical advances have occurred in the analysis of oligosaccharides, making it now feasible to study them in detail. These advances include the development of sensitive and specific assays and the availability of numerous purified enzymes (glycosidases) with a high degree of specificity (the glycobiologist’s equivalent of restriction enzymes). Thus, the time has come to include oligosaccharide molecules in the overall lexicon of molecular biology.

In spite of all these recent advances, many analytical techniques in glycobiology have remained in the domain of the few laboratories that specialize in the study of oligosaccharides. Likewise, published compendia of carbohydrate methods are designed mainly for use by experts. This chapter attempts to “democratize” this technology and place some of it within easy reach of any laboratory with basic capabilities in biochemistry and molecular biology. The techniques described here include modern versions of time-honored methods and recently developed methods, both of which have widespread applications. However, it is important to emphasize that the protocols presented here are by no means comprehensive. Rather, they serve as a starting point for the uninitiated scientist who wishes to explore the structure, biosynthesis, and biology of oligosaccharide chains. In most cases, further analysis using more sophisticated techniques will be required to obtain final and definitive results. Nonetheless, armed with results obtained by techniques described here, the average molecular biologist can make intelligent decisions about the need for such analyses.

The appearance of many commercial kits for analysis of glycoconjugates is another sign that the technology has arrived and that many laboratories have developed an interest in glycobiology. It is worth noting that while some of these kits seek to simplify the use of well-es-

and Analysis of
Glycoconjugates**

17.0.5

Supplement 22

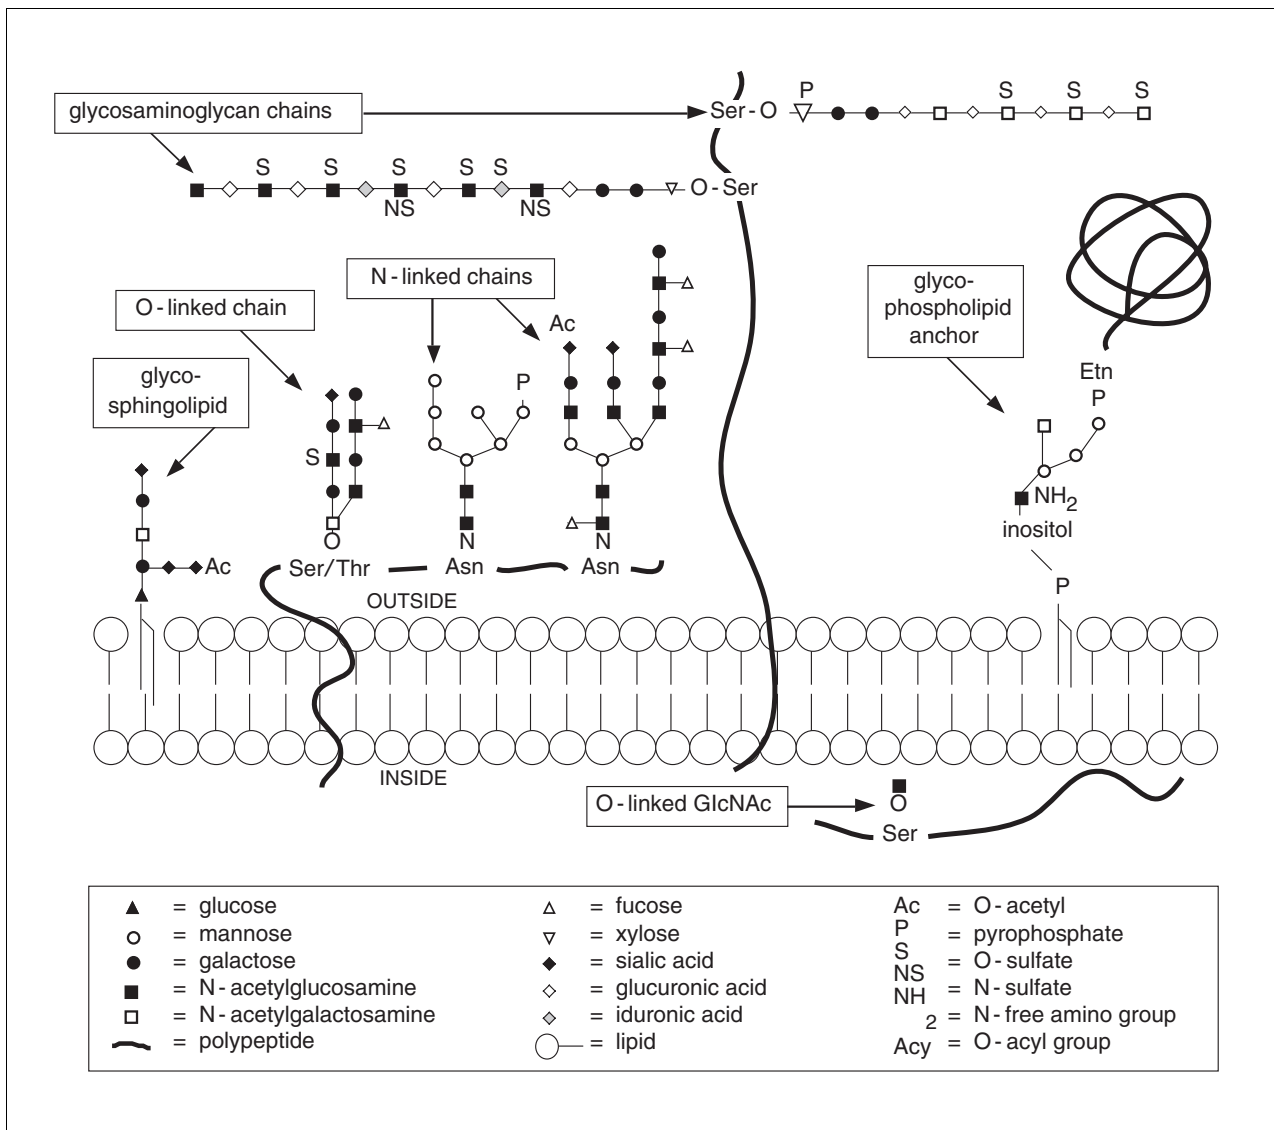

Figure 17.0.1 Common oligosaccharide linkage regions on animal cell glycoconjugates. The most common types of oligosaccharides found in animal glycoconjugates are shown, with an emphasis upon the linkage region between the oligosaccharide and the protein or lipid. Other rarer types of linkage regions and free oligosaccharides that can exist naturally (e.g., hyaluronan) are not shown.

established techniques, others contain methodologies that have been newly developed by the companies themselves. Experience with the latter methodologies may be limited in academic scientific laboratories, and the techniques in question may therefore not be represented in this chapter. However, although the admonition *caveat emptor* is appropriate, some of these kits may well become useful adjuncts to the methods presented in this chapter.

The different types of glycosylation are perhaps best defined by the nature of the linkage region of the oligosaccharide to a lipid or protein (Fig. 17.0.1). Although the linkage regions of these molecules are unique, the sugar chains frequently tend to share common types of outer

sequences. It is important to note that this chapter deals only with the major forms of glycosylation found on higher-animal glycoconjugates—*N*-acetylglucosamine (GlcNAc)-*N*-Asn-linked, *N*-acetylgalactosamine (GalNAc)-*O*-Ser/Thr-linked oligosaccharides on glycoproteins, xylose-*O*-Ser-linked glycosaminoglycans on proteoglycans, ceramide-linked glycosphingolipids, phosphatidylinositol-linked glyco-phospholipid anchors, and *O*-linked *N*-acetylglucosamine (GlcNAc-*O*-Ser). These structures are depicted in Figure 17.0.1. There are many other less common forms of glycosylation that one may need to consider, especially if prior literature suggests their existence in a given situation. Examples

of rarer sugar chains include (1) O-linked glucose, mannose, and fucose; (2) N-linked glucose; (3) glucosyl-hydroxylysine; and (4) GlcNAc-P-Ser (phosphoglycosylation).

Likewise, this chapter deals only with the most common forms of shared outer sequences (e.g., sialylated and fucosylated lactosamines, polylactosamines, *O*-glycosaminoglycan chains, and blood group sequences) and does not deal with rarer sequences (e.g., bisecting xylose residues, N-linked glycosaminoglycans, and β -linked GalNAc residues on N-linked oligosaccharides). Some time-honored techniques of somewhat lesser utility have been excluded, as have some requiring very sophisticated instrumentation. Likewise, several emerging technologies with great promise (such as fluorescent tagging and gel electrophoresis) have not been included. For further information, the reader is directed to the key references section at the end of this introduction.

CHOICE OF TECHNIQUES

For the novice experimenter in glycoconjugate analysis, the greatest difficulty is in deciding which protocols are applicable to the question at hand, are sensitive enough to yield results, and are most likely to give useful answers. The following tables are therefore provided as a general guide to glycoconjugate analysis.

Suggestions are made for the protocols that are most likely to be useful based upon the questions being asked (Table 17.0.1), the amount of material that is available for analysis (Table 17.0.2), and the type of glycoconjugate that is being studied (Table 17.0.3). The user is advised to select protocols based on the information in these tables and then to consult the commentary section of the selected protocols for further information regarding practicality and applicability to a particular experimental situation. Choice of technique may also be dictated by whether the glycoconjugate to be studied is being monitored with a radioactive tracer or by direct chemical analysis, and by what fraction of a precious purified sample can be expended for oligosaccharide analysis.

The techniques in this chapter are not sufficiently inclusive to give final confirmation of the complete structure of an oligosaccharide. In such cases, additional studies of the glycoconjugate may be necessary using more advanced techniques. In some cases, if the sample is highly purified and available in large amounts, use of nondestructive methods such as NMR should be considered before committing the sample to destructive analysis. Alternatively, the information generated by the techniques described in this chapter may be sufficient to answer the biological question(s) at hand.

Table 17.0.1 Protocol Choice for Glycoconjugate Analysis Based on Question Being Asked

Question	Suggested protocols (unit no.)
Is there anything special about purifying my glycoconjugate?	17.1, 17.2, 17.3
Is my protein glycosylated?	17.1, 17.2, 17.4, 17.5, 17.6, 17.7, 17.8, 17.9, 17.10, 17.12, 17.13, 17.17, 17.18
How much of my glycoconjugate consists of sugar chains?	17.9, 17.10, 17.12, 17.13, 17.17, 17.18
What monosaccharides are in my glycoconjugate, and in what ratio?	17.4, 17.9, 17.12, 17.16, 17.18, 17.19
How many glycosylation sites are there on my protein?	17.10, 17.13, 17.14B
Can I specifically label the sugar chains on my glyconjugate?	17.4, 17.5, 17.6
Does my antibody recognize sugar chains on the glycoconjugate?	17.7, 17.8, 17.12, 17.13, 17.17
Can I selectively release the sugar chains from my glycoconjugate?	17.8, 17.13, 17.15, 17.17
Does my protein have a glycopospholipid anchor?	17.4, 17.8
What type of glycosphingolipids does my cell have?	17.3, 17.4, 17.7
Are there glycosaminoglycan chains on my protein?	17.2, 17.13, 17.17, 17.22
Can I alter glycosylation during biosynthesis?	17.10, 17.11
Can I alter glycosylation on the surface of intact cells?	17.6, 17.10, 17.12, 17.13, 17.17
Can I release and isolate intact or fragmented oligosaccharides from my glycoconjugate?	17.8, 17.12, 17.13, 17.14, 17.15, 17.17
What are the basic structural characteristics of the released oligosaccharides?	17.5, 17.6, 17.12, 17.13, 17.20, 17.21, 17.22, 17.23

17.23	U	U	U	U	U*

^aAbbreviations: P, possibly useful; U, useful; * radioactive samples.

^bThe average molecular weight of a monosaccharide unit of sugar chains is ~200. To start, assume the glycoconjugate contains 5 to 10 mol monosaccharide/mol glycoconjugate. Radioactive samples should have a specific activity from 0.1 to 1 Ci/mmol.

STEREOCHEMISTRY AND DIAGRAMMATIC REPRESENTATION

Basic Stereochemistry of Monosaccharides

In addition to this discussion, the reader is referred to Allen and Kisalius (1992) for a more detailed discussion of the principles of carbohydrate structure. The italicized terms in the discussion below are defined in the glossary at the end of this unit.

Glyceraldehyde, the simplest monosaccharide, has only one chiral (asymmetric) carbon (C-2). Therefore, it is a chiral molecule that shows optical isomerism; it can exist in the form of two nonsuperimposable mirror images called *enantiomers* (see Fig. 17.0.2). These enantiomers have identical physical properties, except for the direction of rotation of the plane

of polarized light (–, left hand; +, right hand). Historically, the (+)-glyceraldehyde was arbitrarily assigned the prefix **D** (for dextrorotatory), and the (–)-glyceraldehyde, the prefix **L** (for levorotatory). The pair of enantiomers also have identical chemical properties, except toward optically active reagents. This fact is particularly important in biological systems, because most enzymes and the compounds they work on are optically active.

The configuration of the highest-numbered asymmetric carbon atom in the chain of higher monosaccharides is determined by comparison with the configuration of the chiral (or asymmetric) carbon of glyceraldehyde. Thus, a prefix **D**- is added to the name of each monosaccharide having the configuration of **D**-glyceraldehyde at the highest-numbered asymmetric carbon, and the prefix **L**- to those having the configuration of **L**-glyceraldehyde at the high-

Figure 17.0.2 Enantiomers of glyceraldehyde.

est-numbered asymmetric carbon. The direction of rotation of the plane of polarized light for the compound needs to be determined experimentally, and is indicated with the – or + sign, between parentheses, immediately after the prefix D or L (e.g., D-(+)-glucose). In biological systems, where stereochemical specificity is the rule, D molecules may be completely active and L molecules may be completely inert, or vice versa. All known naturally

occurring monosaccharides in animal cells are in the D configuration, except for fucose and iduronic acid, which are in the L configuration.

Each *aldose* is usually present in a cyclic structure, because the *hemiacetal* produced by reaction of the aldehyde group at C-1 with the hydroxyl group at C-5 gives a six-membered ring, called a *pyranose* (see Fig. 17.0.3). When five-membered rings are formed by reaction of the C-1 aldehyde with the C-4 hydroxyl, they

^aThis chapter deals only with the most common forms of glycosylation on glycoconjugates.

^bAbbreviations: P, possibly useful; U, useful.

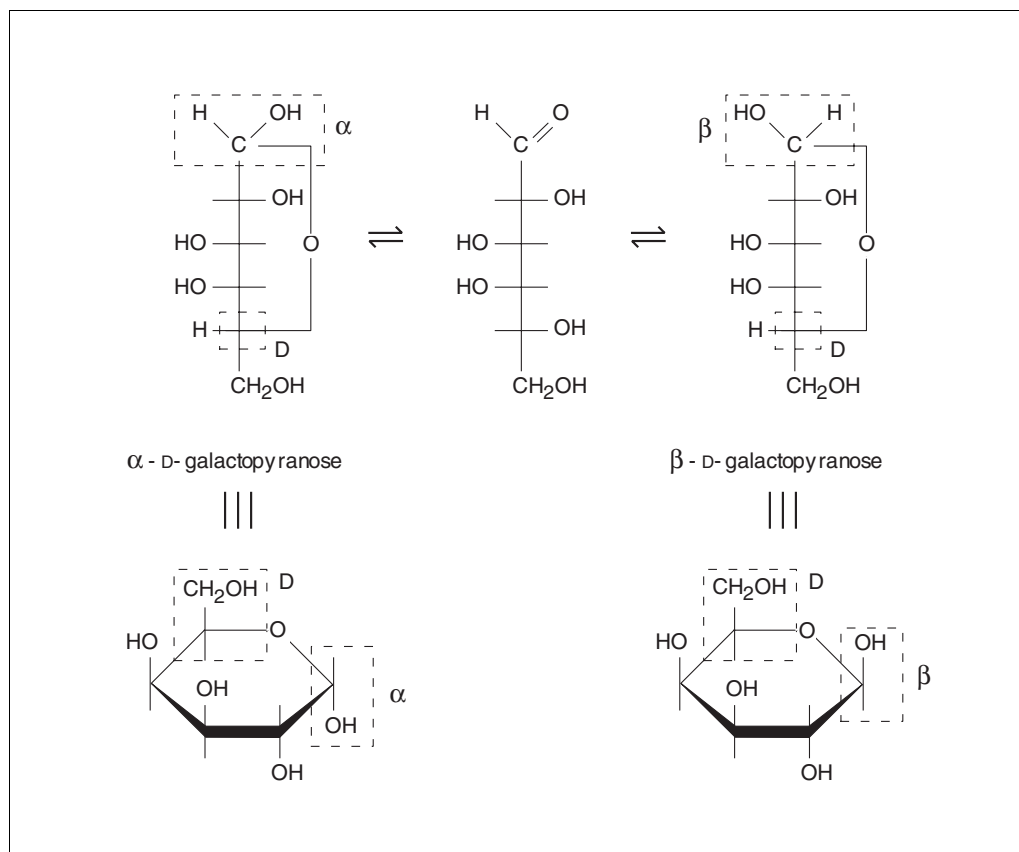

Figure 17.0.3 Formation of cyclic structures: open and ring forms of galactose.

are called *furanoses*. Hexoses commonly form pyranosidic rings, and pentoses form furanosidic rings, although the reverse is possible. Similarly, ketoses (e.g., sialic acids) can form *hemiketals* by reaction of the keto group at C-2 with the hydroxyl group at C-6.

These ring forms are the rule in intact oligosaccharides. The formation of the ring produces an additional chiral center at C-1 (or C-2 for keto sugars). Thus, two additional isomers are possible, and these are called *anomers*. These anomers are designated α and β . Because glycosidic linkages occur via anomeric centers, they are called α linkages and β linkages.

Diagrammatic Representations of Monosaccharides

Monosaccharides are conventionally presented in the Fisher projection or the Haworth representation (see Fig. 17.0.4).

The Fisher projection

The carbon chain of the monosaccharide is written vertically with carbon atom 1 at the top. Horizontal lines represent bonds projecting out

from the plane of the paper, whereas vertical lines represent bonds projecting behind the plane. When the hydroxyl group at the highest-numbered asymmetric carbon is on the right, the monosaccharide belongs to the D series. When this group is on the left, the monosaccharide belongs to the L series.

The Haworth representation

The six-membered ring with the oxygen at the upper-right corner is approximately perpendicular to the plane of the paper, with the groups attached to the carbons above or below the ring. All groups that appear to the right in the Fisher projection appear below the plane of the ring in the Haworth representation. The carboxymethyl group (C-6) lies above the ring in D series hexoses, below it in L series. The only difference between the α and β anomers of a given hexose is the relative position of the hydroxyl and the hydrogen at C-1. In the α anomer, the hydrogen is below the ring for the D series (above it for L series); in the β anomer the hydrogen is above the ring for the D series (below for L series).

Figure 17.0.4 Fisher projections and Haworth representations of monosaccharides.

Conformation of Monosaccharides in Solution

The Haworth representation does not depict the real conformation of these molecules. The preferred conformation in solution of the six-membered ring monosaccharides is a chair conformation, in which each group can adopt either an *equatorial* or *axial* position.

Two possible chair conformations called *conformers* exist in equilibrium. The direction of equilibrium varies among monosaccharides depending on the relative position of hydroxyl

groups or other substituents. The preferred conformation has the lowest number of bulky groups in an axial position (Fig. 17.0.5).

Formulas for Representation of Oligosaccharide Chains

Full and correct representation of the formula of an oligosaccharide chain requires notation of the complete stereochemistry of the component monosaccharides. Thus, the simple tetrasaccharide commonly called sialyl-Lewis^x

Figure 17.0.5 D-Mannose chair conformation.

(attached to an underlying oligosaccharide, R), would be written as follows:

In more common practice, the D and L configurations and nature of ring structures are assumed, and the formula is written as:

3
|
1
Fuc α

Higher-Order Structures

The presence of monosaccharides with different types of glycosidic linkages in oligo- and polysaccharides creates further complexity, with the development of secondary and tertiary structures in these molecules. The approximate shape adopted in solution by a given carbohydrate chain can be predicted according to the type of glycosidic linkages involved. These higher-order structures may be critical for the biological roles of glycoconjugates.

GLOSSARY

aldose monosaccharide with a carbonyl group at the end of the carbon chain (aldehyde group); the carbonyl group is assigned the lowest possible number (i.e., carbon 1).

carbohydrates polyhydroxyaldehydes or polyhydroxyketones, or compounds that can be hydrolyzed to them.

diastereoisomer compound with identical formulas that have a different spatial distribution of atoms (e.g., galactose and mannose).

enantiomers nonsuperimposable mirror images of any compound (e.g., D- and L-glucose).

epimers two monosaccharides differing only in the configuration of a single chiral carbon.

Fuc L-fucose type of deoxyhexose (see also *types of monosaccharides*).

Gal D-galactose type of hexose (see also *types of monosaccharides*).

GalNAc (N-acetyl-D-galactosamine) type of hexosamine (see *types of monosaccharides*).

ganglioside anionic glycolipid containing one or more units of sialic acid.

Glc D-glucose type of hexose (see also *types of monosaccharides*).

GlcNAc (N-acetyl-D-glucosamine) type of hexosamine (see also *types of monosaccharides*).

glyceraldehyde simplest monosaccharide (an aldotriose; i.e., with three carbon atoms).

glycoconjugate natural compound with one or more mono- or oligosaccharide units covalently linked to a noncarbohydrate moiety.

GLUA or GIA (D-glucuronic acid) type of uronic acid (see also *types of monosaccharides*).

glycolipid or glycosphingolipid oligosaccharide attached via glucose or galactose to the terminal primary hydroxyl group of ceramide, which is composed of a long-chain base (i.e., sphingosine) and a fatty acid. Glycolipids can be neutral or anionic (negatively charged).

glycophospholipid anchor glycan bridge between phosphatidylinositol and a phosphoethanolamine in amide linkage to the C terminus of a protein; constitutes the sole membrane anchor for such proteins.

glycoprotein glycoconjugate in which a protein carries one or more oligosaccharide chains covalently attached to a polypeptide backbone via N-GlcNAc- or O-GalNAc-linkages.

glycosaminoglycan linear copolymers of disaccharide-repeating units, each composed of hexosamine and hexose or hexuronic acid; these oligosaccharide chains define the proteoglycans. The type of disaccharide unit can define glycosaminoglycans as chondroitin or dermatan sulfate, heparan or heparin sulfate, hyaluronic acid, and keratan sulfate. Glycosaminoglycans (except hyaluronic acid) also contain sulfate esters substituting hydroxyl or amino groups (*N*- or *O*-sulfate groups).

glycosidic linkage linkage of a monosaccharide to another residue via the anomeric hydroxyl group.

IdUA or IdA (*L*-iduronic acid) type of uronic acid (see also *types of monosaccharides*).

ketose monosaccharide with a carbonyl group in an inner carbon; the carbonyl group is assigned the lowest possible number (i.e., carbon 2).

Man *D*-mannose type of hexose (see also *types of monosaccharides*).

monosaccharide carbohydrate that cannot be hydrolyzed into simpler units (see also *types of monosaccharides*).

mucin large glycoproteins that contain many (up to several hundred) *O*-GalNAc-linked oligosaccharide chains that are often closely spaced.

***N*-linked oligosaccharide** oligosaccharide covalently linked to an asparagine residue of a polypeptide in the consensus sequence: -Asn-X-Ser/Thr. The many different kinds of *N*-linked oligosaccharides have certain common features: (1) a common core pentasaccharide containing two mannosyl residues α -linked to a third mannosyl unit, in turn β -linked to a chitobiosyl group; (2) a chitobiosyl group β -linked to the asparagine amide nitrogen. *N*-linked oligosaccharides can be divided into three main classes: high-mannose, complex, and hybrid.

Neu5Ac (*N*-acetyl-*D*-neuraminic acid) type of sialic acid (Sia; see also *types of monosaccharides*).

***O*-linked oligosaccharide** oligosaccharide linked to the polypeptide via *N*-acetylgalactosamine (GalNAc) to serine (or threonine). Note that other types of *O*-linked oligosaccharides also exist (e.g., *O*-GlcNAc) but that the *O*-GalNAc linkage, being the most well-known, is often described by this generic term.

oligosaccharide branched or linear chain of monosaccharides attached to one another via glycosidic linkages (see also *polysaccharides*).

polylactosaminoglycan long chain of repeating units of the disaccharide β -Gal(1-4)-GlcNAc. These chains may be modified by sialylation, fucosylation, or branching. When sulfated, they are called keratan sulfate (see *glycosaminoglycans*).

polysaccharides branched or linear chain of monosaccharides attached to each other via glycosidic linkages that usually contain repetitive sequences. The number of monosaccharide residues that represents the limit between an oligosaccharide and a polysaccharide is not defined. A tetra-fucosylated, sialylated tetraantennary carbohydrate moiety containing eighteen monosaccharide units, present in a glycoprotein, is considered an oligosaccharide, while a carbohydrate composed of eighteen glucose residues linked β -(1-4) present in a plant extract is considered a polysaccharide.

polysialic acid homopolymer of sialic acid selectively expressed on a few vertebrate proteins and on the capsular polysaccharides of certain pathogenic bacteria.

proteoglycan glycoconjugate having one or more *O*-xylose-linked glycosaminoglycan chains (rather than *N*-GlcNAc- or *O*-GalNAc-linked oligosaccharides) linked to protein. The distinction from a glycoprotein is otherwise arbitrary, because some proteoglycans can have both glycosaminoglycan chains and *N*- or *O*-linked oligosaccharides attached to them.

reducing sugar sugar that undergoes typical reactions of aldehydes (e.g., is able to reduce Ag^+ or Cu^{++}). Mono-, oligo-, or polysaccharides can be reducing sugars when the aldehyde group in the terminal monosaccharide residue is not involved in a glycosidic linkage.

saccharide modifications hydroxyl groups of different monosaccharides can be subject to phosphorylation, acetylation, sulfation, methylation, or fatty acylation. Amino groups can be free, *N*-acetylated, or *N*-sulfated. Carboxyl groups are occasionally subject to lactonization to nearby hydroxyl groups.

Sia (*sialic acid*) generic name for a family of acidic nine-carbon monosaccharides (e.g., Neu5Ac).

types of monosaccharides monosaccharides may have a carbonyl group at the end of the carbon chain (aldehyde group), or in an inner carbon (ketone group). The carbonyl group is assigned the lowest possible number, e.g., carbon 1 (C-1) for the aldehyde group; carbon 2 (C-2) for the most common ketone groups. These two types are named aldoses and ketoses.

The simplest monosaccharide is glyceraldehyde (see Fig. 17.0.2), an aldotriose (containing three carbon atoms). Natural aldoses with different number of carbon atoms in their chain are named accordingly (e.g., aldohexoses, containing six carbon atoms). Two monosaccharides differing only in the configuration of a single chiral carbon are called epimers. For example, glucose and galactose are epimers of each other at C-4. Common monosaccharides present in animal glycoconjugates are (1) deoxyhexoses (e.g., L-Fuc); (2) hexosamines, usually N-acetylated (e.g., D-GalNAc and D-GlcNAc); (3) hexoses (e.g., D-Glc, D-Gal, and D-Man); (4) pentoses (e.g., D-Xyl); (5) sialic acids (Sia; e.g., Neu5Ac); (6) uronic acids (e.g., D-GlA and L-IdA).

Xyl D-xylose type of pentose (see also *types of monosaccharides*).

Further detailed information on the analysis of oligosaccharides is provided in the specific literature cited in individual protocol units. The following sources also can be used for general information, details on specific methods, and for many methods that are not included in this chapter.

SPECIAL CONSIDERATIONS OF GLYCOCONJUGATES AND THEIR PURIFICATION

Because of their unique composition and structural characteristics, there are instances in which glycoconjugates can be studied in biological mixtures directly, without purification. However, as Arthur Kornberg has said, to answer a biological question the best course of action is usually to “purify, purify, purify.” Indeed, the complete elucidation of any biological system involving a glycoconjugate will require that it be purified for structural and functional characterization.

This section describes general principles for purifying three major classes of glycoconjugates—glycoproteins, glycolipids, and proteoglycans. These classes have been described in the chapter introduction and glossary. Each is a large and polydisperse family of molecules with widely ranging structural and functional characteristics. Needless to say, many of the classic principles used for purification of other macromolecules (e.g., size fractionation and selective precipitation) apply to each of these types of glycoconjugates; on the other hand, an individual situation may provide unique opportunities for selective purification of a particular molecule.

The units presented in this section take the middle road and outline the principles particularly applicable to the purification of each class of glycoconjugate, taking advantage of group-specific properties. Glycoproteins usually have sugar chains that can be recognized by specific plant lectins; thus, affinity chromatography using immobilized lectins is a powerful technique, when properly applied (*UNIT 17.1*). Proteoglycans are characterized by a high density of negative charge and frequently by unusual buoyant densities and sedimentation properties, which can be used to advantage in their purification (*UNIT 17.2*). Glycolipids as a group are more hydrophobic than the other glycoconjugates, yet have amphipathic properties that allow them to be purified away from other lipids (*UNIT 17.3*).

Selective purification of these groups of molecules facilitates their further fractionation and final characterization. However, it is important to realize that exceptions can be encountered (e.g., glycoproteins with unusually high negative charges or glycolipids with extremely hydrophilic properties). Also, the phenomenon of microheterogeneity in oligosaccharide structure can cause even a single glycoconjugate to manifest a range of properties. For example, if a single glycoprotein from a single cell type has heterogeneity in N-linked oligosaccharide processing, some (but not all) of the protein may be recovered during affinity chromatography on wheat germ agglutinin (WGA)-Sepharose (*UNIT 17.1*).

At the present time there is no generalized purification scheme that will provide good yields of all of the major classes of glycoconjugates from a single starting sample. For example, the organic extractions required for glycolipids (*UNIT 17.3*) irreversibly denature most glycoproteins and proteoglycans. Conversely, the glycolipids are usually irretrievable from the detergent extractions used for membrane-bound glycoproteins (*UNIT 17.1*). Thus, if there is a need to examine all of the major glycoconjugates in a given cell or tissue, it is advisable to purify the major classes of molecules in parallel with one another, using separate aliquots of the same batch of starting material.

Even when studying a specific molecule, it is usually worthwhile to carry out a group-specific purification as a first step—e.g., to extract total cellular lipids before purifying away a specific disialoganglioside (*UNIT 17.3*). If the glycoconjugate in question has been radiolabeled (see *UNIT 17.4*), one also has the advantage that purification to “radiometric homogeneity” is sufficient for many types of analyses. Thus, if a glycoprotein has been

metabolically labeled with [2-³H]mannose and the intent is to study the N-linked oligosaccharides, it may not matter that various unlabeled proteins or lipids are contaminating the final preparation. In the final analysis, the broad principles outlined in *UNITS 17.1-17.3* must be adapted by the investigator to the situation at hand.

UNIT 17.1

Special Considerations for Glycoproteins and Their Purification

Glycoproteins contain a variety of different sugar chains. Some glycoproteins have many large and highly charged chains while others have only a single neutral sugar residue that is easily overlooked. This enormous diversity makes it impossible to recommend any single procedure for purifying glycoproteins. Most procedures used to purify nonglycosylated proteins are equally useful for glycoproteins. However, the presence of large amounts of carbohydrate on glycoproteins often endows them with higher charge, increased density, larger apparent size, and greater solubility than nonglycosylated proteins. Decades ago, these physical properties were cleverly exploited to purify and characterize many of the most abundant glycoproteins (Gibbons, 1972). More recently, greater knowledge of carbohydrate structure and biosynthesis has led to development of techniques that rely on more subtle and specific aspects of carbohydrate structure. Some of these approaches can also be used to detect a single sugar on a few picomoles of protein (see *UNIT 17.7*).

This unit begins by describing some properties of glycoproteins—e.g., subcellular location and solubility—that may be useful in determining which purification techniques to try. This discussion is followed by two protocols describing preparative glycoprotein purification using lectin-affinity chromatography, as well as an outline for a small-scale pilot procedure designed to check lectin binding and elution conditions. Lectins are often used for purifying glycoproteins because, in contrast to conventional purification procedures (e.g., gel filtration and ion-exchange chromatography; *UNITS 10.9 & 10.10*) that exploit general physical properties of glycoproteins, lectins recognize specific three-dimensional structures created by a cluster of sugar residues. Conventional purification procedures are generally tried before applying lectin-affinity chromatography.

SPECIAL CONSIDERATIONS IN THE PURIFICATION OF GLYCOPROTEINS

Subcellular Location of Glycosylated Proteins

Most protein glycosylation occurs in the lumen of the endoplasmic reticulum and the Golgi apparatus, but certain types of glycosylation also occur in the cytoplasm (see *UNIT 17.13*). Secreted proteins, membrane proteins, and proteins that enter vesicles such as lysosomes are good candidates for having some type of carbohydrate component. The most common types of sugar chains are found in N- and O-linkages to proteins and as components of glycopospholipid anchors. Each of these types of glycosylation can occur individually or in any combination. The physical properties they impart can be effectively used for some purifications. Knowledge of the type of glycosylation is thus necessary in order to determine the optimal purification method. The methods outlined below may be helpful for determining glycosylation type.

Secreted glycoproteins. It is relatively simple to determine if the protein is secreted by analyzing conditioned medium used to culture the cells. This may require dialysis and concentration of the conditioned medium. If the cells must be grown in the presence of added serum components during the time when the protein is secreted, it may be very difficult to use any specific glycoprotein purification approach to enrich for your protein because competing serum glycoproteins will probably be in great excess. Thus it is important to determine if the target molecule can be secreted into serum-free medium.

Cytoplasmic glycoproteins. If the protein is not secreted, cells can be ruptured in an iso-osmotic medium (e.g., sucrose) and centrifuged to separate insoluble membranes and vesicles

from soluble cytoplasmic components (UNIT 17.6). Glycoproteins are not commonly found in the soluble fraction. If the protein of interest is detected in the soluble fraction and is later found to be glycosylated, it may have been proteolyzed from a membrane. This is the most likely explanation for N-linked glycoproteins that are found in the soluble fraction. It is also possible that the protein is one of the recently described cytoplasmic or nuclear glycoproteins that contain O-linked *N*-acetylglucosamine (GlcNAc), in which case it may bind to wheat germ agglutinin (WGA, from *Triticum vulgare*; alternate protocol).

Organelle glycoproteins. If the protein of interest is not present in the soluble cytoplasmic fraction, the membrane and vesicle pellet is then resuspended in the presence of protease inhibitors and briefly exposed to a hypo-osmotic medium (or frozen and thawed) to lyse sensitive organelles and release their soluble contents. Membranes are again sedimented by centrifugation. Glycoprotein solubilized by this procedure will be accompanied by lysosomal enzymes. These proteases are potentially troublesome, but protease inhibitors will lessen or eliminate their effect. Various exo- and endoglycosidases may also be released by this procedure, but they are usually present at such a low concentration that they do not degrade the sugar chains on other glycoproteins.

Membrane-bound and glycopospholipid-anchored proteins. If the protein of interest is not solubilized by any of the above procedures, it is probably a peripheral or integral membrane protein, or it is anchored to glycopospholipid. Different nonionic detergents or increasing concentrations of a single detergent can be used to solubilize these proteins. Detergents that have high critical micelle concentrations (CMC) and can be easily dialyzed are preferred, e.g., hexyl-, heptyl-, and octyl-glucosides or glucamide detergents (MEGA-8, Calbiochem). However, a glucose-based detergent such as octyl-glucoside may block protein binding on some lectin columns such as Concanavalin A (Con A)-Sephacrose, or may produce a very high background in direct sugar analysis (UNIT 17.9) even after extensive dialysis. If the protein is glycopospholipid-anchored, the lipid component will cause it to partition into the detergent phase of a Triton X-114/water two-phase system (UNIT 17.8) and to interact strongly with hydrophobic matrices such as phenyl-Sephacrose. In some instances, the lipid portion of the anchor may be removed by digestion with phosphatidylinositol-specific phospholipase C

(UNIT 17.8). This cleavage leaves the carbohydrate portion of the anchor associated with the protein and converts the lipophilic protein into a soluble, more hydrophilic protein. Phospholipase digestion reduces the protein's affinity for hydrophobic matrices and results in its extraction into the aqueous phase of Triton X-114/water mixture (UNIT 17.8).

Solubility Properties

The solubility properties of a glycoprotein with a small amount of carbohydrate (~5%) will not be influenced much by the sugar component. If the carbohydrate is part of a glycopospholipid anchor, detergent solubilization may be required. Standard ammonium sulfate or ethanol precipitation (UNIT 10.9) works well for many glycoproteins, but those with high sugar content may remain soluble, even in relatively high concentrations of ethanol. Very anionic proteins with abundant sialic acid or sulfate esters may be resistant to precipitation with trichloroacetic acid or perchloric acid (APPENDIX 2). This unusual solubility is sometimes exploited as a purification step because most other proteins will be precipitated under these conditions. However, a combination of 10% trichloroacetic acid and 2% phosphotungstic acid will precipitate even highly charged proteins. Prolonged exposure to low pH may cause partial loss of sialic acid and deamidation of Asn and Gln, resulting in unwanted protein microheterogeneity. Extremes of pH should be avoided because of the possibility of hydrolysis of labile groups such as phosphodiester or acetyl esters.

Nonglycosylated proteins band in cesium chloride gradients at ~1.3 g/ml and polysaccharides at ~1.6 to 2.0 g/ml. This substantial difference in density can be used to separate very highly glycosylated proteins from those containing lesser amounts of carbohydrate. This treatment may permanently denature or inactivate some proteins, and is useful only if the protein is stable, is active in the presence of CsCl₂, or renatures once the CsCl₂ is removed.

Chromatographic and Staining Properties

Gel-filtration columns and SDS-PAGE. Proteins with high carbohydrate content (>20 to 30%) elute much earlier on gel-filtration columns (UNIT 10.9) than nonglycosylated proteins of similar size. If the amount of carbohydrate is variable, it may broaden the peak as well. Migration of proteins in SDS-PAGE (UNIT 10.2) is also affected by the extent of glycosylation. A protein with multiple anionic sugar

chains, each with a variable number of sialic acids or sulfate esters, can broaden a single protein band into a smear on gels. Closely clustered, short, O-linked sugar chains can appear to contribute as much as ten times their actual mass to the apparent molecular weight of a protein.

Very anionic glycoproteins may not stain with the normal Coomassie brilliant blue or silver staining procedures (UNIT 10.6). Some glycoproteins may even be seen as negative bands against the brownish background of silver-stained gels. Other stains, such as the Coomassie-based ProBlue stain (Integrated Separation Systems) or the cationic dyes toluidine blue and alcian blue, are often used for staining proteoglycans and other highly anionic proteins.

Ion-exchange and isoelectric focusing chromatography. The presence of sialic acids and sulfate esters makes some glycoproteins bind well to ion-exchange columns (e.g., DEAE-Sephadex, DEAE-Sephacel; UNIT 10.10). High-salt solutions elute these glycoproteins well after most other proteins have been eluted. The variable number of negative charges can also give multiple separate or very broad and poorly resolved protein peaks (UNITS 10.3 & 10.10). Multiple peaks or broad bands are also encountered in isoelectric focusing gels. Sialidase or endoglycosidase digestions can sometimes simplify these patterns by removing negative charges.

In the case of “mucins” (highly charged glycoproteins with closely clustered or extended O-linked GalNAc chains) or proteoglycans, ion-exchange columns may need to be run in 6 M urea to prevent protein aggregation.

Preparation of Protein Samples for Carbohydrate Analysis

Carbohydrate contamination. A highly purified protein that gives only a single band by SDS-PAGE analysis may still be unsuitable for carbohydrate analysis. Glucose is only very rarely found on sugar chains of proteins. On the other hand, it is almost always a readily available contaminant. DEAE- and CM-cellulose, agarose, Sephadex, Kimwipes, sucrose, glycerol, starch powder used on latex gloves, and glucoside-based detergents are all carbohydrates and can make a relatively large contribution to the sugar content of a sample, depending upon exactly how the material is analyzed. If proteins are purified on sucrose gradients, extracted with glucose-based detergents, or normally stored in glycerol, these sugar contaminants must first be completely removed by

dialysis. Acrylamide-based gels (e.g., Bio-Gel series) are preferred over the dextran-type gels (Sephadex) for gel-filtration purification because the latter can contribute fragments of beads as soluble but nondialyzable material (UNIT 10.9). As a final precaution, protein-containing solutions should be filtered through a 0.2- μ m filter to remove any particles that may have come from ion-exchange or affinity columns. If glucose is found by compositional analysis even after taking these precautions, it is still most likely to be a contaminant and not a component of the glycoprotein.

Lectin-affinity chromatography. The most frequently used specific purification procedure for glycoproteins is lectin-affinity chromatography. Dozens of plant lectins have been identified and in many cases their sugar specificity is known. This sugar specificity is the basis for the separation and structural analysis of many individual oligosaccharides and glycopeptides described in this chapter, and for the identification of lectin-binding glycoproteins in UNIT 17.7. Glycoproteins often contain multiple chains of a given sugar type and multiple interactions with the immobilized lectin may make it difficult to elute some of the proteins from the lectin column. The presence of multiple low-affinity sugar chains can still give substantial interaction with a lectin-containing column even though the individual sugar chains may themselves have a low affinity. Thus, one should be careful not to interpret too much about sugar chain structure from a protein's binding to a lectin column. This by no means belittles their usefulness for glycoprotein purification; lectin-affinity chromatography may be used to partially purify glycoproteins and to provide rather limited qualitative information about the nature of their carbohydrate components. Other preparative purification steps, such as ammonium salt precipitation (UNIT 11.3) and gel-filtration and ion-exchange chromatographies (UNITS 10.9 & 10.10), are usually done prior to using lectins, but this is not necessary.

Many different lectins are commercially available in an immobilized form suitable for glycoprotein purification, but some can be rather expensive. Con A-Sepharose is the most commonly used lectin for glycoprotein purification. It is relatively inexpensive, it is stable, and it can bind to many different glycans. Bound proteins can be eluted with α -methyl-D-mannoside (α MM). WGA is the next most popular lectin for the same reasons although it is somewhat more expensive.

Other notable lectins used to purify glycoproteins include *Ricinus communis* lectin (RCA I) for proteins that carry Gal-terminated sugar chains, and pea or lentil lectins for those N-linked oligosaccharides that have a fucose residue in the chitobiosyl core region. The utility of these lectins for characterizing glycopeptides is described in *UNIT 17.7*. Limited availability, higher price, limited track records, and, in some cases, the requirement for exotic sugars to elute bound proteins make some of these lectins less appropriate for routine use in glycoprotein purification. However, the principles of Con A–Sepharose and WGA-agarose lectin-affinity chromatography should apply to these other lectins as well. A broad range of immobilized lectins is available from E-Y Laboratories, Pharmacia Biotech, Vector Labs, and Sigma (*APPENDIX 4*).

Examples of lectin-affinity chromatography purifications. The basic and alternate protocols presented below describe the use of lectins for preparative glycoprotein purification. Con A–Sepharose and WGA-agarose were chosen for convenience and availability. The support protocol describes a small-scale pilot procedure to test for lectin binding and to determine elution conditions. There are many variations on the basic procedure in the literature, but all use the same principles: bind the protein to immobilized lectin through its sugar chain, wash away unbound protein, and elute bound protein with a simple sugar that resembles the sugar ligand of the bound protein. Because many proteins have sugar chains that can bind to a specific lectin, this procedure seldom yields a pure protein.

CON A–SEPHAROSE AFFINITY CHROMATOGRAPHY

Con A–Sepharose chromatography is used to partially purify glycoproteins that contain terminal mannose or glucose residues; the steps presented below are typical conditions for this type of chromatography, although a variety of approaches have been utilized. In this protocol, bound glycoproteins are eluted with α -methyl-D-mannoside (α MM) after the column is first washed to remove unbound and weakly bound proteins. Before proceeding, it is advisable to conduct a pilot study to test the protein of interest for lectin binding and elution conditions (see support protocol).

Materials

- 10 mg/ml Con A–Sepharose (Pharmacia Biotech or Sigma)
- Column buffer
- 0.5 M α MM in column buffer
- Protein sample in column buffer
- Glass wool
- 1.5 \times 30–cm glass or disposable chromatographic column
- Additional reagents and equipment for degassing solutions (*UNIT 10.12*), phenol–sulfuric acid assay for sugars (*UNIT 17.9*) and specific assay for detecting the protein of interest

NOTE: This procedure should be carried out at room temperature if the protein to be isolated will tolerate this condition. If not, carry it out in a cold room, and prechill all solutions to maintain temperature.

1. Gently resuspend 50 ml settled Con A–Sepharose (10 mg lectin/ml packed resin) in 50 ml column buffer to make a slurry. Degas the slurry.

This volume of lectin beads should be sufficient to bind ~100 mg glycoproteins. If a 1.5 \times 30–cm column is not available, either the dimensions of the column or the total amount of resin can be modified. A 1.0 \times 30–cm column will bind ~50 mg total glycoprotein. If the amount of glycoprotein in the sample is considerably less than 50 to 100 mg, decrease the volume of the column accordingly. The ratio of input protein to lectin does not seem to matter as long as the column is not overloaded.

BASIC PROTOCOL

Preparation and Analysis of Glycoconjugates

17.1.5

2. Pack a glass wool plug over a scintered glass or polypropylene frit at the bottom of the column and pour the degassed slurry into the column.

The glass wool is important to prevent the beads from clogging the frit and slowing the flow rate.

3. Continue packing the column until the desired level is reached; for a 50-ml volume this is ~28 cm. Wash the gel with 2 to 3 column volumes of column buffer to remove any loosely bound or degraded Con A.
4. Wash with 2 to 3 column volumes of 0.5 M of α MM in column buffer or the highest concentration of α MM that will be used.
5. Wash the column with >5 column volumes of column buffer *without* α MM to reequilibrate.

It is important to prewash the column with the eluting sugar and then to reequilibrate the column to remove any materials which might have previously bound to the column. Check the completeness of washing by the phenol-sulfuric acid assay (UNIT 17.9). Estimate the amount of residual sugar using α MM as a standard. An acceptable level is <0.1 mM or ~20 μ g/ml.

6. Slowly load the protein sample on the column to permit binding without disturbing the surface. A flow rate of ~1 ml/min (~0.5 ml/min per cm² of area) is desirable.
7. Wash column with column buffer and monitor the flowthrough and subsequent wash fractions by measuring the A_{280} until it approaches baseline value.

If the A_{280} does not rapidly return to baseline, it may indicate weak interaction of some proteins with the lectin, or overloading of the column.

8. Assay flowthrough and wash fractions for the presence of the protein of interest.

To check the lectin-binding properties, see support protocol below. To determine whether the column was overloaded, add a small amount of the flowthrough (1%) to a small volume of beads as described in the support protocol. If the sample is bound to the beads as determined by the appropriate assay, overloading of the original column is indicated. In this case, reapply the flowthrough with excess glycoprotein to the larger column after the bound proteins of the first run are eluted with α MM and the column is reequilibrated.

9. Elute the column with 0.5 M α MM in column buffer and monitor fractions for A_{280} and activity. Pool peak-activity fractions.

Very broad peaks may result during elution with the sugar if the protein dissociates very slowly. When this happens, sample recovery can be improved by filling the column with 0.5 M α MM in column buffer and allowing the column to stand for a few hours. This allows dissociation of the bound material; when the flow is started again, it should give a very sharp peak. Other possible remedies include warming a cold column to room temperature in the presence of α MM, increasing the concentration of α MM to 1 M, or increasing the NaCl concentration to 1 M. A combination of these may be needed to elute a tightly bound protein.

10. Regenerate the column by washing it with 10 vol column buffer or until the α MM concentration is <20 μ g/ml.

Column may now be used for another run or stored indefinitely at 4°C in column buffer containing 0.02% (w/v) NaN₃. Reequilibrate in column buffer before using again.

PILOT STUDY TO DETERMINE LECTIN BINDING AND ELUTION CONDITIONS

If the target protein can be detected easily, it is worthwhile to test a small sample to establish binding and elution conditions before applying the entire sample to a large column. The easiest approach is to mix a small amount of sample with a measured amount of Con A–Sepharose beads in a series of microcentrifuge tubes. If the material in the sample binds, it can then be eluted from the washed beads with various amounts of competing α MM to determine when the activity is eluted into the supernatant. This shows whether binding occurs and what concentration of competing sugar (or other conditions) will be required to elute it from the column. An abbreviated version of this procedure can be done with a single sample to determine if the protein binds and if it can be eluted with only one concentration (0.75 M) of α MM. It is important to keep the temperature constant, because changes can affect binding and dissociation of the ligands.

Additional Materials

Sepharose 4B (Pharmacia Biotech) or other beaded gel to fill space in the tubes
 α MM: 0, 0.1, 0.2, 0.4, 0.8, 1.0, and 1.5 M concentrations, in column buffer

1. Prepare a 50% slurry of Con A–Sepharose in column buffer. Cut ~2 to 3 mm off the small end of a 1000- μ l pipet tip. Resuspend the slurry immediately before each pipetting, and use the truncated tip to dispense 200 μ l of slurry into a series of seven microcentrifuge tubes. To one of these tubes—the no-lectin control—add an equal volume of 50% slurry of Sepharose 4B. Allow gel to settle to see if the dispensing was reasonably accurate.

Gel material is needed in the controls to account for the volume changes caused by adding the gel. Other nonionic beaded gels, such as Sephadex (Pharmacia Biotech) or Bio-Gel (Bio-Rad) may be substituted.

2. Add the protein sample in 50 μ l column buffer and allow 15 min for binding (shake the tube occasionally). Microcentrifuge the gel beads 1 min at 1000 \times g to sediment. Remove the supernatant and save for analysis in step 6.
3. Use an appropriate assay for the protein of interest to determine if it binds to Con A–Sepharose and not to control beads.
4. Wash the gel beads with three 1.4-ml washes of column buffer; after each wash microcentrifuge the beads using conditions in step 2.
5. Resuspend gel beads in 200 μ l of buffer containing 0, 0.1, 0.2, 0.4, 0.8, 1.0, or 1.5 M α -MM for each of the seven tubes containing Con A–Sepharose. Add the same volume of column buffer or 1.5 M α MM in column buffer to the control.
6. Incubate 15 min and centrifuge the gel beads as in step 2. Analyze the supernatants using the appropriate detection assay to determine if the protein has been eluted and at what concentration of competing sugar.

Increasing the concentration of α MM should elute the target protein from the Con A–Sepharose. If it is not eluted, longer incubation times (10 hr) in the presence of α MM or higher temperature may be needed to elute the protein from the beads. Although the entire procedure can be done in the cold, binding is tighter at low temperature, and this may make elution more difficult. Once the conditions are established for a particular sample or a lectin, scaling up the preparation for the basic protocol should proceed smoothly.

WHEAT GERM AGGLUTININ (WGA)–AGAROSE AFFINITY CHROMATOGRAPHY

WGA-agarose chromatography is used to purify proteins that contain terminal *N*-acetylglucosamine (GlcNAc) or sialic acid residues. A protein sample is applied to the column, the column is washed to remove unbound and weakly bound proteins, and bound glycoproteins are eluted with GlcNAc. Most of the advice for purification of glycoproteins on Con A columns applies to similar columns containing immobilized WGA. It is best to test the binding of the target protein to the lectin using a pilot study like that for Con A (support protocol) before running a large column, substituting GlcNAc for the α MM.

Additional Materials

- 5 mg/ml wheat germ agglutinin (WGA)–agarose (E-Y Laboratories, Pharmacia Biotech, Sigma)
- Phosphate-buffered saline (PBS; APPENDIX 2)
- 0.1 M *N*-acetylglucosamine (GlcNAc) in PBS
- Protein sample in PBS
- 1.0 × 10–cm glass or disposable column

1. Resuspend 1 vol WGA-agarose in 2 to 3 vol PBS to make a slurry.

One milliliter of gel should be enough to bind 1 to 2 mg glycoprotein. To be safe, assume ~5% to 10% of total cell lysate can bind. If target protein requires detergent to solubilize it, WGA is still active in 25 mM Tris-Cl (pH 7.5)/1% Lubrol PX/0.1% sodium deoxycholate. Triton X-100 or NP-40 (~2% to 3% v/v final) may also be used.

2. Place a glass wool plug over the frit at the bottom of a column whose length is 10 times its diameter. Pour the slurry into the column. Wash the column with ~2 column volumes of PBS to remove any unbound or degraded WGA, then wash with 1 column volume PBS containing 0.1 M GlcNAc. Finally, wash with 5 column volumes PBS.

The length of the column should be ~10 times its diameter so that weakly bound proteins can be eluted by prolonged PBS wash in the absence of any competing sugar. This will separate them from proteins that do not interact at all, and differs from using Con A where continued buffer wash in the absence of α MM does not usually elute weakly bound protein. The choice of these column dimensions for WGA and for most other lectins is based on the successful fractionation of individual glycopeptides by serial lectin-affinity chromatography.

3. Add protein sample in ~0.1 column volumes at a flow rate of ~2 ml/cm² per hour, and wash the column with PBS until the A_{280} returns to baseline.

With a small sample volume it is easier to detect proteins that do not bind to the column at all and elute promptly as a sharp peak in the flowthrough. Proteins that bind weakly to the column are gradually washed off by continued elution with PBS alone; these proteins would “smear” as a trailing peak. If a preliminary test run of the target protein shows that it binds strongly to the lectin, and if the column is not overloaded, the sample can be added to the column in a larger volume. The flow rate can be varied. Sometimes the protein of interest can be absorbed to the lectin simply by gently mixing the two components for several hours before pouring the loaded gel into the column. The protein can then be eluted after washing as determined by the pilot study.

4. Elute the column with 2 to 3 column volumes of 0.1 M GlcNAc in PBS, and assay the fractions for the protein of interest.

Generally, 0.1 M GlcNAc is sufficient to elute the protein. If this does not work, try a higher GlcNAc concentration (e.g., up to 0.25 M), temporarily turn off the column, or raise the temperature to elute the sample, as with Con A. Also, adding 0.5 M NaCl to the GlcNAc-containing elution buffer can sometimes improve recovery. A pilot study to determine elution conditions, similar to that described for Con A (support protocol), is highly recommended.

5. Regenerate the column by washing with ≥ 10 column volumes of PBS or until reducing sugar content is below 20 $\mu\text{g/ml}$. The column can be reused immediately or stored at 4°C in column buffer containing 0.02% (w/v) NaN_3 .

REAGENTS AND SOLUTIONS

Column buffer

0.01 M Tris-Cl, pH 7.5

0.15 M NaCl

1 mM CaCl_2

1 mM MnCl_2

Store indefinitely at room temperature

Prepare the MnCl_2 within a day or two of use and add it to the buffer only after the pH has been adjusted. The final concentration of metal ions can be decreased 10-fold or more if needed.

If detergents are required to solubilize the protein, Triton X-100 or Nonidet P-40 at $\leq 2\%$ have a negligible effect on lectins. Do not use glucoside-based detergents because they may interfere with binding.

COMMENTARY

Background Information

See the introductions to Chapter 17 and to this unit for discussions concerning properties of glycoproteins that relate to their purification.

Critical Parameters

Like most protein purification procedures, successful lectin-affinity chromatography is empirical, so few parameters are “written in stone.” However, in using lectins, it is important to first determine the binding and elution conditions in a pilot study. Blindly loading a sample onto a column and then trying different elution conditions may give very low yields, either because the protein may become inactivated or because it cannot be eluted under those particular conditions. It is usually easy to bind the protein to the column, but elution may be more difficult. There are a number of ways to elute tightly bound protein: increase the concentration of sugar in the buffer used for elution, increase temperature, increase the salt (NaCl) concentration, or stop the column flow for an extended period during the elution with sugar. A combination of these may be needed.

These modifications might cause a protein to elute differently from the same column. Thus, it may be useful to perform two consecutive runs with different elution conditions to separate the protein of interest from different contaminants. Ketcham and Kornfeld (1992) describe the purification of a rare glycosyl transferase using WGA, whereby the lectin-affinity chromatography step alone yielded a 160-fold purification. Another important point

to remember is that environmental carbohydrate contamination may contribute significantly to the total quantity of carbohydrate in a preparation. Follow the suggestions given within the protocols to minimize this effect.

Anticipated Results

Lectins can give 2- to >100 -fold purifications of glycoproteins and nearly quantitative yields, depending upon the source of the sample and elution conditions. If the protein of interest is reasonably stable at high salt concentrations and room temperature, it is likely that specific elution conditions can be found that will produce good yields.

Time Considerations

Initial determination of the binding and elution conditions can easily be done in a day, assuming that the detection assay for the target protein is simple and fast. The amount of time needed to conduct a single run once the elution conditions are known can vary depending upon the size of the sample, the column, and whether elution requires long-term incubation in the presence of the sugar. Even assuming the extremes of sample size and elution conditions, a single run should be completed in 2 to 3 days.

Special Considerations for Proteoglycans and Glycosaminoglycans and Their Purification

UNIT 17.2

Proteoglycans (PG) contain long linear glycosaminoglycan (GAG) chains that consist of repeats of disaccharides and therefore differ from the short branched oligosaccharides found on glycoproteins and glycolipids. The principal GAGs of animal tissue PGs include chondroitin sulfate, dermatan sulfate, heparan sulfate, or keratan sulfate. Heparin, the commonly used anticoagulant, is a highly modified form of heparan sulfate; it is made solely by connective tissue mast cells. Repeating disaccharide units composed of glucuronic acid (GIUA) or iduronic acid (IdUA) and an *N*-acetylhexosamine residue (GlcNAc or GalNAc) make up the backbone of most GAGs. Keratan sulfate, however, contains disaccharides of Gal and GlcNAc. All GAGs, except hyaluronan, contain a large number of sulfate residues that, together with the uronic acids, impart a large negative charge to the chains. The high density of negative charges on GAGs distinguishes these polysaccharides from the oligosaccharides found on glycoproteins and glycolipids, and is the basis for their physical separation. This property facilitates GAG and PG purification by anion-exchange chromatography and precipitation with cetylpyridinium chloride (CPC) and ethanol.

The synthesis of GAGs occurs while they are attached to core proteins; free chains can accumulate because of proteolysis and endoglycolytic cleavage of the PG. For example, heparin chains are initiated and elongated on a core protein called serglycin. Soon after assembly of the heparin proteoglycan, proteases degrade the serglycin core, and an endoglucuronidase generates short heparin oligosaccharides that sort to secretory granules. Most cells constitutively secrete specific PGs into extracellular fluids and matrix. They also express several membrane-intercalated PGs that are shed from the cell surface by proteolysis. Fragmentation of matrix proteoglycans often occurs and gives rise to GAG chains attached to short peptides. Hyaluronan, a nonsulfated GAG, does not assemble while linked to protein, but associates noncovalently with PGs that contain specific binding domains.

In general, the problems encountered in purifying PGs are those encountered in purification of other protein glycoconjugates. The purification protocol must ensure efficient extraction of tissue or cells, high recovery in separation and purification steps, and negligible degradation. This unit describes two simple methods for extracting PGs and GAGs—one using high-salt/detergent extraction (first basic protocol) and one using alkali treatment (first alternate protocol). These are complemented by two techniques for concentrating samples that also yield a significant degree of purification—anion exchange chromatography (second basic protocol) and precipitation with CPC (second alternate protocol).

HIGH-SALT/DETERGENT EXTRACTION OF PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

**BASIC
PROTOCOL**

Efficient extraction of PGs requires the use of chaotropic salts in an appropriate buffer. Detergent is included to ensure extraction of membrane-intercalated PGs, to prevent aggregation, and to decrease adsorption to glassware. In this protocol, samples (tissue, conditioned medium, biological fluid, or cultured cells) are treated with a high-salt/detergent (guanidine·HCl/Zwittergent 3-12) extraction buffer to extract PGs as well as free GAG chains and GAGs with a short peptide chain. Extracted material can be concentrated and partially purified by anion-exchange chromatography or CPC and ethanol precipitation (second basic and alternate protocols, respectively). Studies involving proteoglycans are conducted at 4°C in the presence of protease inhibitors to minimize degradation of core proteins; work with glycosaminoglycans can be done at room temperature.

**Preparation
and Analysis of
Glycoconjugates**

17.2.1

Supplement 22

Materials

Tissue sample, conditioned medium, biological fluids, *or* cultured cells
Guanidine-HCl/Zwittergent 3-12 extraction buffer *or* Triton X-100 extraction buffer, at 4°C

200× protease inhibitor stock solutions

Centrifuge and rotor (e.g., Sorvall SS-34) *or* microcentrifuge, at 4°C

Additional reagents and equipment for measurement of uronic acids (UNIT 17.9) and metabolic radiolabeling (UNIT 17.4)

1a. *To extract from tissue samples:* Chill, mince, and mix tissue with 5 to 10 vol of 4°C guanidine-HCl/Zwittergent 3-12 extraction buffer per gram of tissue (wet weight). Stir the sample overnight at 4°C.

1b. *To extract from conditioned medium or biological fluids:* Chill samples to 4°C and dissolve solid guanidine-HCl to 4 M (final), Zwittergent 3-12 detergent to 0.2% w/v (final) and EDTA to 10 mM (final). Add protease inhibitors from stock solutions to achieve final concentrations of 10 mM NEM, 1 mM PMSF, 1 µg/ml pepstatin A, and 0.5 µg/ml leupeptin.

The reagents are added in this way to minimize the increase in volume.

1c. *To extract from cultured cells:* Add ~1 ml of guanidine-HCl/Zwittergent 3-12 or extraction buffer per 10⁷ cells (in a pellet), or 3 to 5 ml per 75 cm² of cell monolayer. Cell pellets and monolayers will dissolve within 1 hr at 4°C.

The PGs of cultured cells, conditioned medium, and biological fluids will also solubilize in Triton X-100 extraction buffer (see reagents and solutions), but the efficiency of extraction should be tested (critical parameters). The use of Triton X-100 extraction buffer eliminates the need to remove guanidine-HCl before further purification.

2. Centrifuge 20 min at 12,000 × g (10,000 rpm in a Sorvall SS-34 rotor), 4°C, or microcentrifuge 10 min at maximum speed, 4°C, to remove insoluble residue. Collect the supernatant. If necessary, reextract residue with fresh extraction buffer, centrifuge as before, and combine the supernatants.

For conditioned medium, biological fluids, and cultured cells, the initial treatment with extraction buffer is usually sufficient. Tissue samples may need to be reextracted (see critical parameters).

3. Purify the GAGs by anion-exchange chromatography or by treating with CPC and ethanol (second basic and alternate protocols, respectively).

4. Quantitate the amount of GAG present by measuring the uronic acid content chemically, or by measuring the amount of radioactive material present if the starting material was radiolabeled with ³⁵S₄ or [³H]GlcN.

The measurement of uronic acid is also described in Bitter and Muir (1962) and Filisetti-Cozzi and Carpita (1991).

ALTERNATE PROTOCOL

Special Considerations for Proteoglycans and Glycosamino- glycans and Their Purification

ALKALI EXTRACTION OF PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

If the primary objective is simply to determine whether a sample contains PGs or GAGs, an aliquot can be extracted with alkali. Alkali extraction results in some elimination of chains from core proteins and possible cleavage of the core, so this technique is unacceptable for isolating intact PGs. Alkali-extracted samples are usually subjected to exhaustive proteolysis or complete β-elimination (UNIT 17.15) to liberate GAG chains. The GAGs are then purified by anion-exchange chromatography or precipitation with CPC and ethanol

17.2.2

(second basic and alternate protocols, respectively) and quantitated chemically or radiochemically. This protocol is suitable for cultured cells, conditioned medium, or biological fluids; tissue samples should be extracted using the high-salt/detergent procedure (first basic protocol).

Additional Materials

0.1 N or 10 N sodium hydroxide (NaOH; *APPENDIX 2*)
10 N acetic acid

Additional reagents and equipment for β -elimination (*UNIT 17.15*)

1. Solubilize samples in 0.1 N NaOH at room temperature. Incubate 10 min at 25°C.
Generally 0.5 ml of 0.1 N NaOH is sufficient for 10^7 cells as a pellet or 2 ml per 75 cm^2 of cell monolayer. Cells suspended in culture medium can be extracted by adding 10 μl of 10 N NaOH per milliliter medium.
2. Neutralize sample with 10 μl of 10 N acetic acid per milliliter sample. Remove any precipitate that forms by centrifuging 20 min at $12,000 \times g$ (10,000 rpm in a Sorvall SS-34 rotor), 4°C, or microcentrifuging 10 min at maximum speed, 4°C.
3. Treat neutralized samples with a nonspecific protease, such as Pronase or proteinase K or subject samples to β -elimination conditions to liberate individual GAG chains.
4. Purify the GAGs by anion-exchange chromatography or by treating with CPC and ethanol (second basic and alternate protocols, respectively).
5. Quantitate the amount of GAG present by measuring the uronic acid content chemically or by measuring the amount of radioactive material present if the starting material was radiolabeled with $^{35}\text{SO}_4$ or $[^3\text{H}]\text{GlcN}$.

ANION-EXCHANGE CHROMATOGRAPHY OF PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

BASIC PROTOCOL

PGs and GAGs can be purified by anion-exchange chromatography on weak anion-exchange resins (*UNIT 10.10*). This step allows collection of very small amounts of material from a large volume of solution, thus concentrating the sample. Anion-exchange chromatography allows separation of different types of GAGs, but the low-salt elution conditions described here will yield a mixture of all GAGs and PGs regardless of composition.

Materials

PG-GAG extract (first basic or alternate protocol)
Urea/Zwittergent 3-12 buffer
20 mg/ml chondroitin sulfate or heparin in 20 mM Tris·Cl, pH 7.0
DEAE-Sephacel (Pharmacia Biotech)
0.2 M NaCl/50 mM sodium acetate, pH 6.0
DEAE wash buffer
DEAE elution buffer
Sephadex G-25 (Pharmacia Biotech)
10% ethanol
20 mM Tris·Cl, pH 7.4 (*APPENDIX 2*)
Centrifuge and rotor (e.g., SS-34) or microcentrifuge, at 4°C

Additional reagents and equipment for dialysis (*APPENDIX 3*) and gel filtration and ion-exchange chromatography (*UNITS 10.9 & 10.10*)

1. If the extract contains guanidine-HCl/Zwittergent 3-12, dialyze it against urea/Zwittergent 3-12 buffer. Remove any precipitate that forms during the exchange of urea

Preparation and Analysis of Glycoconjugates

17.2.3

for guanidine by centrifuging 20 min at $12,000 \times g$ (10,000 rpm in a Sorvall SS-34 rotor), 4°C, or microcentrifuging 10 min at maximum speed, 4°C.

Gel-filtration chromatography or ultrafiltration also can be used to change buffers. Extracts prepared in Triton X-100 extraction buffer (see critical parameters) can be chromatographed without further manipulation. Protease inhibitors can be included as long as they do not contribute significantly to the ionic charge of the sample solution.

2. Add 1 to 2 mg chondroitin sulfate as carrier if the total GAG content of the sample is $<100 \mu\text{g}$ and if the addition will not interfere with subsequent analysis.

If the amount of PG or GAG is to be quantitated by measuring uronic acid, carrier GAG must be omitted. Chondroitin sulfate is preferred because it is less expensive than heparin or heparan sulfate. Heparin can inhibit chondroitinases that are used to establish the presence and composition of chondroitin sulfate chains.

3. Prepare the DEAE-Sepharose column. Wash the resin three times with 0.2 M NaCl/50 mM sodium acetate, pH 6.0. Pour a small column by placing 0.5 to 1 ml resin in a polypropylene pipet tip (P-1000) plugged with a small piece of glass wool. Cut the tip slightly (1 to 2 mm) to widen the opening and improve flow rate. Remove the bottom one-third of a second tip with a razor blade and insert it into the first tip. This provides ~ 2.5 ml of additional head space above the resin bed.

The upper tip will accommodate a disposable 10-ml pipet for adding solutions. Larger column beds can be poured in commercial columns.

4. Equilibrate the column with ~ 5 column volumes of DEAE wash buffer.
5. Apply the sample to the equilibrated column. Elute contaminants with 20 to 30 column volumes of DEAE wash buffer. Elute the PGs and GAGs with 5 column volumes of DEAE elution buffer and collect as one fraction.

Avoid exceeding the binding capacity of the resin (~ 5 mg of chondroitin sulfate, heparan sulfate or heparin per milliliter of resin).

Buffers prepared without urea, detergent, and protease inhibitors can be substituted if these reagents interfere with subsequent analysis (e.g., enzymatic digestions by polysaccharide lyases). Chromatography of free GAGs does not require urea or protease inhibitors, but detergent should be included to improve recovery. Fast flow rates can be used.

6. Desalt sample using a Sephadex G-25 gel-filtration column run in 10% ethanol.

If the sample volume is ≤ 2.5 ml, disposable PD-10 columns (Pharmacia Biotech) can be used.

7. Lyophilize the sample and rehydrate it in 20 mM Tris·Cl, pH 7.4 or other suitable buffer. Store at 4°C until further use.

CPC/ETHANOL PRECIPITATION OF PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

ALTERNATE PROTOCOL

This protocol describes the concentration and partial purification of extracted PGs and GAGs with the lipophilic cation cetylpyridinium chloride (CPC). The CPC binds to charged groups along the GAGs, rendering them insoluble. This method of precipitation should be used only when the concentration of PGs and GAGs in the original sample is large enough to avoid use of carrier or when the addition of carrier is of no consequence—e.g., when the sample is extracted from cells biosynthetically labeled with $^{35}\text{SO}_4$ or [^3H]GlcN (UNIT 17.4).

Additional Materials

- 20 mM Tris·Cl/0.2 M NaCl, pH 7.4
- 5% (w/v) cetylpyridinium chloride hydrate (CPC; Aldrich), in water
- 0.5 M sodium acetate (APPENDIX 2)
- 95% ethanol, 4°C
- 0.5 M sodium acetate in 10% (v/v) ethanol (sodium acetate/ethanol)
- Additional reagents and equipment for ethanol precipitation (UNIT 2.1)

1. If the extract contains guanidine·HCl/Zwittergent 3-12 or high salt (≥ 0.2 M), dialyze it against 20 mM Tris·Cl/0.2 M NaCl (pH 7.4) or use gel-filtration chromatography to exchange the buffers.

Electrolytes and detergents compete with CPC precipitation of GAGs. All GAGs will precipitate if the salt concentration is ≤ 0.2 M. Protease inhibitors can be included if they do not contribute significantly to the ionic charge of the sample.

2. Add chondroitin sulfate as carrier so that the final GAG content of the sample is ≥ 0.1 mg/ml.

Precipitation with CPC requires that the GAG concentration be ≥ 0.1 mg/ml for high recovery. If carrier is added, it is not possible to quantitate GAGs by measuring uronic acid content.

3. Add 1 ml of 5% CPC/4 ml sample. Incubate 1 hr at 37°C.
4. Centrifuge 20 min at $12,000 \times g$ (10,000 rpm in a Sorvall SS-34 rotor), or microcentrifuge 10 min at maximum speed, room temperature. Remove the supernatant and resuspend the pellet in a small volume of 0.5 M sodium acetate so that the final GAG concentration is ~ 10 mg/ml.

Centrifugation must be done at room temperature or the CPC will precipitate. If necessary, briefly incubate the sample in a boiling water bath to dissolve the pellet.

5. Add 4 vol of ice-cold 95% ethanol, mix, and incubate ≥ 2 hr at 4°C.

Precipitation with ethanol requires salt and adequate mass for high recovery. The samples should contain 0.1 M to 0.5 M salt and 0.1 mg/ml GAG. If adequate material is not present, add additional chondroitin sulfate as carrier.

6. Centrifuge 20 min at $12,000 \times g$ (10,000 rpm in a Sorvall SS-34 rotor), or microcentrifuge 10 min at maximum speed, to pellet the white precipitate that forms. Remove and discard supernatant.
7. Dissolve pellet in a small volume of 0.5 M sodium acetate/10% ethanol such that the final concentration is ~ 1 mg/ml. Repeat the ethanol precipitation.
8. Dry precipitate under vacuum and resuspend in 20 mM Tris·Cl, pH 7.4 or other suitable buffer. Store at 4°C until further use.

Preparation and Analysis of Glycoconjugates

17.2.5

REAGENTS AND SOLUTIONS

10 N acetic acid

Dilute 65.4 ml glacial acetic acid (15.3 M, ACS reagent grade) with water to a total volume of 100 ml. Store indefinitely at room temperature.

DEAE elution buffer

Add 58.5 g NaCl (1 M final) to 1 liter urea/Zwittergent 3-12 buffer. Store at 4°C for several months.

DEAE wash buffer

Add 11.7 g NaCl (0.2 M final) to 1 liter urea/Zwittergent 3-12 buffer. Store at 4°C for several months.

Guanidine·HCl/Zwittergent 3-12 extraction buffer

382.1 g guanidine·HCl (4 M)
2 g Zwittergent 3-12 (0.2% w/v)
4.1 g sodium acetate (50 mM)
3.8 g EDTA (10 mM)
5 ml NEM stock solution (10 mM)
5 ml PMSF stock solution (1 mM)
5 ml pepstatin A stock solution (1 µg/ml)
5 ml leupeptin stock solution (0.5 µg/ml)

Dissolve guanidine·HCl Zwittergent 3-12, sodium acetate, and EDTA in 800 ml water. Add protease inhibitors just before use. Adjust pH to 6.0 and bring volume to 1 liter.

200× protease inhibitor stock solutions

Leupeptin (0.1 mg/ml). Dissolve 5 mg leupeptin (Ac-Leu-Leu-Arg-al hemisulfate, MW 475.6) in water and adjust volume to 50 ml. Store in aliquots at -20°C.

Leupeptin inhibits cathepsin B.

N-ethylmaleimide (NEM; 2 M). Dissolve 25 g NEM in ethanol and adjust volume to 100 ml. Store in aliquots at -20°C.

NEM inhibits thiol proteases and prevents nonspecific disulfide exchange.

Pepstatin A (0.2 mg/ml). Dissolve 5 mg pepstatin A (Isovaleryl-Val-Val-Sta-Ala-Sta) in ethanol and adjust volume to 25 ml. Store in aliquots at -20°C.

Pepstatin A inhibits cathepsin D.

Phenylmethylsulfonyl fluoride (PMSF; 0.2 M). Dissolve 3.5 g PMSF in ethanol and adjust volume to 100 ml. Store in aliquots at -20°C.

PMSF inhibits serine proteases.

0.5 M sodium acetate/10% (v/v) ethanol.

Dissolve 4.1 g sodium acetate in water and adjust volume to 90 ml. Add 10 ml ethanol.

Triton X-100 extraction buffer

5 g Triton X-100 (0.5% w/v)
8.77 g NaCl (0.15 M)
2.42 g Tris base (20 mM Tris·Cl)
3.8 g EDTA (10 mM)
5 ml NEM stock solution (10 mM)

continued

5 ml PMSF stock solution (1 mM)
5 ml pepstatin A stock solution (1 µg/ml)
5 ml leupeptin stock solution (0.5 µg/ml)

Dissolve Triton X-100, NaCl, Tris base, and EDTA in ~800 ml water. Add protease inhibitors just before use. Adjust pH to 7.4 and bring volume to 1 liter.

Urea/Zwittergent 3-12 buffer

240 g urea (ultrapure grade, 4 M)
2 g Zwittergent 3-12 (0.2% w/v)
4.1 g sodium acetate (50 mM)
3.8 g EDTA (10 mM)
5 ml NEM stock solution (10 mM)
5 ml PMSF stock solution (1 mM)
5 ml pepstatin A stock solution (1 µg/ml)
5 ml leupeptin stock solution (0.5 µg/ml)

Dissolve urea, Zwittergent 3-12, sodium acetate, and EDTA in ~800 ml water. Add protease inhibitors just before use. Adjust pH to 6.0 and bring volume to 1 liter.

COMMENTARY

Background Information

Proteoglycan (PG) extraction methods were first developed for studying PGs in cartilage. These methods use high salt and guanidine-HCl to disrupt ionic interactions and they are considered to be “dissociative” because their effectiveness depends on the dissociation of PGs from aggregates containing hyaluronan and matrix proteins (Sajdera and Hascall, 1969). PGs and glycosaminoglycans (GAG) present in other tissues, biological fluids, and cultured cell lines (Kjellén and Lindahl, 1991) differ significantly in structure and composition from those found in cartilage, but the original extraction methods remain effective. Many PGs associate with membranes through hydrophobic domains or glycosyl phosphatidylinositol anchors (UNIT 17.8). Membrane PGs require detergent to disrupt hydrophobic interactions and to produce a micellar dispersion. Current extraction and purification protocols employ both denaturants and detergents (Yanagishita et al., 1987; Hascall and Kimura, 1982).

Critical Parameters and Troubleshooting

Extraction efficiency. The guanidine-HCl/Zwittergent 3-12 extraction buffer should render the majority of macromolecules soluble. However, some tissues (e.g., aorta) may resist dispersion, leaving some PGs in the insoluble residue. Mechanical homogenization of samples in extraction buffer may improve recovery. To determine the overall efficiency of extraction, measure the release of PGs over time. Incubate aliquots of sample in extraction buffer

and at certain intervals, separate the PGs from other constituents by anion-exchange chromatography (second basic protocol) or precipitation with cetylpyridinium chloride (CPC) and ethanol (second alternate protocol). If sufficient material is present (≥ 50 µg of uronic acid), monitor the uronic acid content of a sample to measure PG and GAG release. Alternatively, if cultured cells are labeled biosynthetically with $^{35}\text{SO}_4$ or $[6\text{-}^3\text{H}]\text{GlcN}$ (UNIT 17.4), extraction of PGs from cultured cells is easily followed radiochemically. When the yield of uronic acid or radioactivity in the extract reaches a plateau, no additional material can be obtained under these conditions. Any insoluble residue should be dissolved in 0.1 N NaOH and residual GAGs measured. If more than 10% of the material remains in the residue, the extractions condition may be varied by using a different detergent (e.g., 1% Triton X-100 or 1% deoxycholate), by adding other salts (e.g., LiCl), by treating samples with collagenase, by altering the pH, or by adding a reductant (e.g., 2-mercaptoethanol). Kimura et al. (1981) showed that sequential addition of detergent and guanidine-HCl extracts more proteoglycan from chondrosarcoma than adding both agents simultaneously.

Recovery. As in any purification scheme, adequate starting material is required to ensure high recovery. Samples should ideally contain at least 0.1 mg of GAG as determined by uronic acid content. Because cell cultures tend to yield small amounts of material (0.1 to 1 µg of GAG uronic acid per 10^6 cells), carrier GAGs should be added. Commercial preparations of chon-

droitin sulfate are inexpensive and provide a suitable carrier for purifying PGs as well as GAGs. However, addition of carrier makes it impossible to monitor recovery by chemically measuring uronic acid, so carrier should only be added to samples labeled biosynthetically with $^{35}\text{SO}_4$ or $[^3\text{H}]\text{GlcN}$. Sufficient mass (≥ 0.1 mg/ml) is critical for efficient precipitation with CPC and ethanol.

Inclusion of protease inhibitors is critical to maintain the integrity of PG core proteins. The buffers used in these protocols contain leupeptin (to inhibit cathepsin B), NEM (to inhibit thiol proteases and prevent nonspecific disulfide exchange), Pepstatin A (to inhibit cathepsin D), PMSF (to inhibit serine proteases), and EDTA (to inhibit metalloproteases). In addition, samples should be chilled rapidly and processed immediately, and the pH should be maintained at pH 6.0 to diminish the activity of acidic lysosomal proteases and neutral tissue proteases.

If degradation of core protein occurs under the conditions described in the protocols (as detected by variable recovery), other inhibitors should be used. For example, benzamidine-HCl at 1 mM inhibits serine proteases; 6-aminohexanoic acid at 0.1 M inhibits cathepsin D; phosphoramidon at 0.5 mM inhibits collagenases, metalloendoproteinases, and stromelysin; soy bean trypsin inhibitor at 0.1 mg/ml inhibits trypsin-like proteases; and bestatin at 0.1 mM inhibits several aminopeptidases. Sodium dodecylsulfate (SDS) can also inhibit proteases because of its ability to denature proteins. However, SDS is difficult to remove; its incompatibility with anion-exchange chromatography and CPC precipitation complicates further purification steps. Nevertheless, SDS helps maintain solubility of aggregating proteins and should be considered as an additive in purification steps after CPC precipitation or anion-exchange chromatography.

Zwitterionic (e.g., Zwittergent 3-12) and nonionic detergents (e.g., Triton X-100) help solubilize membrane PGs and improve recovery by blocking nonspecific binding and aggregation. These detergents remain soluble both in the presence of high concentrations of salts and at low temperature, and are compatible with most purification methods.

Purity. Purification of PGs to chemical homogeneity (a single species of PG with no contaminants) presents a challenging problem. The procedures described in this unit should yield material enriched in PGs because few macromolecules exhibit the charge charac-

teristics imparted by the polyanionic GAG chains. Nucleic acids tend to copurify with PGs and GAGs, but nucleic acids and weakly charged or neutral oligosaccharides and polysaccharides are not precipitated efficiently by CPC. If necessary, samples can be treated with DNase and RNase (*UNIT 3.12*) to reduce the content of nucleic acids.

Some contaminants associate with PGs through ionic interactions with the GAG chains. Other purification methods should be tried, including density-gradient centrifugation in CsCl (Hascall and Kimura, 1982), gel-filtration chromatography in high salt or guanidine-HCl (*UNIT 10.9*), reversed-phase chromatography on octyl-Sepharose (Yanagishita et al., 1987), and affinity purification using monoclonal antibodies (*UNIT 10.11A*; Hascall and Kimura, 1982; Yanagishita et al., 1987). With the exception of affinity purification protocols that use immobilized proteins or antibodies, most of these methods are compatible with dissociative conditions.

Some protein contaminants may aggregate with core proteins through interchain disulfide bonds. Some matrix PGs may not extract efficiently if they are linked by disulfides to insoluble matrix proteins (Parthasarathy and Spiro, 1981). Reduction with 10 mM dithiothreitol at elevated temperature followed by alkylation (e.g., with iodoacetamide) should help dissociate these proteins.

The purification protocol described above does not separate free GAG chains from PGs. Free chains usually have different Stokes radii than PGs, and gel-filtration chromatography frequently separates GAGs from PGs. Shift of material into more included fractions after β -elimination or proteolysis confirms that PGs were present in the original sample. If sufficient material is present, colorimetric quantitation of proteins (*UNIT 10.1*) can also help distinguish PGs from GAGs, but the presence of contaminating proteins may complicate this analysis. Labeling PGs biosynthetically with radioactive amino acids and $^{35}\text{SO}_4$ or $[^3\text{H}]\text{GlcN}$ provides another way to monitor elution of PGs and GAGs.

Several excellent reviews describe detailed procedures for further characterization of intact PGs, their protein cores, and the GAG chains (Rodén et al., 1972; Hascall and Kimura, 1982; Yanagishita et al., 1987).

Anticipated Results

The high-salt/detergent and alkali extraction methods will reliably extract the majority

of PGs from most tissues and cells. Ion-exchange chromatography and precipitation with CPC and ethanol will yield a preparation of PGs or GAGs of adequate concentration and purity for compositional analysis.

Time Considerations

Tissues usually require overnight extraction, but extraction of cultured cells occurs very rapidly, usually within an hour. Complete dialysis requires several buffer changes over a period of 24 to 48 hr. Anion-exchange chromatography and CPC precipitation take ~1 day to complete. Thus, it should take 3 to 4 days to extract, partially purify, and concentrate PGs and GAGs from biological samples.

Special Considerations for Glycolipids and Their Purification

The term “glycolipid” refers to a large class of heterogeneous and rather ill-defined conjugates composed of sugar and lipid. They range from the large oligosaccharide conjugates of polyprenols and dolichols (intermediates in the biosynthesis of bacterial-cell-wall polysaccharides and animal-cell glycoproteins, respectively) to membrane components of plants, yeast, mycobacteria, and animal cells. This unit presents methods for preparing glycosphingolipids, the most commonly studied glycolipids, for analysis. In general, these studies are used for comparison of glycosphingolipids from different cells or cell lines or for comparison of experimentally treated and control cells or cell lines.

The first basic protocol describes the extraction of all glycosphingolipids, including those carrying large oligosaccharides, from small amounts of tissue or cultured cells, and their subsequent separation based on their relative solubilities in polar and nonpolar solvents (Folch partitioning). A support protocol describes the preparation and use of Sep-Pak C₁₈ cartridges for use in the first basic protocol. The second basic protocol describes preparation of gangliosides from the final product of the previous protocol (Folch upper phase) and their separation into mono-, di-, and polysialylated gangliosides by DEAE-Sephadex chromatography. The alternate protocol describes a more rapid method for separation of gangliosides from the total lipid extract generated partway through the first basic protocol.

STRATEGIC PLANNING

Whether a class of glycolipids is involved in biosynthesis of other glycoconjugates or in the anchoring of specific oligosaccharides or proteins to cell membranes, the unique hydrophilic and hydrophobic properties that play a significant role in their function also present unique challenges for their isolation and purification. Because of their diversity, no single protocol is convenient for purification of all classes of glycolipids; the method of choice will depend on what glycolipids are of interest. Discussion of the purification of all of the diverse classes of glycolipids is beyond the scope of a single unit. However, similarities in physical properties do permit the use of many similar or related techniques for the different classes.

Most research has focused on cell-surface glycolipids of animal cells, particularly glycosphingolipids and glycosyl phosphatidylinositol (GPI) membrane anchors (UNIT 17.8). Glycosphingolipids are glycolipids composed of a ceramide (a fatty acyl derivative of the long-chain base sphingosine) glycosidically linked to a monosaccharide, usually glucose or galactose, that may in turn be modified with additional sugar molecules (see Fig. 17.3.3). Glycosphingolipids are heterogeneous in their properties due to variation in the fatty acid and/or sphingosine structure of the ceramide component as well as the diversity of the oligosaccharide component. For example, glycosphingolipids composed of ceramides with short fatty-acid side chains and large oligosaccharide chains will be much more soluble in polar solvents than glycosphingolipids composed of ceramides with long fatty-acid side chains and short oligosaccharide chains. In addition, charged residues on oligosaccharides will decrease their hydrophobicity.

The two classes of glycosphingolipids to be considered in this unit are (1) the neutral glycosphingolipids—from monohexosylceramides up to very large neutral glycolipids that have been referred to as polyglycosyl ceramides; and (2) the negatively charged glycosphingolipids—primarily gangliosides, which are glycosphingolipids containing negatively charged sialic acid residues.

The first basic protocol separates the lipid extract into a nonpolar lower-phase fraction containing neutral glycolipids smaller than tetrahexosylceramides along with contaminating neutral and zwitterionic lipids, and a polar upper-phase fraction containing gangliosides and neutral glycolipids generally larger than tetrahexosylceramides. The upper-phase fraction is desalted by elution from a Sep-Pak C₁₈ cartridge. The lower phase can subsequently be fractionated using methods unaffected by contaminating neutral lipids and phospholipids. These lower-phase separations are not affected by neutral lipid and phospholipid contaminants if they are labeled with radioactive sugar precursors, because only the sugars will be detected by the separation technique. Contaminated lower phases can also be analyzed with carbohydrate-specific reagents if the cells used as starting material were metabolically radiolabeled (UNIT 17.4). Thin-layer chromatography (TLC; UNITS 10.12-10.14) combined with autoradiography (APPENDIX 3) can be used for separation and detection. This permits detection and characterization of extremely small amounts of glycolipids without the use of expensive instrumentation, such that single culture dishes of radiolabeled cells can be used to obtain significant structural information on purified, radiolabeled glycosphingolipids. Alternatively, high-performance liquid chromatography (HPLC; UNIT 9.6) or overlay analysis of thin-layer chromatograms using ¹²⁵I-labeled carbohydrate-binding proteins may be employed. The upper phase can be treated as described in the second basic protocol to purify the gangliosides. If only the gangliosides (and not the neutral glycosphingolipids) are of interest, the process can be shortened by carrying out just the first nine steps of the first basic protocol followed by the rapid ganglioside extraction method described in the alternate protocol. Like the first basic protocol, both protocols for purifying gangliosides are suitable for analysis of radiolabeled glycoconjugates (UNIT 17.4). All of these protocols are compatible with subsequent extraction and analyses of total membrane glycopeptides or glycoproteins (UNITS 17.1, 17.4 & 17.5) from the same sample. Figure 17.3.1 diagrams the fractionation process and relates it to the individual protocols.

CAUTION: If cells being used are metabolically radiolabeled (UNIT 17.4), appropriate procedures for manipulation and disposal of radioactive samples should be employed.

NOTE: Deionized, distilled water or its equivalent should be used throughout this unit.

EXTRACTION AND PURIFICATION OF GLYCOLIPIDS FROM CELLS OR TISSUES

BASIC PROTOCOL

Because glycosphingolipids contain both oligosaccharide and ceramide components, they are amphipatic—i.e., present the contradictory properties of being both hydrophilic and hydrophobic. Depending on the relative content of polar, nonpolar (neutral sugar), and charged substituent groups, glycosphingolipids behave differently in aqueous and nonaqueous solvents. Thus, a wide variety of methods for extracting and separating these compounds based on solubility have been developed. This protocol details a method for extracting not only the nonpolar glycosphingolipids but also the charged and highly glycosylated derivatives from cultured cells or small amounts of tissue (≤ 0.5 g). Total cell lipids are first extracted with organic solvents, then separated into fractions by the Folch partition method (Fig. 17.3.2).

Materials

- Tissue sample or cell culture from one to several culture plates
- Methanol (HPLC grade)
- Chloroform (HPLC grade)
- 4:8:3 (v/v/v) chloroform/methanol/water
- 1:1 and 2:1 (v/v) chloroform/methanol
- 100% ethanol

Preparation and Analysis of Glycoconjugates

17.3.2

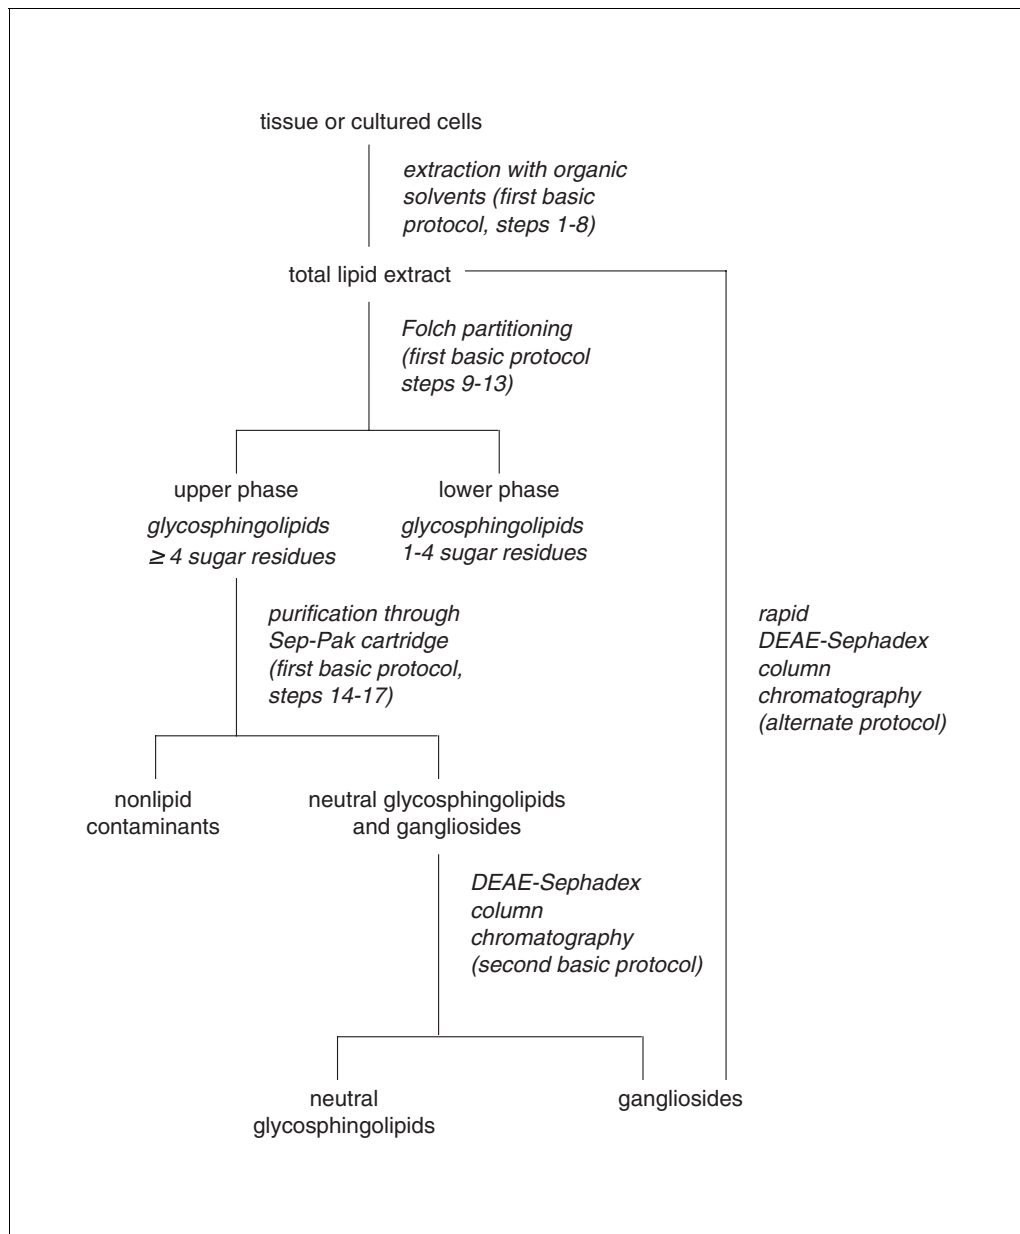

Figure 17.3.1 Flow chart showing fractionation of glycosphingolipids from total lipid extract of cells.

0.1 M KCl

1:1 (v/v) methanol/0.1 M KCl

1:1 (v/v) methanol/H₂O

Sep-Pak C₁₈ cartridge (support protocol)

Blender (Waring), tip sonicator (Branson), or Tissuemizer (Tekmar) equipped with a probe of appropriate size

Bath sonicator

Rotary evaporator, Speedvac (Savant), Vortex-Evaporator (Labconco), or nitrogen dryer

1.5-ml polypropylene microcentrifuge tubes resistant to chloroform or 12-ml conical glass centrifuge tubes

Additional reagents and equipment for quantitation of protein (UNIT 10.1), and protein electrophoresis (UNITS 10.2-10.5)

Figure 17.3.2 Folch partitioning of glycosphingolipids.

Extract sample with organic solvents

1. If using cultured cells, harvest and wash by centrifuging, removing supernatant, resuspending pellet in PBS or a suitable isotonic solution, centrifuging again, and discarding supernatant, according to the usual procedure for the cell type (this removes serum components and, in the case of metabolic labeling experiments, unincorporated radioactive precursor). Suspend tissue or cell pellet in 2° to 4°C water, using 2 to 3 ml water per gram of tissue (wet weight) or enough water to make a suspension of cultured cells containing 0.1 to 6 mg/ml protein. Homogenize using a blender, sonicator, or Tissuemizer.

Efficient extraction of glycolipids from lyophilized cell preparations is very difficult and should be avoided. For cultured cells, a pellet from one to several 60-mm plates of cells may be suspended in 0.24 ml of water in a 1.5-ml microcentrifuge tube. With microcentrifuge tubes, homogenization can be carried out using a bath sonicator. For larger samples (up to 1 ml), 12-ml conical glass centrifuge tubes should be used.

Samples should be kept on ice between homogenization and extraction to prevent digestion of the carbohydrates by endogenous glycosidases.

2. To 3 vol aqueous homogenate, add 8 vol methanol followed immediately by 4 vol chloroform, mixing continuously while adding the solvents. For small volumes, this step can be carried out in a bath sonicator.

In the case of a sample initially suspended in 0.24 ml, 0.64 ml methanol should be added, followed by 0.32 ml chloroform, for a total extract volume of ~1.2 ml.

3. Incubate sample in a bath sonicator 30 min at 20° to 30°C.

Temperatures of 20° to 30°C may destroy labile O-acetyl groups and/or induce transacylation of O-acetylated derivatives of sialic acids. Lower temperatures may be required if information on sialic acid acetylation is critical to subsequent analyses; in this case solvents should be chilled to the appropriate temperature before use. Temperatures at or below room temperature can be maintained by adding ice to the bath sonicator.

4. Centrifuge the sample 1 min at $8800 \times g$ (e.g., 11,000 rpm in a microcentrifuge) and collect supernatant.
5. Extract the pellet from step 4 with a volume of 4:8:3 chloroform/methanol/water roughly approximating the total extract volume in step 2 (e.g., ~1 ml may be used for a sample initially suspended in 0.24 ml water). Centrifuge sample 1 min at $8800 \times g$. Collect supernatant and pool with that from step 4.
6. Extract the pellet from step 5 three more times as described in step 4, using 1:1 chloroform/methanol, 2:1 chloroform/methanol, and 100% ethanol, respectively. Pool all the supernatants with that from steps 4 and 5.
7. If desired, analyze the ethanol-washed pellet (containing primarily lipid-free proteins and glycoproteins) for total proteins by one- or two-dimensional gel electrophoresis or digestion with protease for isolation of total glycopeptides. Do not allow pellet to dry; resuspend in a buffer containing SDS and store at -20° or -80°C prior to further manipulation if desired.

The two chloroform/methanol washes, using solvents with increasingly higher concentrations of nonpolar solvents compared to the sample, ensure the extraction of less polar glycolipids (i.e., mono- or disaccharide derivatives of ceramide that are more hydrophobic than glycolipids with larger oligosaccharide components). The ethanol wash removes the chloroform and methanol to avoid any detrimental effects these solvents may have on subsequent treatment of the cell pellet.

8. Evaporate the pooled supernatants from steps 4 to 6 to dryness using a rotary evaporator, Vortex-Evaporator, Speedvac, or nitrogen dryer.

Evaporating the sample under a stream of nitrogen requires considerably more time to remove the final traces of H_2O than does evaporation with a rotary evaporator, Vortex-Evaporator, or Speedvac. Dry crude lipid extract can be stored desiccated at -20°C prior to further manipulation.

Carry out Folch partitioning of glycosphingolipids

9. Dissolve the crude lipid extract from step 8 in 1.0 ml of 2:1 chloroform/methanol (or 10% to 25% the volume of the initial suspended sample if this is larger than 1 ml).
10. Partition by adding 0.2 ml (or 0.2 vol) of 0.1 M KCl and mixing vigorously by vortexing. Centrifuge 1 min at $8800 \times g$ (it will separate into two phases).

For small-scale preparations, this can be done in a 1.5-ml polypropylene microcentrifuge tube. For larger volumes, phase separation may be accomplished by allowing the mixture to stand at room temperature until separated (or in a separatory funnel overnight at 4°C).
11. Carefully remove the upper phase (~50% of the total volume) with a Pasteur pipet. Wash lower phase by adding 1:1 methanol/0.1 M KCl in a volume equivalent to the removed upper phase, mixing, and centrifuging 1 min at $8800 \times g$ to separate the phases (this removes contaminating upper phase).
12. Collect the upper phase and pool with the first upper phase. Wash the lower phase once more with 1:1 methanol/0.1 M KCl and pool with upper phases from step 11.

13. Wash the combined upper phases with 0.5 vol of 2:1 chloroform/methanol. Combine the lower phases from the washes with the pooled lower phases from step 12.

The combined lower-phase fractions contain neutral glycolipids with oligosaccharides smaller than tetrasaccharides, neutral lipids, and phospholipids. Tetrasaccharide-ceramides usually partition between the two phases, causing slight contamination. The combined upper-phase fractions contain all of the gangliosides and most of the larger neutral glycolipids (>tetrahexosylceramides) as well as all water-soluble materials from the original extract and inorganic salts introduced during washes of the lower phase. When metabolically radiolabeled cells are used, the upper phase will also contain radioactive sugar precursors and their intermediates.

The combined lower-phase fractions can now be analyzed for glycosphingolipids using methods unaffected by contaminating neutral and phospholipids—e.g., TLC and autoradiography of glycolipids (if cells were radiolabeled with monosaccharide precursors), overlay analysis of thin-layer chromatograms using ¹²⁵I-labeled carbohydrate-binding proteins, or HPLC (Kannagi, 1987). The combined upper-phase fractions can be processed as described in the following steps and further purified as described in the last two protocols.

Prepare combined upper-phase fractions for analysis

14. Dilute combined upper-phase fraction to 5 to 10 ml with 1:1 methanol/water and apply it to a Sep-Pak C₁₈ cartridge prepared as described in the support protocol below. Collect effluent in a test tube and reapply to the cartridge; repeat once.

The liquid should be applied to the Sep-Pak C₁₈ cartridge as described in the support protocol. Passing the upper-phase fraction through the cartridge removes salts and other nonlipid contaminants. Collecting and reapplying the effluent to the cartridge ensures complete absorption of all lipid-containing compounds in the sample.

15. Wash the cartridge five times with 10-ml aliquots of water (50 ml total) to ensure removal of all polar contaminants.

When radiolabeled cells are used, these washes can be pooled for further analysis of radiolabeled precursors, but should contain no glycolipid. They should be discarded as radioactive waste.

16. Elute gangliosides and high-molecular-weight neutral glycolipids from the column by washing five times with 1:1 chloroform/methanol and three times with 4:8:3 chloroform/methanol/water.

The final wash with more polar solvent elutes glycolipids containing large oligosaccharides (when present in the sample) that were not eluted with 1:1 chloroform/methanol.

17. Combine solvent washes and evaporate to dryness. Store residue desiccated at –20°C until needed.

PREPARATION OF SEP-PAK C₁₈ CARTRIDGES

This protocol details preparation of Sep-Pak C₁₈ cartridges for use in removing salts and other nonlipid contaminants from the upper-phase glycolipid fraction of Folch-partitioned material. All lipid-containing compounds will be retained by the Sep-Pak C₁₈ cartridge, water-soluble contaminants are eluted with polar solvents, and lipid-containing material is eluted with nonpolar solvent.

Additional Materials

- 0.1 M ammonium acetate in 1:1 (v/v) methanol/water
- Sep-Pak C₁₈ cartridges (Waters)
- 10-ml glass syringe with locking hub (e.g., Becton Dickinson Luer-Lok)

SUPPORT PROTOCOL

Preparation and Analysis of Glycoconjugates

17.3.6

1. Remove plunger from the barrel of the syringe and attach the Luer-Lok hub of the syringe to the long end of a Sep-Pak C₁₈ cartridge. Pump 10 ml methanol through the cartridge by adding the liquid to the barrel of the syringe, inserting the plunger into the syringe, and slowly pushing the liquid through the cartridge. Collect eluant methanol in a beaker or other appropriate container. Remove the cartridge from the syringe *before* removing the plunger. Remove the plunger and reattach the cartridge.
2. In the same fashion, carry out the following further washes (10 ml each):
 - 3 washes with 1:1 chloroform/methanol
 - 1 wash with methanol
 - 2 washes with 0.1 M ammonium acetate in 1:1 methanol/water.

Sep-Pak cartridges may be reused at least five times. They should be prepared for storage by flushing the last of the methanol/water wash out with air and stored dry at room temperature. Preparation steps should be repeated after storage prior to use.

BASIC PROTOCOL

PREPARATION OF GANGLIOSIDES

Fractionation of the glycolipid extract into neutral glycolipids and gangliosides can be easily accomplished by separating charged glycolipids from neutral glycolipids of the upper-phase fraction obtained by Folch partitioning (the material from step 17 above). A simple column chromatographic procedure is described here, but more sophisticated methods, including anion-exchange HPLC (UNIT 10.13), may be used. This protocol is adapted from a method originally developed to isolate the gangliosides from the upper phase of extracts from 50 g of tissue but also works well on a small scale for isolating gangliosides from the upper phase of extracts of metabolically radiolabeled cultured cells.

Materials

Methanol
 DEAE-Sephadex equilibrated in 100% methanol,
 50% slurry (reagents and solutions)
 Purified Folch upper-phase fraction (first basic protocol)
 0.01, 0.2, and 0.5 M ammonium acetate in methanol
 Glass wool

1. Set up a DEAE-Sephadex column in a 5-in. Pasteur pipet as follows: secure the Pasteur pipet to a ring stand with a small clamp so that the column effluent can be collected into a beaker or into tubes in a test tube rack for manual processing. Use a 9-in. pipet to position a small ball of glass wool in the narrow portion of the Pasteur pipet.

If the amount of glass wool is too large, or if it is packed too tightly into the tip of the pipet, the flow rate will be restricted. Alternatively, a column with appropriate solvent-resistant fittings can be used with a fraction collector for automatic sample collection.

2. Wash the glass wool with methanol to determine an appropriate flow rate in the empty column (this also removes any contamination from the glass wool). If the flow rate is less than 1 drop/sec, repack the glass wool to ensure a reasonable flow rate when the column is packed with DEAE-Sephadex.
3. Add sufficient 50% slurry of DEAE-Sephadex in methanol to the pipet to obtain a column of resin 2 to 4 cm high.

A 4-cm column has a bed volume of ~1 ml; half that volume is normally sufficient capacity for radiolabeled material.

4. Wash the column with 2 to 3 column volumes of methanol.
5. Dissolve the upper-phase fraction in 0.1 to 1 ml methanol and apply to the column of DEAE-Sephadex.

The upper-phase fraction is free of salts and other nonlipid contaminants. Because the charged glycolipids (gangliosides) will be retained by the column under these conditions, the sample volume is not critical.

6. Elute neutral glycolipids in the upper phase by washing the column with 5 column volumes of methanol. Evaporate the eluant to dryness (e.g., using a nitrogen dryer).

This fraction contains desalted neutral glycolipids that are larger than trihexosylceramides. These desalted neutral glycolipids can be combined with the lower-phase fraction that contains the remainder of the neutral glycolipids. This is a convenient fraction for many analyses including thin-layer chromatography (TLC) and TLC overlay analyses.

7. Elute gangliosides that contain a single sialic acid (monosialylgangliosides) from the column with 5 column volumes of 0.01 M ammonium acetate in methanol.

Eluant may be collected in equal-sized fractions if the elution profile is important, or it may be collected in a single container. Concentrate monosialylgangliosides (e.g., by evaporation under nitrogen). If this fraction is to be used for TLC analysis, it must be desalted. This can conveniently be done by adding water to 50% and applying the material to a Sep-Pak C₁₈ cartridge (support protocol).

8. Elute the gangliosides that contain two sialic acids per oligosaccharide with 5 column volumes of 0.2 M ammonium acetate in methanol.

9. Elute polysialylgangliosides (tri- and tetrasialylgangliosides) with 5 column volumes of 0.5 M ammonium acetate in methanol.

These fractions can be concentrated and/or desalted on Sep-Pak cartridges as described for monosialylgangliosides in step 7.

If the sample contains sulfated glycolipids, it may be necessary to elute them with 0.8 to 1.0 M ammonium acetate in methanol.

RAPID PURIFICATION OF GANGLIOSIDES

For projects that focus on the analysis of only gangliosides, this protocol describes a method for rapid preparation of total gangliosides from total cellular lipid extract using an ion-exchange column equilibrated in a more polar solvent.

Additional Materials

DEAE-Sephadex equilibrated in 60:30:8 methanol/chloroform/water (reagents and solutions)

Total lipid extract (step 8 of first basic protocol)

60:30:8 (v/v/v) methanol/chloroform/water

60:30:8 (v/v/v) methanol/chloroform/0.8 M aqueous KCl

1. Prepare a DEAE-Sephadex column as described in step 1 of the second basic protocol, but using DEAE-Sephadex equilibrated in 60:30:8 methanol/chloroform/water.
2. Dissolve the total lipid extract from cells or tissues from step 8 of the first basic protocol in 60:30:8 methanol/chloroform/water.

The wash volume is not critical; a volume equivalent to the volume of the original extract is generally appropriate.

**ALTERNATE
PROTOCOL**

**Preparation
and Analysis of
Glycoconjugates**

17.3.8

3. Apply total lipid extract to the column slowly (<1 ml/min) to ensure complete absorption of charged lipids.
4. Elute the column with 10 column volumes of 60:30:8 methanol/chloroform/water to remove uncharged and zwitterionic lipids.

The flow rate can be increased for this and subsequent elution steps.

5. Elute gangliosides and other acidic lipids with 10 column volumes of 60:30:8 methanol/chloroform/0.8 M aqueous KCl.

REAGENTS AND SOLUTIONS

DEAE-Sephadex, equilibrated

Suspend 5 g dry DEAE-Sephadex resin in 60 ml of 60:30:8 methanol/chloroform/0.8 M aqueous KCl. Allow resin to settle and remove supernatant by aspiration. Repeat this procedure twice and allow the final slurry to equilibrate overnight (this prepares the resin in its acetate form). Remove the supernatant and equilibrate the resin by repeated washing with 60:30:8 methanol/chloroform/water through filter paper or a coarse-porosity sintered-glass funnel.

The equilibrated resin can be stored as a 50% slurry in 60:30:8 methanol/chloroform/water for immediate application in the alternate protocol for rapid preparation of gangliosides. For separation of upper-phase gangliosides, equilibrate the resin in 100% methanol and store as a 50% slurry in methanol.

COMMENTARY

Background Information

Most research on glycolipids has focused on the analysis of cell surface glycolipids of animal cells which include the glycosphingolipids and the glycosyl phosphatidylinositol (GPI) membrane anchors. Glycosphingolipids are composed of ceramide, which is a fatty acyl derivative of the long-chain base sphingosine, glycosidically linked to a monosaccharide, usually glucose or galactose (Fig. 17.3.3). Other sugars may be added to the monosaccharide. One of the GPI anchors first described attaches *Trypanosoma brucei* variant surface glycoprotein (VSG) to the plasma membrane. This glycolipid anchor is composed of phosphatidylinositol linked glycosidically to a tetrasaccharide that terminates with a phosphoethanolamine moiety (Doering et al., 1990). The ethanolamine is linked by an amide linkage to the α -carboxyl group of a protein to form the covalent attachment of VSG to a membrane glycolipid. Variations of this GPI structure have been found in protozoans, yeast, slime molds, and most animal cells.

Because glycosphingolipids are found in the mammalian-cell plasma membrane, they are

Figure 17.3.3 The structure of galactosylceramide.

the most-studied and best-characterized of all the glycolipids. They are currently of interest to molecular and cellular biologists investigating structure and function of cell surface carbohydrates. In animal cells, glycosphingolipids function as anchors for surface carbohydrate antigens and as potential receptors for attachment of bacteria, viruses, and toxins (Karlsson, 1989). Glycosphingolipids may also have more dynamic functions as modulators of cellular interactions and transmembrane signaling (Hakomori, 1990).

The oligosaccharides of glycosphingolipids can be very complex; their heterogeneity is reviewed by Stults et al. (1990), who have cataloged the structures of 267 glycosphingolipids. In general glycosphingolipids can be divided into three classes based on their carbohydrate structures: neutral glycolipids with uncharged oligosaccharides; gangliosides with oligosaccharides containing one or more negatively charged sialic acid residues; and sulfato-glycosphingolipids with oligosaccharides derivatized with sulfate esters. The oligosaccharide “core” structure of most animal-cell glycolipids consists of lactose linked glycosidically to ceramide. Elongation of this lactosylceramide by monosaccharide addition results in several families of glycolipids based on the sequence and linkages of sugars. Table 17.3.1 (based on Machler and Sweeley, 1978; Weigandt, 1985; and Makaanu et al., 1992) lists prefixes used in naming glycolipids and their associated structures.

Variations on the basic glycolipid structure are found throughout nature. Plants, yeast, and

fungi express inositol-containing sphingolipids, and methods for their isolation and characterization have been reviewed by Laine and Hsieh (1987). These glycolipids are glycosphingolipids made up of a common core of inositol joined in a phosphodiester linkage to ceramide, with longer oligosaccharide chains glycosidically linked to the inositol moiety. Mycobacteria contain several novel classes of glycolipids including the lipo-oligosaccharides, glycopeptidolipids, and phenolic glycolipids; the structure, isolation, and antigenicity of these compounds have been reviewed by McNeil et al. (1989).

Glycosphingolipids are minor components in animal cells and much of the difficulty in their characterization is associated with their limited availability. This unit describes protocols that can be used to characterize the small amounts of material available in cultured cells. Glycosphingolipids are unique among glycoconjugates in that, regardless of their oligosaccharide complexity, each species carries only a single oligosaccharide moiety. A chromatographically pure sample generally represents a glycosphingolipid with a single oligosaccharide. The oligosaccharide structures of purified glycosphingolipids are determined using many of the structural analytical techniques described in this chapter. The apparent fidelity of structure (one glycosphingolipid, one oligosaccharide) makes it possible to assign structures based on co-chromatography of unknown structures with known standards on TLC, using chemical methods for sugar detection to locate individual glycosphingolipids. This approach

Table 17.3.1 Oligosaccharide Structures and Prefixes^a

Prefix	Structure
Arthro	GlcNAc β 1-3Man β 1-4GlcCer
Gala	Gal α 1-4GalCer
Ganglio	Gal β 1-3GalNAc β 1-4Gal β 1-4GlcCer
Globo	GalNAc β 1-3Gal α 1-4Gal β 1-4GlcCer
Globoiso	GalNAc β 1-3Gal α 1-3Gal β 1-4GlcCer
Lacto	Gal β 1-3GlcNAc- β 1-3Gal β 1-4GlcCer
Lactoneo	Gal β 1-4GlcNAc- β 1-3Gal β 1-4GlcCer
Muco	Gal β 1-3Gal β 1-4Gal β 1-4GlcCer
Mollu	Man α 1-3Man β 1-4GlcCer
Schisto	GalNAc β 1-4GlcCer

^aThese prefixes are used in designations of structures within each family. For example, the structure listed for the Lactoneo series is lactoneotetra-glycosylceramide and that listed for the Globo series is globotetra-glycosylceramide. Extensive discussion of nomenclature is beyond the scope of this unit; for more information, refer to Weigandt, 1985, and Macher and Sweeley, 1978.

has generated considerable information on the specific tissue and species distribution of glycosphingolipids. As more sensitive techniques have become available, glycosphingolipids, like glycoproteins, have been found to possess far greater structural variety than originally assumed. Research in this field is shifting from structural to functional analysis. The development of methods that define receptor function or immunological reactivity of glycolipids prior to their structural analysis has been important to functional studies.

The protocols in this unit are based on several procedures for analysis of glycosphingolipids extracted from mammalian tissues. In Folch partitioning, lipid extracts are partitioned into upper and lower phases based on differential solubility of glycolipids with different-sized oligosaccharide chains (Folch et al., 1957; Esselman et al., 1972; Ledeen and Yu, 1982). The extraction procedure is fundamentally that described by Svennerholm and Fredman (1980) for the quantitative extraction of gangliosides from animal tissues—a procedure selected to ensure complete extraction of glycolipids. The application of this procedure to the extraction and analysis of glycolipids and glycoproteins from the same sample was suggested by Finne and Krusius (1982), who used the method to obtain lipid-free glycopeptides. Isolation and fractionation of gangliosides by DEAE-Sephadex chromatography is adapted from Momoi et al. (1976). These protocols have been used successfully in the isolation, purification, and identification of immunologically reactive glycosphingolipids from both unlabeled (Magnani et al., 1982) and metabolically radiolabeled (Clark et al., 1991) cultured animal cells.

Critical Parameters and Troubleshooting

The use of metabolically radiolabeled cells as described in *UNIT 17.4* permits analysis of a small number of cells to obtain significant information on the carbohydrate composition and structure of glycosphingolipids.

The success of the separation and purification procedures will be obvious upon analysis of the glycosphingolipid fractions obtained. Poor resolution of glycolipids during most chromatographic analyses is generally associated with the presence of salts in the sample or with poorly equilibrated columns. Use of the Sep-Pak C₁₈ cartridge is the most convenient method for removal of salt from the sample

(Williams and McClure, 1980).

The combined lower-phase neutral glycolipid fraction will contain non-glycolipid contaminants of the lower phase, including neutral and zwitterionic lipids such as cholesterol, lecithin, ethanolamine, phosphoglycerides, etc. For many analyses this contamination does not contribute to, or interfere with, separation or detection methods. For example, in the case of material from cells metabolically labeled with monosaccharide precursors, essentially all of the detected label will be in the sugars. Label can, however, appear in non-glycolipid components of the lower phase of a Folch extract. In extracts of Chinese hamster ovary cells, such material was tentatively identified as phosphatidylinositol (Smith et al., 1990). *UNIT 17.16* describes how to determine the composition of radiolabeled monosaccharides of isolated glycolipids. When specific reactions such as sugar-specific stains or carbohydrate-specific antibodies are used to identify glycolipids on TLC plates, these contaminants will not react. If removal of the contaminants is necessary, it can be accomplished by saponification followed by chromatography on silicic acid (Ledeen and Yu, 1982). However, these procedures will destroy the base-labile substitutions of sialic acid on the gangliosides.

Contaminating phospholipids can also be removed by saponification followed by dialysis. Conditions that affect sialic acids should be considered when planning extraction and purification of gangliosides. To preserve any *O*-acetyl derivatives of the sialic acid residues on gangliosides, which may be very important in functional analyses, it is important to avoid the use of bases. The *O*-acetyl derivatives of sialic acid are extremely labile and migrate via transacylation reactions in these cases.

The plastic microcentrifuge tubes used in this unit must be resistant to chloroform-containing solvents. Most polypropylene tubes claim resistance to chloroform, but it is worth testing the tubes to be sure. Centrifugation steps involving microcentrifuge tubes should be carried out in a cold room, because heat buildup during centrifugation can increase pressure inside capped tube (containing volatile solvents) and cause them to open during centrifugation, resulting in loss of solvent and possibly sample. For large-scale preparations, and where physical methods such as mass spectroscopy are to be used for structural analyses, use a solvent-resistant apparatus and substitute glass for plastic to avoid contamination with plasticizers.

Anticipated Results

The protocols described in this section are intended to provide the investigator with methods for preparing neutral and/or acidic glycosphingolipids from cultured animal cells or small samples of tissue. Because the glycosphingolipids make up such a small amount of total cell mass, it is very difficult to obtain information related to the theoretical yield of glycolipid; however, these protocols will provide a representative sample of the neutral glycolipids and gangliosides present in the starting material. The results of each isolation step and how each sample may be used for further analysis are described throughout the unit. The final samples of neutral glycolipid and/or ganglioside are to be used for further analysis or characterization.

Time Considerations

The total extract can be obtained and dried in ~3 hr, depending upon the method used for evaporation. Folch partitioning of the total extract into upper and lower phases will require 30 to 60 min. The preparation of the DEAE-Sephadex requires an overnight equilibration step; if large amounts of resin are equilibrated and stored, only a brief wash of the resin with the starting solvent is required before each time the procedure is carried out. Preparation of a Sep-Pak C₁₈ cartridge according to the support protocol will require ~30 min. The desalting step using a Sep-Pak cartridge is somewhat cumbersome and time-consuming because multiple samples must be processed individually and the procedure requires considerable manipulation of syringe and cartridge. If multiple samples are being processed, commercial vacuum manifolds that accommodate large numbers of cartridges may be used. Several hours are required to run the DEAE-Sephadex column with a flow rate of 1 to 2 ml/min and multiple solvent systems to fractionate gangliosides. From extraction to fractionation of gangliosides can take up to 2 days. Rapid isolation of the ganglioside fraction (steps 1 to 12 of the first basic protocol) for use in the alternate protocol can be accomplished within 1 to 2 hr; the alternate protocol will produce neutral and acidic fractions within 1 day.

DETECTION OF SACCHARIDES ON GLYCOCONJUGATES

The first step towards analyzing the structure and function of oligosaccharides on a glycoconjugate is the detection of the sugar chains themselves. The units presented in this section describe a variety of ways in which this can be achieved. In some cases, such studies may provide the first evidence that the molecule being examined is a glycoconjugate. In other cases, these methods may be used to qualitatively or quantitatively analyze the nature of the sugar chains on a molecule that is already known to be a glycoconjugate. For help in deciding which protocols to use, the user is referred to the section entitled “Choice of Techniques” found in the introduction to this chapter.

Introducing a label into the sugar chains of the glycoconjugate of interest is often informative, and can be very convenient for further analyses. This can be achieved by metabolic radiolabeling (*UNIT 17.4*), chemical labeling (*UNIT 17.5*), or transferring label from a radioactive sugar nucleotide using a glycosyltransferase (*UNIT 17.6*). Each of these approaches has its advantages and disadvantages, in terms of specificity, sensitivity, and practical utility. The user is advised to read the commentaries of each of these units before choosing an approach to take.

It has been recently recognized that many membrane glycoproteins acquire a glycospholipid anchor during biosynthesis. A set of methods designed to detect and analyze such anchors is presented in *UNIT 17.8*. There are also many well-established methods for the direct chemical analysis of the oligosaccharides present in glycoconjugates. In this supplement, the classic phenol–sulfuric acid assay for hexoses and pentoses is presented (*UNIT 17.9*); others will follow in future updates. Finally, oligosaccharides on many glycoconjugates can be altered with a variety of commercially available inhibitors and competitive substrates that can work in whole cells or organisms. In this supplement, the prevention of N-linked glycosylation on glycoproteins is described (*UNIT 17.10*).

There are, of course, many other approaches to the direct analysis of oligosaccharides on glycoconjugates that could have been presented in this section. The current and upcoming choices for inclusion (see Chapter 17 table of contents) were dictated by the need to “keep it simple” and to meet the criterion of broad general utility to the average molecular biologist. As “glycotechnology” improves and simplifies, further additions to this section are anticipated.

Metabolic Radiolabeling of Animal Cell Glycoconjugates

Some useful information about glycoconjugates can be obtained by labeling their aglycone (noncarbohydrate) portions—e.g., labeling proteins with radioactive amino acids (*UNIT 10.18*)—then using techniques described elsewhere in this chapter to infer indirectly the presence, type, and nature of oligosaccharide chains. This unit describes metabolic labeling techniques that provide more specific information about the structure, sequence, and distribution of the sugar chains of glycoconjugates. Although these techniques provide less information than complete sequencing of the sugar chains, the partial structural information derived is sufficient for many purposes. Following metabolic labeling, the radioactive glycoconjugate of interest is isolated, individual glycosylation sites are identified and separated if necessary, and the labeled oligosaccharides are subjected to structural analysis. Metabolic labeling has the advantages of being simple and easy to perform and of requiring no sophisticated instrumentation other than a scintillation counter. Also, purification of the glycoconjugate to radiometric homogeneity is sufficient for further analysis. Important practical considerations for metabolic labeling experiments include selecting the type of experiment and the labeled precursor, understanding the specificity of labeling, and maximizing uptake and incorporation (see critical parameters). Before proceeding with experiments to label glycoconjugates metabolically, labeling conditions should be evaluated to ensure that cell viability and metabolism are not altered, and optimized for uptake and incorporation of the precursor (this should be done for each combination of precursor and cell line).

In the basic protocol, actively growing cell cultures are grown through several population doublings in complete medium supplemented with radiolabeled glycoconjugate precursors to reach a steady-state level of incorporation. In the alternate protocols, cells are cultured for a short period of time in a deficient medium that contains a high concentration of radiolabeled precursor. A pulse or pulse-chase labeling procedure (first alternate protocol) can be used to analyze precursor-product relationships. With sequential pulse-labeling (second alternate protocol), it is possible to obtain quantities of labeled glycoconjugates with the use of a minimal amount of labeled precursor by using the same medium to pulse-label a series of cultures. A support protocol describes the preparation of multiply deficient medium (MDM) for use in making appropriate deficient media.

NOTE: Conventional protocols for handling, monitoring, shielding, and disposing of radioactivity and radioactive waste (*APPENDIX 1*) and for tissue culture of cells and sterile handling of media (Chapter 9) should be followed throughout these protocols.

BASIC PROTOCOL

STEADY-STATE LABELING WITH RADIOACTIVE PRECURSORS

When studying glycoconjugates in an established tissue culture cell line, molecules of interest can be labeled for structural characterization. In the following protocol, actively growing cultures of cells are grown to a steady-state level of incorporation in complete medium supplemented with radiolabeled glycoconjugate precursor.

Optimizing Conditions

An attempt should be made to label the molecules as close as possible to metabolic steady state—i.e., a constant level of radioactivity per mass unit of a given monosaccharide in all glycoconjugates in the cell—under conditions of normal growth. In practice, this is somewhat difficult to achieve with most cell types. The maximum possible number of cells should be grown for the longest possible period of time in the minimum possible volume of complete medium supplemented with the maximum possible amount of

radioactive label. Before labeling is attempted, the following growth characteristics should be determined for the cell type of interest: (1) population doubling time, (2) maximum degree of dilution upon splitting that is compatible with proper regrowth, (3) maximum cell density compatible with healthy growth and metabolism (confluence), and (4) minimum volume of medium that will sustain regrowth from a full split to confluence. If these parameters are properly defined, growth from full split to confluence will allow at least three population doublings during the labeling period for most cell lines. In some cases, however (e.g., with very slowly growing cell lines, lines requiring frequent medium changes, or cells that cannot be diluted to low density when splitting), this may not be feasible.

Materials

Radioactive precursor: ^3H - or ^{14}C -labeled monosaccharide, [^{35}S]sulfate, [^3H]acetate, or [^{32}P]orthophosphate; at highest available specific activity
Complete tissue culture medium appropriate for long-term growth of tissue culture cell line, supplemented as necessary
Established tissue culture cell line, either suspension or monolayer
Phosphate-buffered saline (PBS; *APPENDIX 2*), pH 7.2

Sterile plastic syringes with Luer-/Lok fittings
Disposable 0.22- μm filters with Luer-Lok fittings
Disposable flasks fitted with 0.22- μm filters
Tissue culture plates or flasks
Tabletop centrifuge, 4°C, and appropriate screw-cap centrifuge tubes
Rubber policeman or disposable cell scraper

Additional reagents and equipment for trypsinization (e.g., Chapter 9 introduction)

1. If necessary, dry radioactive precursor to remove organic solvents. Dissolve in a small volume of complete tissue culture medium.
2. Filter sterilize radioactive medium, using a standard disposable 50-ml vacuum suction filter device (filter flask fitted with 0.22- μm filter) for volumes ≥ 10 ml or a 0.22- μm filter attached directly to the tip of a disposable sterile syringe (both syringe and filter with Luer-Lok fittings) for smaller volumes. Wash out the original container with additional medium and use this fluid to wash through the filter (this maximizes recovery of label).

CAUTION: Dispose of the radioactive filter and/or syringe appropriately.

The radioactive precursor may be available in a sterile aqueous medium, ready for use. However, such preparations are more expensive, and after repeated opening of such packages, filtering is recommended to ensure continued sterility.

3. Add additional medium if necessary to bring up the volume to the amount needed for the experiment. Warm the medium to the temperature at which labeling will be done in an incubator or water bath.
4. Using a sterile pipet tip, aliquot a small amount of radioactive medium and save for scintillation counting in step 8.
5. Split cells according to standard method (e.g., detach by trypsinization), resuspend in radioactive medium, and plate out onto tissue culture plates. For suspension culture, dilute directly in radioactive medium or concentrate as follows: place culture in an appropriately sized screw-cap centrifuge tube and centrifuge in a tabletop centrifuge 5 min at $\sim 500 \times g$. Discard supernatant and resuspend cell pellet in radioactive medium. Incubate under standard conditions for the cell line being studied.

The number of cells needed, and therefore the culture vessels and volume of medium used, will depend on the growth characteristics of the particular cell line being studied and should be optimized as described above.

6. When the cells reach maximum growth (near confluence or late log phase), chill culture on ice and harvest cells, scraping monolayer cells from plate using a rubber policeman. Pellet cells 5 min at $\sim 500 \times g$, 4°C. Decant the labeled medium and save an aliquot for scintillation counting in step 8.

If the glycoconjugates in the conditioned medium are to be studied, the medium should be filtered through a 0.22- μm filter to remove any broken cell debris remaining after centrifugation.

7. Wash the cell pellet twice in a >50 -fold excess of ice-cold PBS, pH 7.2.

At this stage, the labeled cell pellet can be frozen at -20°C to -80°C for later analysis if desired.

8. Using a scintillation counter, determine the efficiency of incorporation by measuring the radioactivity incorporated into an aliquot of the cells and the sample of conditioned medium from step 6. As a control, measure the radioactivity of the sample of sterile radioactive medium from step 4.

It may be necessary to dilute the medium to get an accurate count.

ALTERNATE PROTOCOL

PULSE OR PULSE-CHASE LABELING WITH RADIOACTIVE PRECURSORS

If steady-state labeling (basic protocol) does not yield sufficient incorporation of label into the glycoconjugate of interest, it may be desirable to provide labeled precursor in the absence of or with the decreased amounts of the unlabeled form. The pulse procedure described in the following protocol—in which cells are cultured briefly in deficient medium supplemented with a radioactive precursor—may be used in these cases. Alternatively, the procedure can be expanded into a pulse-chase by adding a chase of nonradioactive medium; this permits brief labeling of the glycoconjugate of interest to establish precursor-product relationships. These procedures are most useful for labeling monosaccharides that compete with glucose for uptake—Gal, Glc, Man, and GlcNH₂ (see commentary). They are of limited value for monosaccharides that are not usually taken up efficiently by cells—GlcNAc, GalNAc, ManNAc, Neu5Ac, Fuc, Xyl, and GlcA—unless very large quantities of such labeled molecules can be used for pulse labeling. Because pulse labelings are typically done for a short time (e.g., minutes or hours), cells are usually used in a nearly confluent state, to maximize uptake and incorporation.

Optimizing Conditions

Before the experiment is performed, several pilot experiments should be carried out to determine the optimal conditions for labeling.

Determining base incorporation level and the effect of glucose. MDM medium appropriate for growing cultures of the cell line of interest should be reconstituted (support protocol) to 100% levels of all components except the one being presented as a radiolabeled precursor or competing molecule (e.g., glucose). If required by the cells, dialyzed serum should be added to the appropriate final concentration. Finally, radiolabeled precursor should be added. A small-scale pilot labeling should be carried out by culturing cells in the labeled medium and monitoring incorporation of the label into the macromolecule of interest or whole-cell glycoproteins. If the radiolabeled precursor is a monosaccharide, the effect of glucose on incorporation of radiolabeled precursor should be

assessed by carrying out this pilot experiment in duplicate using one lot of medium prepared as described and one prepared the same way but without glucose.

Determining optimal concentration of radiolabeled precursor. Enough MDM medium for several pilot experiments should be reconstituted to 100% levels of all components except the one being presented as a radiolabeled precursor. Radiolabeled precursor should be added and the medium divided into aliquots. The aliquots should be supplemented with an unlabeled 100× stock solution of the same precursor to yield a series of media containing different concentrations of the unlabeled precursor (e.g., 0%, 5%, 10%, 20%, 50%, and 100% of the concentration in normal medium). These should be used for small-scale pilot labelings of the cell line of interest for defined periods of time and incorporation of label monitored as described above. Incorporation should be plotted against the total precursor concentration. The point at which the curve breaks—i.e., where the percentage of label incorporated is markedly decreased by further addition of unlabeled compound—is the point at which the precursor concentration is no longer limiting for biosynthetic reactions (see Fig. 17.4.1). The optimal concentration of unlabeled precursor will be a little higher than the break point for the curve, where unlabeled precursor is not limiting but incorporation is still good.

Checking cell growth at optimal precursor concentration. Reconstituted MDM medium containing radioactive precursor plus the optimal concentration of unlabeled precursor should be prepared and cells grown in this medium for the desired period of time. Incorporation of radiolabeled precursor should be monitored and linearity of uptake and incorporation of label over time should be assessed. Measures of cell growth, stability, and general biosynthetic capability [e.g., cell counts, Strober (1991a); trypan blue exclusion, *UNIT 11.5*; and radioactive amino acid incorporation, *UNIT 10.18*] should also be assayed to determine if reducing the concentration of the precursor into this range has

Figure 17.4.1 Incorporation of radiolabeled sulfates into macromolecules into cells labeled in sulfate-free medium and the effect of adding increasing amounts of unlabeled sulfate. The arrow indicates the point at which the sulfate is no longer limiting.

any detrimental effect upon the cells. It is sometimes necessary to reach a compromise between the opposing factors of lowered concentration, labeling time, and cell viability. An attempt should be made to determine the lowest concentration of the unlabeled precursor that can be used for the desired period of time without affecting cell growth, viability, and biosynthesis of macromolecules in general. It should be kept in mind that the use of partially deficient medium may selectively alter glycoconjugate makeup (e.g., lowering sulfate concentration too much can result in undersulfation of glycosaminoglycans in some cell types).

Additional Materials

Multiply deficient medium (MDM; Table 17.4.1 and support protocol),
supplemented as appropriate
Fetal calf serum (GIBCO/BRL), dialyzed (*APPENDIX 3*) against sterile
0.15 M NaCl until glucose concentration reaches $\sim 270 \mu\text{M}$, to remove
small molecules that could dilute the radioactivity

1. Determine optimal conditions for labeling as described above. Grow monolayer cells in complete medium to near confluence or suspension cells to late log phase.
2. Based on the pilot experiments for optimizing conditions described above, reconstitute MDM to prepare a stock of medium partially deficient in only the precursor of interest.
3. Add an appropriate quantity of radioactive precursor. Add dialyzed fetal calf serum if required for growth of the cell line being studied. Filter sterilize, warm the medium to 37°C , and reserve an aliquot of radioactive medium as described in steps 2 to 4 of the basic protocol.
4. For monolayer cells, aspirate culture medium from plate; for suspension cells, microcentrifuge or centrifuge briefly and decant the supernatant medium. Add an appropriate quantity of radioactive labeling medium (step 3). Incubate cells for the desired period of time.

Labeling time should be based on the length of time the cells can survive in deficient medium as determined in the optimizing pilot experiment.

Save radioactive medium for analysis, if necessary.

5. For pulse-labeling, proceed to step 6. For pulse-chase labeling, remove medium as described in step 4, add a chase of nonradioactive complete medium, and incubate for the desired period of time.

For a pulse-chase experiment, several vessels of each cell culture should be set up and chased for varying periods of time.

6. Harvest and wash the cells. Determine efficiency of incorporation as described in steps 6 to 8 of the basic protocol.

SEQUENTIAL PULSE OR PULSE-CHASE LABELING WITH REUSE OF RADIOACTIVELY LABELED MEDIUM

ALTERNATE PROTOCOL

In some cases, incorporation of label into the glycoconjugate of interest may be inadequate, even under defined conditions with selectively deficient medium. Also, prolonged exposure to deficient medium may result in alterations in synthesis of proteins or other macromolecules. In these situations, it may be desirable to expose a series of plates of cells sequentially to a small volume of medium containing a high concentration of label. This also conserves potentially expensive radiolabeled precursor. In the following protocol, multiple sets of cell cultures are sequentially pulse-labeled. One set is incubated in labeling medium for the pulse period, then the labeling medium is removed and added to the next set. For a pulse experiment (designed to obtain a sizable quantity of material with a high level of incorporation), the cells are harvested at this point; for a pulse-chase, a chase of nonradioactive complete medium is added to the first set of cultures. This process is repeated until all cells have been labeled (Fig. 17.4.2). Because the incubation period is relatively short (e.g., a few hours), it is assumed that only a very small fraction of the radiolabeled precursor is consumed from the medium during each labeling cycle and that the concentrations of other essential components are not substantially changed. To further conserve labeled medium, some investigators freeze it after limited usage and thaw it to reuse (the pH of thawed medium should be adjusted before use). When reusing medium, experimental results should be interpreted carefully, especially with regard to the specific activity of labeled products and the possibility of metabolic effects of secreted molecules.

Additional Materials

Multiply deficient medium (MDM; Table 17.4.1 and support protocol),
supplemented as appropriate

Fetal calf serum (GIBCO/BRL), dialyzed (*APPENDIX 3*) against sterile 0.15 M NaCl
until glucose concentration reaches $\sim 270 \mu\text{M}$, to remove small molecules that
could dilute the radioactivity

1. Determine optimal conditions for labeling as described in the introduction to the previous protocol. Set up several identical sets of monolayer or suspension cells to be labeled sequentially and grow to confluence or late log phase.

For suspension cultures in which it is possible to use <1 ml of labeling medium, cells may be grown in tightly capped 1.5-ml screw-cap microcentrifuge tubes and incubated at 37°C on a rotating end-over-end mixer.

2. Prepare radioactive labeling medium and label the first set of cell cultures as described in steps 2 to 4 of the previous protocol for the appropriate length of time.

Labeling time will vary from minutes to hours, depending upon the cell type and the objective of the labeling.

3. For monolayer cells, aspirate the radioactive medium from the first set of cultures; for suspension cells, microcentrifuge briefly (~ 10 sec at top speed) and decant the supernatant radioactive medium. Transfer the radioactive medium to the second set of cultures.
4. For pulse-labeling, harvest cells from first set of cultures. For pulse-chase labeling, add a chase consisting of an adequate quantity of nonradioactive complete culture medium to the first set of cultures and continue incubating.
5. Repeat transfers until all sets of cells have been labeled.
6. Harvest all plates. For pulse-labeling, pool all the pellets together. For pulse-chase labeling, keep the individual cell pellets separate (see Fig. 17.4.2).

Preparation and Analysis of Glycoconjugates

17.4.7

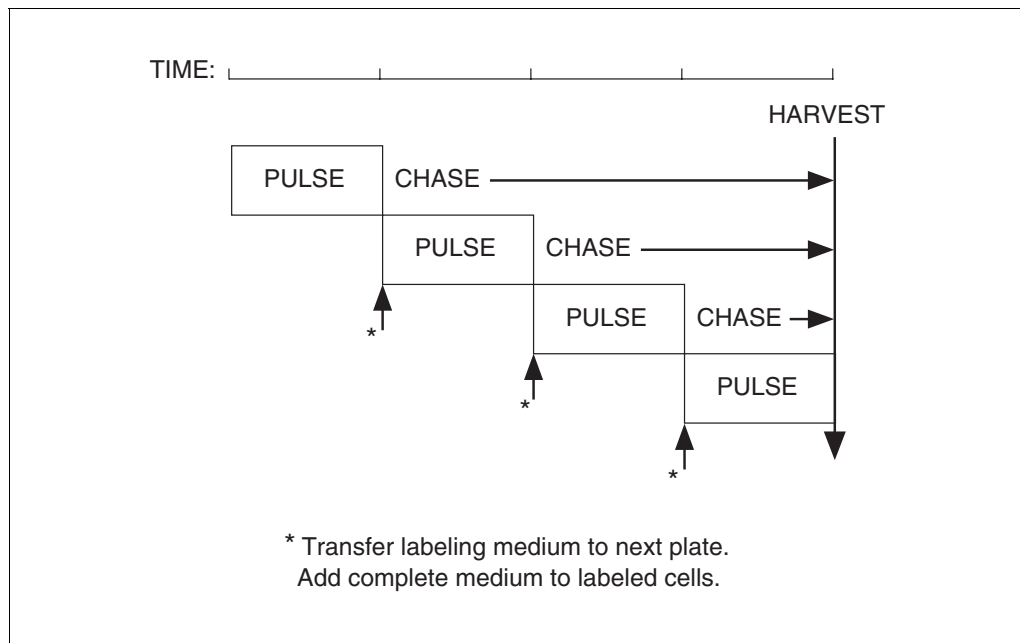

Figure 17.4.2 Scheme for sequential pulse-labeling of cells reutilizing radioactive medium.

**SUPPORT
PROTOCOL**

**PREPARATION AND SUPPLEMENTATION OF MULTIPLY
DEFICIENT MEDIUM (MDM)**

Some types of selectively deficient media are available commercially at reasonable prices, and some companies will custom-prepare selectively deficient media on request. For a laboratory where labeling experiments with a variety of deficient media are frequently carried out, it is convenient to prepare a basic multiply deficient medium (MDM) that is completely lacking in several commonly studied components. This medium can be used to make up different selectively deficient media as needed. The following MDM, based on α -MEM medium (GIBCO/BRL), supports growth of most tissue culture cells.

For labeling experiments, MDM can be reconstituted with ^3H - or ^{14}C -labeled monosaccharides, [^{35}S]sulfate, ^{35}S -labeled methionine or cysteine, or [^3H]serine. If desired, other specific components can also be omitted and replaced with their radiolabeled forms.

NOTE: Tissue culture grade reagents (including distilled, deionized water) should be used in making MDM. To ensure that reagents do not become contaminated by compounds such as endotoxin as portions are being removed from stock bottles, it is important to pour liquids carefully and use disposable spatulas for removing solids. For the same reason, clean glassware must be used; preferably, a set of glassware should be set aside for this purpose. 100 \times stock solutions of many components can be purchased commercially in sterile form, or may be made up from solids and filter sterilized individually.

Additional Materials

- Stock solutions for multiply deficient medium (MDM; Table 17.4.1)
- 100 \times stock solutions for reconstituting MDM (Table 17.4.2)

1. Based on the experiment to be performed, determine appropriate components for MDM (see box below for example).
2. Make up MDM according to the ingredient list in Table 17.4.1 by dissolving salts and phenol red one by one in ~800 ml water, adding sufficient pyruvate, amino acid, and vitamin stocks for a 1 \times final concentration in 1 liter, and adding water to 1 liter.

SELECTIVE RECONSTITUTION OF MDM MEDIA WITH MISSING COMPONENTS

The following example gives 50 ml of a supplemented MDM for optimal labeling of endothelial cells with [³⁵S]sulfate and [6-³H]glucosamine, which requires a medium with no cysteine, low glucose, and low concentrations of methionine and sulfate (see Roux et al., 1988, for detailed rationale). Stock solutions are as listed in Table 17.4.2.

To 50 ml MDM, add:

500 μl 100× NaHCO₃ stock solution

500 μl 100× glutamine stock solution

500 μl 100× serine stock solution

50 μl 100× glucose stock solution (200 mg/L final)

10 μl 100 mM inorganic sulfate stock solution (20 μM final)

50 μl 100× methionine stock solution (0.1× final)

Just before use, add 0.5 mCi each of [³⁵S]sulfate and [6-³H]glucosamine and mix. Filter sterilize directly into culture vessel.

The total volume of reconstituted medium will be slightly more than 50 ml; for practical purposes, this minor discrepancy can be ignored. The medium should be orange-red, indicating the correct pH range.

3. Filter sterilize (the solution will be yellow). Do not adjust the pH. Freeze 25-ml aliquots in 50-ml tubes at -20°C.
4. Add appropriate components (from those listed in Table 17.4.2) to reconstitute MDM for the labeling experiment (see box for example).

COMMENTARY

Background Information

If sufficient quantities of pure molecules are available (i.e., in the nmol range), complete sequencing of oligosaccharides is best performed by conventional physical techniques. However, isolation of sufficient quantities may not be practical (e.g., in analysis of biosynthetic intermediates or rare molecules). Alternatively, the biological questions underlying the experiment may be adequately answered by partial structural analysis. In these cases, metabolic labeling with radioactive sugars or donors that can transfer label to sugars may provide sufficient structural information about the oligosaccharide chains (Cummings et al., 1989).

Sugar chains of glycoconjugates can be successfully labeled by short-term labeling experiments using radioactive precursors (Tabas and Kornfeld, 1980; Goldberg and Kornfeld, 1981; Roux et al., 1988; Muchmore et al., 1989). Although sugar nucleotides are the immediate donors for glycosylation reactions, they cannot be taken up by cultured cells. Hence, metabolic labeling of sugar chains is accomplished by

providing the cells with radiolabeled monosaccharide precursors (Yurchenco et al., 1978; Yanagishita et al., 1989; Varki, 1991). These are taken up by the cells, activated to sugar nucleotides, and transported into the Golgi apparatus, where lumenally oriented transferases add the monosaccharides to lumenally oriented acceptors (Hirschberg and Snider, 1987). The few known exceptions to this topology are cytosolic and nuclear forms of glycosylation (Hart et al., 1989). For oligosaccharides that contain modifications such as sulfate, acetate, and phosphate ester groups, an alternative metabolic labeling technique is to use a [³⁵S]sulfate, [³H]acetate, or [³²P]orthophosphate label, respectively.

While metabolic labeling can provide useful information regarding glycoprotein oligosaccharides, there are significant limitations to its use. First, it is difficult to determine when true steady-state labeling of a cell is reached (as a rule of thumb, 3 to 4 doublings are usually assumed to be sufficient); thus the numerical ratio between labeled glycoconjugates can be

Table 17.4.1 Composition of Multiply Deficient Medium (MDM)

^aIndividual components are added to MDM at full strength, or lowered concentration or may be left out altogether, depending upon the experiment planned.

^b100× stock solutions are available commercially (e.g., from GIBCO/BRL).

^cUse either NaHCO₃/CO₂ or HEPES·HCl (not both); these control the pH of the final medium.

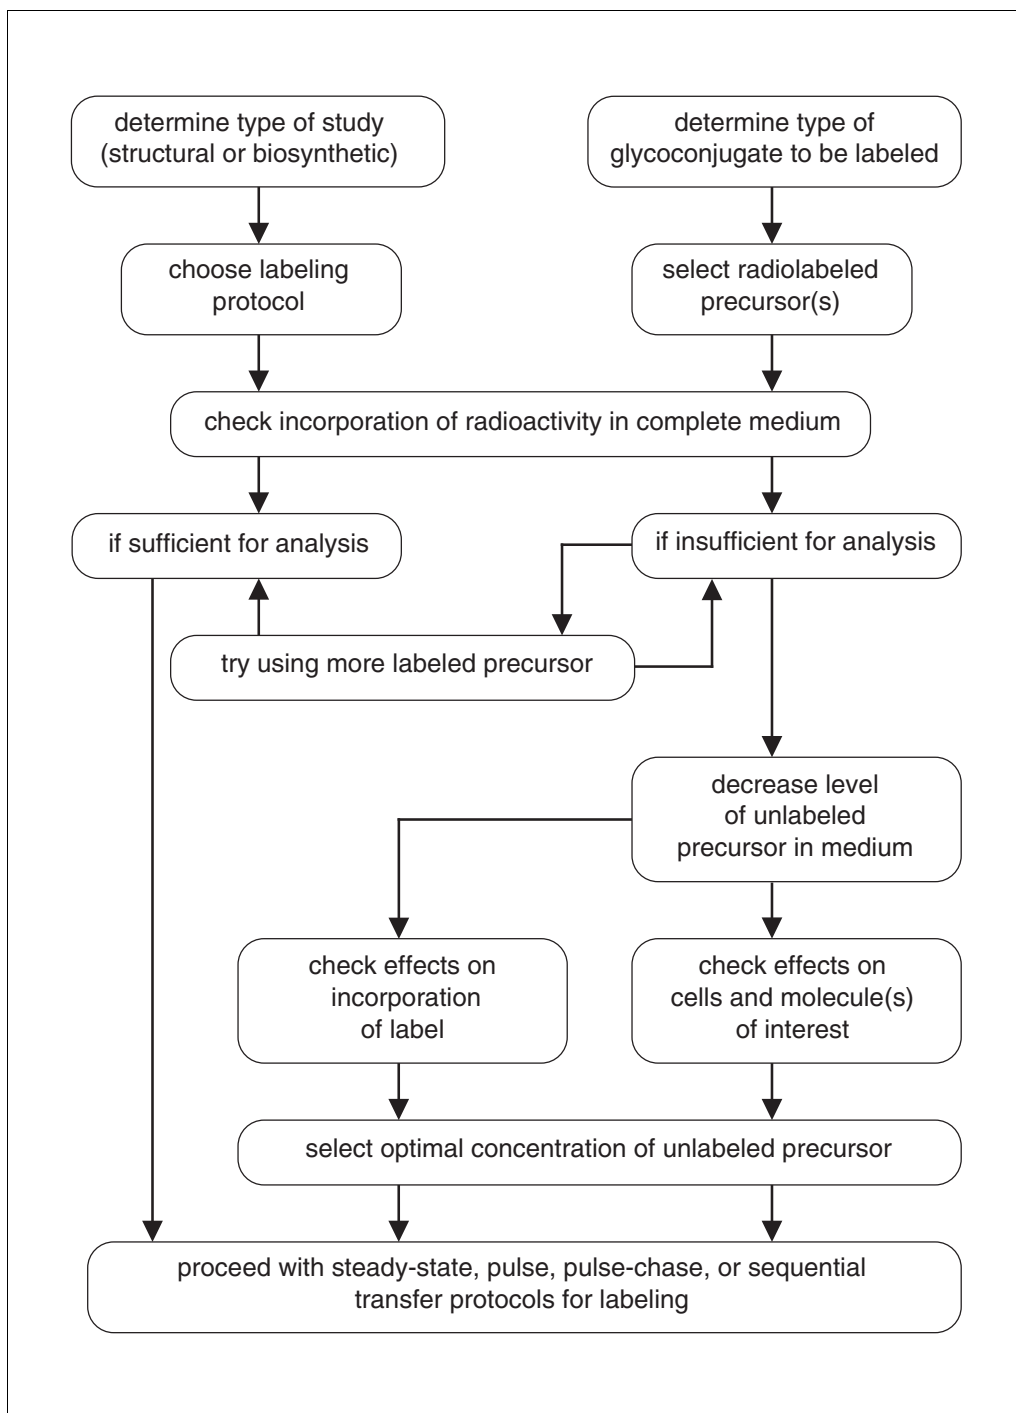

Figure 17.4.3 Strategy for planning metabolic labeling of animal cell glycoconjugates.

misleading. Second, individual precursors show greatly differing uptake and incorporation in different cell types. Third, almost all labeled precursors are only partially specific for certain monosaccharides, and the degree of this specificity can vary depending on cell type. Fourth, while lowering glucose concentration improves the incorporation of monosaccharides that compete with glucose for uptake, the

low glucose supply may also directly affect oligosaccharide precursors in some cell types.

Critical Parameters

As diagrammed in Figure 17.4.3, what labeling protocol is most suitable for a particular study depends on several different considerations. Some of these arise from the objectives of the study and must be investigated by per-

Table 17.4.3 Distribution of Monosaccharides and Modifications in Glycoconjugates^a

Precursor	Type of glycoconjugate

^aThe relative distribution of the different monosaccharides and modifications in the commonly occurring glycoconjugates, indicated by a relative scale from + to +++, is generally valid over many cell types. However, an uncommon monosaccharide may be commonly found in some cell types or glycoconjugate (e.g., most pituitary glycoprotein hormones have GalNAc as a major component of their *N*-linked oligosaccharides). Other symbols: +?, possible distribution; +/-, variably present; –, not identified to date.

forming pilot experiments to determine optimal conditions (see optimizing conditions section of introductions to the first two protocols).

General considerations

If the goal of a study is to obtain labeled material for structural identification and partial characterization, the yield of radioactivity should be maximized by either steady-state or pulse-labeling. For quantitating the relative mass of a molecule in two different samples or comparing the masses of two molecules in the same sample, the oligosaccharide should be labeled to constant specific activity—i.e., steady-state distribution (however, as mentioned above, this may not always be achievable). For establishing precursor-product relationships between molecules, a pulse-chase protocol should be used. If the radioactive precursor is expensive, a sequential procedure may be employed in pulse and pulse-chase experiments to minimize the quantity needed.

Selecting a labeled precursor

Selection of the labeled precursor to be used is based upon several factors, including efficiency of uptake (see below) and type of gly-

coconjugate to be labeled. In most cases, the precursor will be a monosaccharide; for an oligosaccharide chain containing ester modifications of sugars, it is also possible to use a precursor such as acetate, sulfate, or orthophosphate.

Factors affecting specificity and final distribution. In selecting a monosaccharide precursor, it should be noted that the distribution of monosaccharides among different types of vertebrate oligosaccharides is nonrandom (Table 17.4.3). It is also important to consider metabolic pathways for uptake, activation, utilization, and interconversion of the various monosaccharides and their nucleotide sugars, which have been studied extensively (Fig. 17.4.4 and Table 17.4.4). The final distribution and specific activity of label from a given radiolabeled monosaccharide can be significantly affected by dilution from unlabeled compound generated by endogenous pathways, the characteristics of the particular cell type being labeled, and the labeling conditions (Kim and Conrad, 1976; Yurchenco et al., 1978; Yanagishita et al., 1989). The exact position of the tritium label within a monosaccharide can affect the ultimate fate of the label

Table 17.4.4 Cellular Monosaccharides Labeled with Radioactive Precursors^a

Product identified as:	Radiolabeled precursor						
	[2- ³ H]Man	[6- ³ H]Gal	[1- ³ H]Gal	[1- ³ H]Glc	[6- ³ H]GlcNH ₂	[6- ³ H]ManNAc	[6- ³ H]GalNAc
[³ H]Man	+++	+/-	+/-	++	+/-	+/-	+/-
[³ H]Fuc	+++	+/-	+/-	++	+/-	+/-	+/-
[³ H]Gal	-	++++	++++	+++	+/-	+/-	+/-
[³ H]GlcA	-	-	++	++	-	-	-
[³ H]Glc	-	++	++	++++	+/-	+/-	+/-
[³ H]GlcNAc	-	+/-	+/-	++	++++	++	+++
[³ H]GalNAc	-	+/-	+/-	++	+++	+	++++
[³ H]Sia	-	-	-	++	++	++++	+/-

^aThe extent of conversion from the original monosaccharide into minor pathways will vary considerably, depending upon the cell type studied, and the length of the labeling (longer time periods tend to result in more conversion into other monosaccharides). The extent of incorporation is indicated by a relative scale from + to +++++. Other symbols: +/-, variable low-level incorporation; -, not identified to date.

(Diaz and Varki, 1985). Interconversion between monosaccharides (e.g., conversion to glucose; Fig. 17.4.4), which can be expected to occur with prolonged labeling, will eventually result in labeling of nonoligosaccharide components. An exception is labeling with [2-³H]mannose: this is extremely specific, because conversion of the labeled mannose can yield only [2-³H]fucose or unlabeled fructose-6-phosphate. In the latter case, the label is lost as tritiated water, which is diluted into the pool of cellular water. Thus, in most instances, label from [2-³H]mannose remains confined to mannose and fucose residues, regardless of how long the labeling continues.

Factors affecting uptake and incorporation. With radioactive amino acids, high specific activity labeling can be obtained by omitting the unlabeled molecule from the medium (see UNIT 10.18). Labeling with radioactive sugars or other oligosaccharide precursors, however, is usually less efficient. Thus, incorporation into the glycoconjugate of interest must be optimized empirically, taking into consideration the following factors.

Experimental parameters. Amount of label, concentration of label in the medium, cell number, duration of labeling, and number of cell doublings during labeling are obviously important. The goal is to expose the maximum number of cells to the maximum amount of label in the minimum volume of medium for the longest period of time. Some of these factors are at odds with one another, and the correct balance must

be tailored to the particular cell type and the question being investigated.

Competition with glucose. When labeling using a radioactive monosaccharide precursor, it is important to determine whether the monosaccharide competes with glucose for uptake. The high concentration of glucose in normal tissue culture medium (~5 mM) means that monosaccharides competing with glucose for active transport cannot be taken up very well. Thus, lowering glucose concentration can improve uptake. On the other hand, monosaccharides that do not compete with glucose seem to be taken up only by inefficient noncompetitive, passive mechanisms; thus, glucose concentration has little effect upon their already poor uptake. Experience indicates that glucosamine, galactosamine, galactose, and mannose can compete with glucose for uptake into most cells, whereas *N*-acetylglucosamine, *N*-acetylmannosamine, mannosamine, fucose, and xylose do not (Yurchenco et al., 1978). However, members of the glucose transporter family of gene products are tissue-specific in expression; a given cell type may express more than one, each with distinctive kinetic and stereospecific uptake properties (Gould and Bell, 1990). Thus, each monosaccharide must be tested in the specific cell type under study to see if it competes with glucose. A final point that should be considered is that in some cell types, lipid-linked oligosaccharide precursors may become altered when glucose-free medium is used (Rearick et al., 1981).

Other intracellular metabolic factors. Dilution of label by endogenously synthesized monosaccharides, pool size of individual monosaccharides and nucleotides, and flux rates between interconverting pathways can all affect the final specific activity and distribution of the label. If cells are cultured in labeled medium for prolonged periods of time, the medium may become depleted of glucose (Kim and Conrad, 1976; Varki and Kornfeld, 1982). The specific activity of the labeled sugar nucleotides in the cells may then actually rise as the medium glucose concentration falls below the K_m of the cellular glucose transporter(s).

These factors must be considered in designing the labeling protocol, although they can be controlled only to a limited extent. The goal is to obtain sufficient label in the glycoconjugate of interest without significantly altering the metabolic state of the cell.

Metabolic labeling using nonmonosaccharide precursors. Acetylation, sulfation, and phosphorylation can significantly affect the behavior of oligosaccharides both in biological systems and during analysis. Labeled precursors such as [^3H]acetate, [^{35}S]sulfate, and [^{32}P]orthophosphate can be used to label these modified oligosaccharides. These

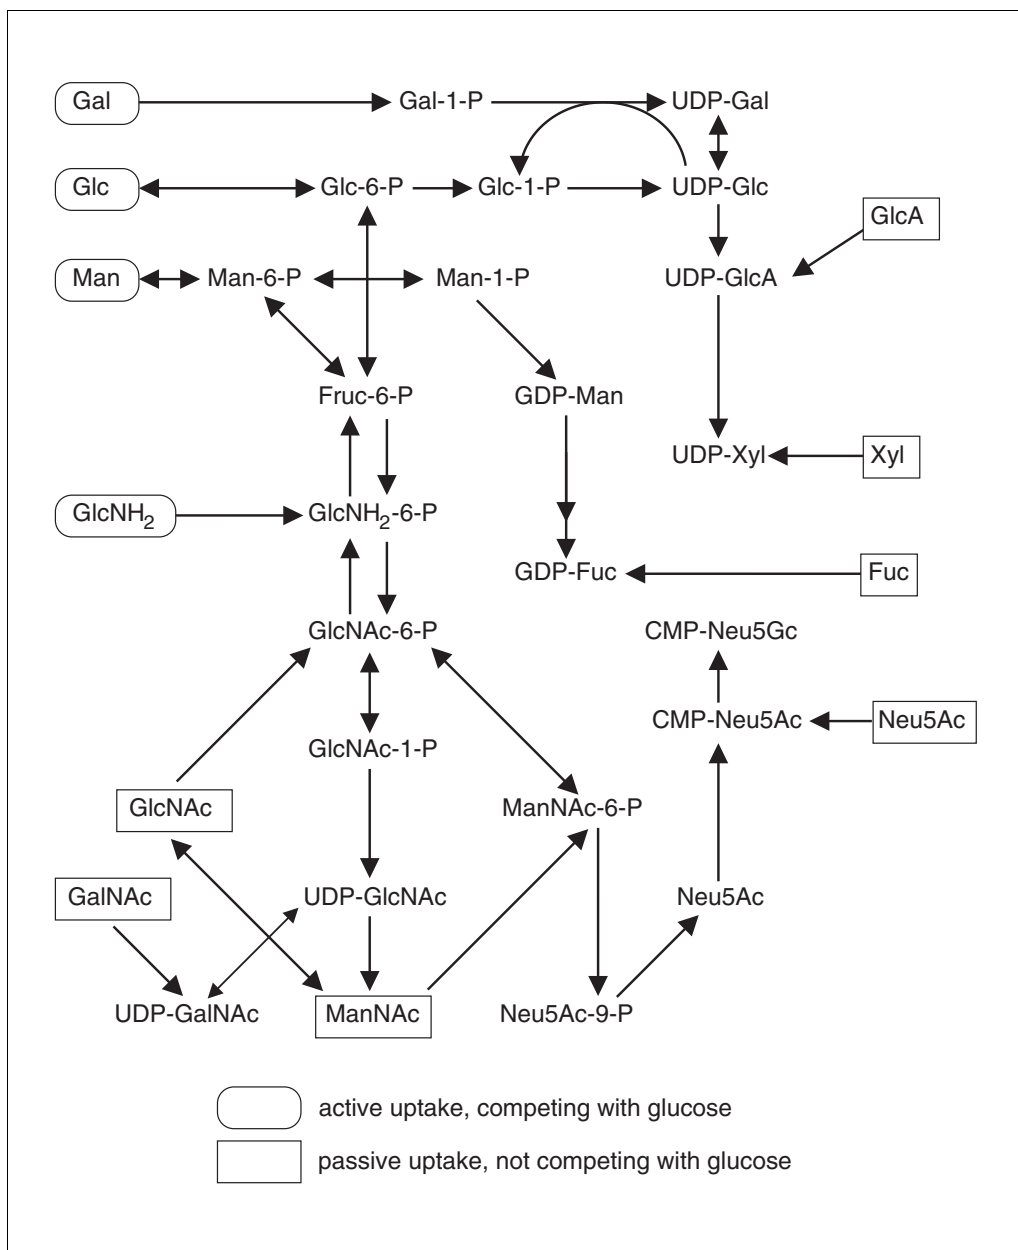

Figure 17.4.4 Cytosolic pathways for the interconversion of monosaccharides and their nucleotide sugar forms.

precursors are expected to enter a variety of other cellular macromolecules, and release and/or isolation of the labeled oligosaccharides with specific endoglycosidases is often required before further analysis. Double-labeling of both the modified oligosaccharide and the underlying sugar chain (e.g., with a ^{14}C - or ^3H -labeled monosaccharide precursor) can be quite useful in monitoring purification and in subsequent structural analysis. With [^{35}S]sulfate, labeling efficiency varies widely with cell type. In many cells, if the endogenous pool of the precursor 3'-phosphoadenosine-5'-phosphosulfate (PAPS) is very small, the specific activity of the exogenously added [^{35}S]sulfate can be practically unaltered inside the cell (Yanagishita et al., 1989). In some cell types, however, the endogenous sulfate pool is constantly diluted by breakdown of the sulfur-containing amino acids methionine and cysteine (Esko et al., 1986; Roux et al., 1988). In this situation, reducing the cysteine and methionine concentrations in the medium can improve incorporation of label into macromolecules (Roux et al., 1988). Sulfate levels can also be affected by certain antibiotics (e.g., gentamicin) that are sulfate salts.

Determining the specific activity of incorporated label

In most instances, the precise specific activity of each monosaccharide pool need not be determined. If steady-state labeling is attempted, a plateau in the rate of incorporation of label per milligram of cell protein can be taken as a rough indication that a steady state has been reached. In some cases, however, the precise specific activity of a given monosaccharide may be of interest. Discussions of how this can be determined can be found in Kim and Conrad (1976), Yurchenco et al. (1978), Yanagishita et al. (1989), and Varki (1991). Endogenous glucose is the normal precursor for hexoses and hexosamines (see Fig. 17.4.4). Experimental manipulations that alter the concentration of glucose can thus alter the concentration of the internal pool of other hexoses and hexosamines. Exogenously added labeled hexosamines become diluted within the cell, making specific radioactivity in the cell lower than that of the starting material.

With the advent of HPAE-PAD (High Performance Anion Exchange Chromatography with Pulsed Amperometric Detection), measurement of monosaccharide levels in the low picomole range is now possible. Thus, it is now feasible to measure the specific activity of a

labeled monosaccharide component of a purified oligosaccharide by acid hydrolysis of a portion of the oligosaccharide (UNIT 17.15) followed by HPAE-PAD. HPLC-based methods for accurate measurement of low quantities of sulfate are also now available.

Troubleshooting

Ideally, the radiochemical purity of the precursor should be checked using an appropriate chromatographic procedure (see UNIT 17.16). As with all tissue culture work, cells should be checked for mycoplasma infection (Strober, 1991b) before the experiments are carried out. If bacterial contamination poses a problem for long-term labeling experiments, appropriate antibiotics should be added to the medium.

Anticipated Results

Levels of incorporation will be highly variable, depending upon the cell type, the culture conditions, and the precursor used. If adequate incorporation into the glycoconjugate of interest is obtained, analyses can be carried out.

Time Considerations

Optimizing conditions for uptake and incorporation of label for each precursor and cell line combination (introductions to the first two protocols) may take one to two weeks, but should not be omitted: the time will be well-spent. The time required for the actual labeling protocols will vary widely depending on the goal of the experiment. Preparation of multiply deficient media can take an entire day, especially if some components must be prepared from scratch. If the amount required for a series of experiments is planned ahead of time, however, this need only be done occasionally. Reconstituting multiply deficient medium takes up to 1 hr (assuming all the stock solutions are already available).

Chemical Labeling of Carbohydrates by Oxidation and Sodium Borohydride Reduction

UNIT 17.5

This unit describes a collection of methods for chemical labeling of carbohydrates—free oligosaccharides or oligosaccharides conjugated to proteins, peptides, or lipids—by oxidation followed by reduction or by direct reduction. Oligosaccharides can be labeled with either radioisotopes or nonradioactive fluorescent molecules. These labelings allow one to follow the oligosaccharides during chromatography and in cells if labeled by fluorescent molecules.

Selective oxidation with mild periodate followed by reduction with tritiated sodium borohydride ($\text{NaB}[^3\text{H}]_4$) results in selective radiolabeling of sialic acid residues on oligosaccharides or glycoproteins (first basic protocol). Alternatively, treatment of samples with galactose oxidase (first alternate protocol) results in oxidation of galactose or *N*-acetylgalactosamine residues at nonreducing termini, rendering these residues susceptible to labeling with $\text{NaB}[^3\text{H}]_4$. Oxidized glycoconjugates can also be labeled using the fluorescent probe lucifer yellow CH (second alternate protocol). Free oligosaccharides can be labeled by reduction with $\text{NaB}[^3\text{H}]_4$ (second basic protocol). The third alternate protocol describes the release and simultaneous labeling of *O*-glycan oligosaccharides by alkaline beta-elimination in the presence of $\text{NaB}[^3\text{H}]_4$.

CAUTION: This procedure should be performed only by personnel trained in the proper use of ^3H isotope and in NRC-licensed sites. Standard precautions to prevent excessive exposure and radioactive contamination of personnel and equipment should be followed at all times.

CAUTION: All $\text{NaB}[^3\text{H}]_4$ manipulations must be performed in a well-vented fume hood.

RADIOLABELING OLIGOSACCHARIDES AFTER MILD PERIODATE OXIDATION

**BASIC
PROTOCOL**

This protocol describes radiolabeling oligosaccharides by mild periodate oxidation followed by reduction with $\text{NaB}[^3\text{H}]_4$, selectively labeling sialic acid residues at nonreducing termini. The reaction is illustrated in Figure 17.5.1. Labeled oligosaccharides are precipitated and separated from unincorporated label by gel-filtration chromatography.

Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

- Oligosaccharide or glycopeptide containing sialic acids, desalted
- 0.2 mM sodium periodate (prepare fresh at room temperature and keep on ice)
- 10 mM sodium acetate, pH 5.5
- 10 mM glycerol (store at 4°C)
- 0.2 M sodium borate buffer, pH 9.5 (UNIT 11.16; adjust quantities of boric acid and 10 M NaOH appropriately)
- 0.5 mCi/ μl tritiated sodium borohydride ($\text{NaB}[^3\text{H}]_4$; 25 to 30 Ci/mmol) in 0.01 M NaOH (see recipe)
- 0.2 M sodium borohydride (NaBH_4)/0.2 M sodium borate buffer, pH 9.5
- 1 M acetic acid in methanol
- Nitrogen (N_2) stream
- Methanol

**Preparation and
Analysis of
Glycoconjugates**

17.5.1

Supplement 26

Figure 17.5.1 Labeling oligosaccharides by periodate oxidation followed by $\text{NaB}[^3\text{H}]_4$ reduction.

7-ml conical glass (Pyrex) test tubes with Teflon-covered caps
 1.0 × 40-cm Sephadex G-15 or G-25 column in water (*UNIT 10.9*), calibrated to identify void volume
 25° to 30°C water bath

CAUTION: Steps 3 to 8 must be performed in a well-vented fume hood to prevent radioactive contamination. Excess $\text{NaB}[^3\text{H}]_4$ should be stored away in a radioactive waste bottle for appropriate disposal.

Label oligosaccharides

- Mix the following in a 7-ml conical glass test tube (200 μl total volume):
 - 5 to 500 μg oligosaccharide or glycopeptide
 - 100 μl 0.2 mM sodium periodate
 - 100 μl 10 mM sodium acetate.

Loosely cover with Teflon-covered cap and incubate 20 min on ice.

- Add 10 μl of 10 mM glycerol and incubate 20 min at 37°C.

The glycerol consumes any excess periodate that remains.

- Add 100 μl of 0.2 M sodium borate buffer and 10 μl of 0.5 mCi/ μl $\text{NaB}[^3\text{H}]_4$ (5 mCi). Incubate 1 hr at room temperature in a fume hood.
- Add 100 μl of 0.2 M NaBH_4 /0.2 M borate buffer and incubate 30 min at room temperature.

Destroy excess $\text{NaB}[^3\text{H}]_4$ and remove borate as methyl borate

- Add 3 ml of 1 M acetic acid in methanol and dry under a nitrogen stream in a 25° to 30°C water bath, in a well-vented hood.
- Repeat step 5.
- Add 3 ml methanol (without acetic acid) and dry sample as in step 5.

Purify labeled oligosaccharides

- Dissolve sample in ~200 μl water and apply to a calibrated $1.0 \times 40\text{-cm}$ Sephadex G-15 or G-25 column. Elute with water and collect 1-ml fractions with a fraction collector.

This step separates the labeled oligosaccharides from the low-molecular-weight breakdown products of $\text{NaB}[^3\text{H}]_4$.

- Count 10- μl aliquots of each fraction in a scintillation counter.
- Pool and dry fractions that contain radioactive oligosaccharides or glycopeptides. Store at -20°C until used (the label is stable for >12 months).

Oligosaccharides or glycopeptides should elute at or near the void volume, followed by a larger peak of breakdown products of $\text{NaB}[^3\text{H}]_4$. Be careful to avoid the second peak.

RADIOLABELING OLIGOSACCHARIDES AFTER GALACTOSE OXIDASE TREATMENT

ALTERNATE PROTOCOL

Oxidation with galactose oxidase and reduction with $\text{NaB}[^3\text{H}]_4$ specifically labels galactose and *N*-acetylgalactosamine residues that are located at nonreducing termini of oligosaccharides. Residues at internal positions are also oxidized and labeled, but much less efficiently. This reaction is illustrated in Figure 17.5.2. Sialic acid attached to galactose hinders oxidation by galactose oxidase. If desired, sialic acid can be removed by treating the sample with sialidase (neuraminidase).

Additional Materials

For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

- 1 U/ μl galactose oxidase (partially purified, Sigma; store aliquots in PBS at -20°C)
- 10 mM sodium phosphate buffer, pH 7.0
- 15-ml conical glass centrifuge tube

CAUTION: Steps 2 to 4 must be performed in a well-vented fume hood to prevent radioactive contamination.

Figure 17.5.2 Labeling oligosaccharides by galactose oxidase treatment followed by $\text{NaB}[^3\text{H}]_4$ reduction.

Preparation and Analysis of Glycoconjugates

17.5.3

1. Mix the following in a 15-ml conical centrifuge tube (110 μ l total volume):

50 to 500 μ g oligosaccharide or glycopeptide
10 μ l 1 U/ μ l galactose oxidase
100 μ l 10 mM sodium phosphate buffer.

Incubate 2 hr at 37°C.

Sialylated oligosaccharides or glycopeptides should be treated with sialidase (UNIT 17.12) before treatment with galactose oxidase because sialic acid hinders oxidation by galactose oxidase. If the sample is treated with sialidase, either the sample should be desalted or the volume of the galactose oxidase reaction should be increased to ensure that the pH is 7.0.

2. Add 100 μ l of 0.2 M sodium borate buffer and 10 μ l of 0.5 mCi/ μ l NaB[³H]₄ (5 mCi). Incubate 1 hr at room temperature in a fume hood.
3. Add 100 μ l of 0.2 M NaBH₄/0.2 M sodium borate buffer and incubate 1 hr at room temperature.
4. Acidify, dry, and purify labeled oligosaccharides or glycopeptides as in steps 5 to 10 of the first basic protocol.

ALTERNATE PROTOCOL

FLUORESCENCE LABELING OLIGOSACCHARIDES AFTER PERIODATE OR GALACTOSE OXIDASE TREATMENT

Following oxidation, oligosaccharide-containing samples may be labeled with the non-isotopic fluorescent probe lucifer yellow CH, instead of being radioactively labeled with NaB[³H]₄. This technique can be used to label oligosaccharides on glycopeptides or glycolipids. Labeled oligosaccharides are separated from unincorporated dye by gel-filtration chromatography.

Additional Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Phosphate-buffered saline (PBS; APPENDIX 2)

Lucifer yellow CH (Aldrich)

0.1 M sodium cyanoborohydride (NaBH₃CN)

0.5 \times 15-cm Sephadex G-15 and 1.0 \times 25-cm Sephadex G-25 columns in water (UNIT 10.9), calibrated

25°C water bath

Oxidize oligosaccharides

1. Oxidize oligosaccharide or glycopeptide sample (steps 1 to 2 of the first basic protocol or step 1 of the first alternate protocol).
2. Apply sample to a 0.5 \times 15-cm Sephadex G-15 column and elute with water. Collect 0.5-ml fractions.
3. Pool and dry fractions that contain the oxidized oligosaccharides or glycopeptides.
The appropriate fractions should be identified based on column calibration with glycopeptide standards (see UNIT 10.9). Oligosaccharides of glycopeptides elute at or near the void volume.
4. Dissolve sample in 100 μ l PBS.

Label oligosaccharides with fluorescent dye

5. Add lucifer yellow CH to 5 mM final concentration and incubate 12 hr at room temperature.
6. Apply reaction mixture to a 1.0 × 25-cm Sephadex G-25 column. Elute with water and collect 1-ml fractions. Wash until the unincorporated dye elutes.

Purify labeled oligosaccharides

7. Pool and dry fractions containing first fluorescent peak (labeled oligosaccharides).

It may be necessary to read UV absorbance or fluorescence of the eluted fractions, as fluorescence is not easily visible.

8. Dissolve sample in 0.1 ml of 0.1 M NaBH₃CN and incubate 15 min at 25°C. Immediately apply to the same Sephadex G-25 column used in step 6 and elute with water (avoid acidic conditions).
9. Collect, pool, and dry fluorescent oligosaccharides—i.e., the fractions at or near the void volume. Avoid light exposure as much as possible after this point.

Fractions that contain fluorescently labeled oligosaccharides or glycopeptides should elute in the void volume.

Remaining solutions should be discarded as toxic waste.

10. Dissolve sample in a minimal amount of water and store at –20°C until used.

RADIOLABELING FREE OLIGOSACCHARIDES

Free oligosaccharides can be obtained from Asn-linked oligosaccharides by hydrazinolysis (UNIT 17.15) or PNGaseF (*N*-glycanase) treatment (UNIT 17.13). In the following procedure, free oligosaccharides are purified by a simple gel filtration and then directly reduced with NaB[³H]₄. After reduction, the aldehyde group at C-1 of the reducing terminus becomes an alcohol with one radioactive tritium (see Fig. 17.5.2). Introduction of ³H at the reducing terminal allows the oligosaccharides to be followed by monitoring radioactivity.

Materials

*For recipes, see **Reagents and Solutions** in this unit (or cross-referenced unit); for common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.*

Free oligosaccharides (UNITS 17.15 & 17.12)

0.3 M sodium borate buffer, pH 9.5 (UNIT 11.16; adjust quantities of boric acid and 10 M NaOH appropriately)

0.5 mCi/μl tritiated sodium borohydride (NaB[³H]₄; 25 to 35 Ci/mmol) in 0.05 M NaOH (see recipe)

1 M sodium borohydride (NaBH₄)

1 M acetic acid in methanol

Nitrogen (N₂) stream

Methanol

7-ml conical glass (Pyrex) tubes

0.5 × 25-cm Sephadex G-25 or G-15 column (UNIT 10.9), calibrated to determine void volume

Additional reagents and equipment for gel-filtration chromatography (UNIT 10.9)

CAUTION: Steps 4 to 8 must be performed in a well-vented fume hood to prevent radioactive contamination.

BASIC PROTOCOL

Preparation and Analysis of Glycoconjugates

17.5.5

1. Desalt 1 to 500 µg free oligosaccharides by gel-filtration chromatography on a calibrated 0.5 × 25-cm Sephadex G-25 or G-15 column. Elute in water. Collect 0.5-ml fractions.

Oligosaccharides must be free from peptides or amino acids that may incorporate label during reduction.

2. Pool and dry fractions that contain free oligosaccharides. Dissolve in 50 µl water.
3. Add 0.3 M sodium borate buffer and water to a 100-µl final volume and a 0.2 M-sodium borate final concentration.

If oligosaccharides are dissolved in water, volume and concentration of buffer should be adjusted to give the desired final concentration.

4. Immediately add 10 to 20 µl of 0.5 mCi/µl NaB[³H]₄ in 0.05 M NaOH (5 to 10 mCi) and incubate 2 hr at room temperature in a fume hood.
5. Add 100 µl of 1 M NaBH₄ and incubate 2 hr at room temperature to complete the reduction.
6. Add 3 ml of 1 M acetic acid in methanol and dry under a nitrogen stream in a 30° to 35°C water bath.
7. Repeat step 6.
8. Add 3 ml methanol and dry under a nitrogen stream in a 30° to 35°C water bath.
9. Dissolve sample in 50 to 200 µl water and store at -70°C until used.

ALTERNATE PROTOCOL

RADIOLABELING O-GLYCAN OLIGOSACCHARIDES

During release from glycoproteins or glycopeptides by beta-elimination, the reducing termini of O-glycans can be labeled by alkaline borohydride treatment in the presence of a large amount of NaB[³H]₄. The reaction, however, must be carried out in the presence of 1 M NaBH₄ to prevent oligosaccharide degradation after release.

Additional Materials

For recipes, see Reagents and Solutions in this unit (or cross-referenced unit); for common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

100 to 1000 µg glycopeptides or ≤5 mg glycoproteins
0.1 to 0.2 mCi/µl tritiated sodium borohydride (NaB[³H]₄; 25 to 30 Ci/mmol) in
1 M NaBH₄/0.05 M NaOH (see recipe)
1 M acetic acid in methanol
Methanol
30° to 35°C and 45°C water baths

CAUTION: Steps 2 to 4 must be performed in a well-vented fume hood to avoid radioactive contamination.

1. Place 100 to 1000 µg glycopeptides or ≤5 mg glycoproteins in a 7-ml conical glass tube. Add 200 µl of 0.1 to 0.2 mCi/µl NaB[³H]₄ in 1 M NaBH₄/0.05 M NaOH (20 to 40 mCi). Incubate 24 to 48 hr at 45°C in a fume hood.

For larger amounts of sample, the volume of solution should be increased to dissolve sample completely and the amount of Na[³H]₄ should be increased to 100 mCi.

2. Add 3 ml of 1 M acetic acid in methanol and dry sample under a nitrogen stream in a 30° to 35°C water bath.

3. Repeat step 2.
4. Add 3 ml methanol and dry under a nitrogen stream in a 30° to 35°C water bath.
5. Dissolve sample in 100 to 200 µl water and store at -20°C until used.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Tritiated sodium borohydride (NaB[³H]₄), 0.5 mCi/µl

Dissolve 100 mCi NaB[³H]₄ (highest available specific activity, usually 25 to 35 Ci/mmol) in 200 µl ice-cold 0.01 or 0.05 M NaOH. Store in 10-µl aliquots for several months at -70°C until use. To make NaB[³H]₄ in 1 M NaBH₄/0.05M NaOH, dissolve solid NaBH₄ in tritiated solution in 0.05 M NaOH.

Alternatively, NaB[³H]₄ can be dissolved in freshly distilled anhydrous dimethylformamide and stored at -20°C in well-sealed tubes. Some investigators report stability for longer periods than with NaOH solutions.

COMMENTARY

Background Information

When sufficient quantities of purified glycoconjugates (e.g., glycoproteins or glycopeptides) are available, their sugar chains can be labeled and used for structural or sequence analysis (Morell and Ashwell, 1972; Takasaki and Kobata, 1978). These sugar chains can be radioactively labeled by periodate or enzymatic oxidation followed by reduction with tritiated sodium borohydride (NaB[³H]₄). Sialic acid residues can be preferentially oxidized by mild periodate oxidation because they contain *cis*-glycols in exocyclic carbons (Fig. 17.5.1). Such glycols are much more reactive with periodate than glycols in cyclic structures because of free rotation at C-8 and C-9. The aldehyde formed at C-7 or C-8 can be reduced by NaB[³H]₄ and radioactively labeled in the process (Fig. 17.5.1). Galactose oxidase treatment oxidizes galactose or *N*-acetylgalactosamine residues at the nonreducing termini, at C-6, forming aldehydes. The resultant aldehydes are reduced and labeled with NaB[³H]₄ (Fig. 17.5.2).

Oxidized samples can also be labeled with fluorescent molecules (Wilchek et al., 1980; Spiegel, 1987). After oxidation by periodate or galactose oxidase treatment, the sample is reacted with a fluorescent dye that contains a hydrazide group. After forming a Schiff base, the linkage can be stabilized by reduction. Once a fluorescent label is attached to an oligosaccharide, it can be detected by a fluorescence or UV detector. Fluorescence-tagged oligosac-

charides can be incubated with cells and incorporated oligosaccharides can be detected by fluorescence microscopy.

These methods have been used to examine the biological significance of oligosaccharide structures and their distribution on glycoconjugates. In one study, the structures of O-linked oligosaccharides were found to vary with the different maturation stages along a cell lineage (Fukuda et al., 1986). In another study, glycosylation of erythropoietin, which is essential for its function, was examined and compared with that of a recombinant erythropoietin (Sasaki et al., 1987).

Critical Parameters

There are two critical parameters for these procedures. First, it is essential that each reaction take place at the designated pH. If the pH of a reaction mixture is not properly adjusted, the reaction will not occur. Second, the quality of the NaB[³H]₄ added is critical. When NaB[³H]₄ is purchased, the reagent should be dark blue or slightly violet in color. When NaB[³H]₄ absorbs water and becomes degraded, it appears white and should not be used for labeling. Free oligosaccharides must be desalted by gel-filtration chromatography to remove salts, free amino acids, and peptides before chemical labeling.

An alternative method is to label the *N*-acetyl groups of *O*-glycans that have already been released from glycoproteins by alkaline beta-

elimination. The reduced *O*-glycans can be treated with hydrazine to remove *N*-acetyl groups and reacylated with radioactive acetic anhydride. This procedure is useful if anhydrous hydrazine is readily available (see Amano and Kobata, 1989).

Anticipated Results

Chemical labeling of carbohydrates by these procedures generally depends on the amount of samples available. For example, NaB[³H]₄ reduction of oligosaccharides is one of the most efficient methods to label oligosaccharides, but it still requires 0.05 to 0.1 μM for efficient labeling. Since NaB[³H]₄ reduction and fluorescence labeling are dependent on reactions with aldehyde groups, it is also an advantage to have a reasonable mass of sample, reducing the contribution from contaminants. Once there is a sufficient amount of sample, however, total radioactivity incorporated will allow many manipulations on radioactively labeled samples.

Time Considerations

In general, all procedures in this unit are simple and rapid. Each of the protocols described should take 1 or 2 days to finish.

Detection and Analysis of Proteins Modified by O-Linked N-Acetylglucosamine

UNIT 17.6

The modification of Ser and Thr residues with O-linked β -N-acetylglucosamine (O-GlcNAc) is a common, dynamic, and essential modification of nuclear and cytoplasmic proteins. O-GlcNAc is ubiquitous, having been identified in all complex eukaryotes studied, including filamentous fungi and plants. O-GlcNAc has been found on a diverse range of proteins including cytoskeletal proteins, nuclear pore proteins, RNA polymerase II (RNA Pol II), transcription factors, proto-oncogene products, tumor suppressors, hormone receptors, phosphatases, and kinases (Comer and Hart, 2000).

The functional consequences of modifying proteins with O-GlcNAc is unclear, but it is required for survival at the single-cell level (Shafi et al., 2000). Three features suggest that O-GlcNAc performs a regulatory role: (1) O-GlcNAc occurs at sites on the protein backbone that are similar to those modified by protein kinases; (2) O-GlcNAc is reciprocal with phosphorylation on some well-studied proteins, such as RNA Pol II, estrogen receptor- β , SV40 large T-antigen, and the *c-Myc* proto-oncogene product; and (3) like phosphorylation, O-GlcNAc is highly dynamic, with rapid cycling in response to cellular signals or cellular stages. Perturbations in the metabolism of GlcNAc, which alter the regulation of many O-GlcNAc proteins, have been implicated in Alzheimer's disease, diabetes, and cancer (Wells et al., 2001).

This unit concentrates on techniques for the detection and analysis of proteins modified by O-GlcNAc, as well as methods for the analysis of enzymes responsible for the addition and removal of O-GlcNAc. We have focused on methods that require standard laboratory equipment. However, in some cases we also discuss more specialized technology.

The unit is set out in a stepwise manner. First, a protocol for increasing the stoichiometry of O-GlcNAc on proteins is given (see Basic Protocol 1). This is followed by simple techniques for the detection/screening of O-GlcNAc modified proteins either by western blotting or lectin affinity chromatography (see Basic Protocols 2 to 4). Separate protocols verify that the glycan is O-linked GlcNAc (see Support Protocols 1 and 2). These methods are followed by protocols for more comprehensive analysis of O-GlcNAc modified proteins, including labeling of O-GlcNAc residues with [3 H]Gal, and subsequent product analysis (see Alternate Protocol 1, see Basic Protocols 5 to 8, and see Support Protocols 3 and 4). The final two protocols assay for O-GlcNAc transferase and O-GlcNAcase activity, respectively (see Basic Protocols 9 and 10 and Support Protocol 5).

INCREASING THE STOICHIOMETRY OF O-GlcNAc ON PROTEINS BEFORE ANALYSIS

**BASIC
PROTOCOL 1**

In many cultured mammalian cells, the number of O-GlcNAc moieties per protein molecule can be increased by treating cells with O-(2-acetamido-2-deoxy-D-gluco-pyranosylidene)-amino-N-phenyl-carbamate (PUGNAc), a potent and cell-permeable inhibitor of O-GlcNAcase (Haltiwanger et al., 1998). Alternatively, streptozotocin (STZ; Roos et al., 1998) and glucosamine (Han et al., 2000) have been used to increase the stoichiometry of O-GlcNAc on proteins. However, STZ has been shown to induce poly-(ADP-ribose) polymerase-mediated apoptosis in Min6 cells (Gao et al., 2000) and should be used with caution. In addition, STZ is only effective in cells that express the glucose transporter GLUT-2 (Schnedl et al., 1994).

**Preparation and
Analysis of
Glycoconjugates**

Materials

Cells of interest growing in monolayer culture, and appropriate culture medium
20 mM PUGNAc (CarboGen Laboratories) stock in Milli-Q water (filter sterilize and store in aliquots up to 6 to 12 months at -80°C)
500 mM glucosamine stock in 500 mM HEPES, pH 7.5 (make just prior to use; filter sterilize)
500 mM streptozotocin (STZ; Sigma) in 100 mM citrate buffer, pH 4.5 (make just prior to use; filter sterilize)
100-mm tissue culture dishes

1. Grow cells in monolayer culture in a sufficient number of 100-mm dishes.
2. Add (or replace growth medium with fresh medium containing) 40 to 100 μM PUGNAc (added from 20 mM stock), 5 mM glucosamine (added from 500 mM stock), or 2 to 5 mM STZ (added from 500 mM stock). Incubate cells in an incubator for 6 to 18 hr.

PUGNAc is taken up by both dividing and stationary cells.

If necessary, cells can be treated by PUGNAc for several days without any apparent cell toxicity. However, prolonged treatment does not appear to result in additional increase in O-GlcNAc compared to the 6 to 18 hr treatment.

When using glucosamine, mannitol is often added at the same concentration. This controls for changes in osmolarity due to the additional sugar in the medium (Heart et al., 2000).

3. At the end of treatment, take the dishes out of the incubator and place on ice. Extract as desired. Separate proteins by SDS-PAGE (UNIT 10.2A) and electroblot onto appropriate membrane (UNIT 10.8).

Alternatively, extract proteins and proceed with protein purification (UNITS 10.9-10.14) or immunoprecipitation (UNIT 10.16).

BASIC PROTOCOL 2

DETECTION OF PROTEINS MODIFIED BY O-GlcNAc USING ANTIBODIES

Recently Comer et al. (2001) showed that an antibody (CTD 110.6) raised against the glycosylated C-terminal domain of the RNA polymerase II large subunit was a general O-GlcNAc antibody. Unlike many lectins, CTD 110.6 shows little cross-reactivity toward terminal GlcNAc on complex glycans. Several other antibodies, HGAC 85 (Turner et al., 1990) and RL2 (Snow et al., 1987), have been reported as O-GlcNAc specific antibodies. However, these antibodies only recognize a subset of O-GlcNAc modified proteins, and RL2 in particular is dependent on the structure of the peptide backbone around the glycosylation site (Holt et al., 1987).

It is important to include an appropriate negative control (100 ng ovalbumin) for cross-reactivity toward N-linked glycans. Using the standard Amersham Pharmacia Biotech enhanced chemiluminescent (ECL) system, the authors have found that 10 μg of cytoplasmic, nuclear, or total cell extract is sufficient. For purified proteins, Comer and co-workers found that 25 to 50 ng of a neoglycoconjugate was sufficient (Comer et al., 2001).

Materials

Purified or crude protein (e.g., Basic Protocol 1) separated by SDS-PAGE (UNIT 10.2A) and electroblotted to polyvinylidene difluoride (PVDF; UNIT 10.8) or nitrocellulose (duplicate blots are needed)
TBS-HT (see recipe)

Antibody: CTD 110.6 ascites (Covance) diluted 1/2500 in TBS-HT (see recipe for TBS-HT)

N-acetylglucosamine (GlcNAc; Sigma)

HRPO-conjugated anti-mouse IgM diluted 1/5000 in TBS-HT

TBS-HD (see recipe)

ECL kit (Amersham Pharmacia Biotech)

Additional reagents and equipment for visualization with chromogenic and luminescent substrates (UNIT 10.8)

1. Block blots by incubating with TBS-HT for 60 min at room temperature.

Batteiger et al. (1982) have shown that high concentrations of Tween 20 substitute for blocking with milk or bovine serum albumin (BSA).

2. Incubate blots with CTD 110.6 (1/2500 dilution in TBS-HT), in duplicate, with and without 10 mM GlcNAc, overnight at 4°C.

To control for specificity it is important to perform a control blot. Here, the antibody is preincubated with 10 mM GlcNAc for ~5 min on ice before being applied to the control blot. Note that the concentration of antibody should be optimized with each new preparation. We find that 1/2500 is a good place to start with ascites (containing antibody in the mg/ml range).

3. Wash blots in TBS-HD twice, each time for 10 min at room temperature.

As the blots are washed under these conditions, prestained markers will fade. This does not appear to be the result of proteins being solubilized off the membranes, but of the dye used to stain the markers. While the markers fade, they do not completely disappear. The authors usually double the amount of marker used to compensate for fading.

4. Wash blots in TBS-HT three times, each time for 10 min, room temperature.

5. Incubate blots with HRPO-conjugated anti-mouse IgM (1/5000 dilution in TBS-HT) for 50 min, room temperature.

The concentration of secondary antibody varies from lot to lot and should be optimized each time with each new preparation.

6. Wash blots in TBS-HD twice, each time for 10 min, room temperature.

7. Wash blots in TBS-HT three times, each time for 10 min, room temperature.

8. Develop the HRPO reaction using, e.g., the ECL system (UNIT 18.4).

Note that the antibody often cross-reacts with pre-stained markers.

DETECTION OF PROTEINS MODIFIED BY O-GlcNAc USING THE LECTIN sWGA

Many lectins are reportedly specific for β -GlcNAc residues. The authors have typically used succinylated wheat germ agglutinin (sWGA), which is widely available and is derivatized with a number of useful functional groups including horseradish peroxidase (HRPO). Before succinylation, WGA will recognize both sialic acid and GlcNAc (Monsigny et al., 1980). For additional information concerning lectin chromatography, see UNIT 17.1.

The amount of “test” protein used is dependent on the technique(s) used to develop the HRPO reaction. Using the standard Amersham Pharmacia Biotech ECL system the authors find that 7.5 μ g of cytoplasmic or nuclear extract is sufficient.

BASIC PROTOCOL 3

Preparation and Analysis of Glycoconjugates

17.6.3

It is important to include an appropriate positive (100 ng ovalbumin) and negative (100 ng of BSA) control. As a control, a portion of the sample should also be treated with hexosaminidase (see Support Protocol 2), to show that reactivity is toward GlcNAc. In addition, the sample should be subjected to reductive β -elimination to verify that lectin/antibody reactivity is towards O-linked glycans (see Support Protocol 1).

Materials

Purified or crude protein separated by SDS-PAGE (UNIT 10.2A) and electroblotted to polyvinylidene difluoride (PVDF; UNIT 10.8) or nitrocellulose (duplicate blots are needed)

5% (w/v) BSA in TBST (see recipe for TBST)

TBST (see recipe)

0.1 μ g/ml HRPO-conjugated sWGA (EY Labs) in TBST (see recipe for TBST): the lectin can be stored at 1 mg/ml in 0.01 M PBS, pH 7.4 (APPENDIX 2), at -20°C for at least 1 year

N-acetylglucosamine (GlcNAc; Sigma)

High-salt TBST (HS-TBST): TBST (see recipe) containing 1 M NaCl

Tris-buffered saline (TBS; see recipe)

ECL kit (Amersham Pharmacia Biotech)

Additional reagents and equipment for visualization with chromogenic and luminescent substrates (UNIT 10.8)

1. Wash duplicate blots for 10 min in 5% BSA/TBST, room temperature.
2. Block by incubating blots in 5% (w/v) BSA/TBST for at least 60 min at room temperature.

IMPORTANT NOTE: Milk cannot be used as the blocking agent, since many of the proteins in milk are modified by glycans that react with sWGA.

3. Wash blots three times, each time for 10 min in TBST, room temperature.
4. Incubate blots in 0.1 μ g/ml sWGA-HRPO in TBST, in duplicate, with and without 1 M GlcNAc, overnight at 4°C .

To control for lectin specificity it is important to perform a control blot. Here, the lectin is preincubated with 1 M GlcNAc for ~ 5 min on ice before being applied to the control blot.

5. Wash blots six times, each time for 10 min, in HS-TBST.
6. Wash blots once in TBS for 10 min.
7. Develop the HRPO-reaction using, e.g., the the ECL system (UNIT 10.8).

Using the ECL system described, 100 ng of ovalbumin should be visualized in 5 to 15 sec.

CONTROL FOR O-LINKED GLYCOSYLATION

Traditionally, mild alkaline reduction (reductive β -elimination) has been used to release O-linked carbohydrates from proteins (Amano and Kobata, 1990). This method has been adapted for blots to show that lectin/antibody reactivity is toward O-linked rather than N-linked glycans (Duk et al., 1997). Proteins blotted to PVDF are treated with 55 mM NaOH overnight (releasing O-linked sugars) and then probed using lectins or antibodies.

There are a number of reasons why lectin/antibody reactivity could be lost after NaOH treatment, e.g., the sugars were destroyed instead of being released, or the protein was degraded. To control for these, it is important to have control proteins with N- and O-linked sugars, and to stain one blot for protein after treatment preferably with an antibody. The

SUPPORT PROTOCOL 1

Detection and Analysis of Proteins Modified by O-Linked N- Acetylglucosamine

17.6.4

authors suggest a control blot of bovine asialofetuin (Sigma) which contains both N- and O-linked sugars terminating in GlcNAc, treated and not treated with PNGase F (*UNIT 17.13A*).

Materials

Protein samples and controls blotted to PVDF (triplicate blots are needed; nitrocellulose is not suitable as it dissolves in 55 mM NaOH)

Tris-buffered saline (TBS; see recipe)

55 mM NaOH

3% (w/v) BSA in TBST (see recipe for TBST)

40°C water bath

Additional reagents and equipment for probing protein blots with protein-specific antibodies (see Basic Protocol 2) or lectins (see Basic Protocol 3)

1. Wash blots once in TBS for 10 min.
2. Incubate two blots in 55 mM NaOH at 40°C overnight; incubate the control blot in Milli-Q water at 40°C overnight.

The blots treated with NaOH will yellow slightly.

3. Wash blots three times, each time for 10 min at room temperature, in TBST.
4. Block by incubating blots in 3% w/v BSA/TBST for 60 min at room temperature.
5. Probe blots (one treated and one untreated) with carbohydrate-specific lectins (see Basic Protocol 3) or antibodies (see Basic Protocol 2). Probe the second NaOH-treated blot with a protein-specific antibody (see Basic Protocol 2).

On the untreated blot, asialofetuin ± PNGase F should react with sWGA, as both the N- and O-linked sugars contain terminal GlcNAc residues. On the treated blot only the asialofetuin – PNGase F should react with sWGA.

DETECTION AND ENRICHMENT OF PROTEINS USING sWGA-AGAROSE

sWGA lectin affinity chromatography provides a convenient method for enriching and detecting O-GlcNAc modified proteins. This procedure has been adapted for detecting proteins that are difficult to purify or are present in low copy number, such as transcription factors. In this protocol, the protein of interest is synthesized in a rabbit reticulocyte lysate (RRL) *in vitro* transcription translation (ITT) system (Promega) and labeled with either [³⁵S]Met, [³⁵S]Cys, or [¹⁴C]Leu. After desalting, the proteins are tested for their ability to bind sWGA agarose in a GlcNAc-specific manner (Roquemore et al., 1994).

Alternatively, the lectin *Ricinus communis* agglutinin 1 (RCA1) has been used to select for O-GlcNAc proteins that have previously been labeled by galactosyltransferase (see Alternate Protocol 1). Proteins modified by terminal Gal are specifically retained on a RCA1 affinity column. Labeled O-GlcNAc proteins are released under mild conditions, while those containing N-linked structures require lactose addition to the buffer before elution results (Hayes et al., 1995; Greis and Hart, 1998). The method described in this protocol can be adapted for RCA1 affinity chromatography by substituting RCA1-agarose (EY Labs) for sWGA-agarose and changing the order of the Gal and GlcNAc elution buffer.

Materials

cDNA subcloned into an expression vector with an SP6 or T7 promoter (~0.5 to 1 µg/µl)

Kit for RRL ITT system (Promega)

BASIC PROTOCOL 4

Preparation and Analysis of Glycoconjugates

17.6.5

Label: [³⁵S]Met, or [³⁵S]Cys, or [¹⁴C]Leu
sWGA-agarose (Vector Laboratories)
sWGA wash buffer: PBS (APPENDIX 2) containing 0.2% (v/v) NP-40
sWGA Gal elution buffer (see recipe)
sWGA GlcNAc elution buffer (see recipe)
1-ml tuberculin syringe with glass wool plug at bottom to support chromatography matrix or Bio-Rad Bio-Spin disposable chromatography column
Additional reagents and equipment for digesting proteins with hexosaminidase (see Support Protocol 2), desalting (see Support Protocol 5), SDS-PAGE (UNIT 10.2A), and autoradiography (APPENDIX 3A)

Prepare proteins

1. Synthesize proteins to incorporate the desired label ([³⁵S]Met, [³⁵S]Cys, or [¹⁴C]Leu) using the RRL ITT system according to the manufacturer's instructions. Include the protein of interest, a positive control for sWGA binding (for example, the nuclear pore protein p62), a negative control (luciferase, supplied with kit), and a no-DNA control.
2. Treat half of each sample with hexosaminidase (see Support Protocol 2).
3. Desalt samples using spin filtration (e.g., Amersham Pharmacia Biotech Microspin G-50 columns) or a 1-ml G-50 desalting column (as for desalting O-GlcNAc transferase; see Support Protocol 5).

The following procedure is carried out at 4°C.

Apply protein samples to chromatography columns

4. Equilibrate sWGA-agarose and pack column as follows:
 - a. If resin is supplied as 50% slurry (i.e., 50% resin/50% storage solution) remove 300 µl (double the volume required) and pipet into a 1-ml tuberculin syringe or disposable chromatography column.
 - b. Let storage solution drain from resin.
 - c. Equilibrate resin by washing column four times, each time with 1 ml of sWGA wash buffer. Cap column.

The volumes given are appropriate for a sample derived from an ITT. For enrichment of other protein samples, the volume of sWGA should be optimized for the protein sample applied. The authors find that 50 mg of cell extract requires 1 ml of sWGA-agarose, assuming that 1% to 2% of the total cell extract is modified by O-GlcNAc.

5. Apply sample (~30 µl of an ITT reaction) to the column and let stand at 4°C for 30 min, or cap and incubate at 4°C for 30 min with rotating or rocking.

Wash column and elute GlcNAc

6. At the end of the 30-min incubation, uncap the column and allow the sample to "run through" the resin. Collect this as the "run through" fraction. Wash column with 15 ml of sWGA wash buffer at 10 ml/hr, collecting 0.5-ml fractions.
7. Load the column with 300 µl of sWGA Gal elution buffer and let stand at 4°C for 20 min.
8. Wash column with 5 ml of sWGA Gal elution buffer, collecting 0.5 ml fractions.
9. Repeat steps 6 to 8 using GlcNAc elution buffer.
10. Count 25 µl of each fraction using a liquid scintillation counter.

11. Pool positive fractions that elute in the presence of GlcNAc and precipitate using TCA or methanol.

To precipitate proteins with methanol, mix 1 vol of sample with 10 vol of ice-cold methanol. Incubate overnight at -20°C . Recover protein by microcentrifuging 10 min at $16,000 \times g$, 4°C , in a microcentrifuge tube (which is the most efficient procedure) or in 15-ml conical centrifuge tubes for 10 min at $3000 \times g$, 4°C . Resuspend samples in SDS-PAGE sample buffer (UNIT 10.2A).

As many proteins in rabbit reticulocyte lysate contain O-GlcNAc and bind WGA, the authors do not recommend the addition of carrier proteins at this point. Typically, a fraction of the GlcNAc elution containing a total of 1000 to 2000 dpm [^{35}S]Met is precipitated and analyzed by SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

The use of acetone to precipitate proteins is not recommended, as free GlcNAc will also precipitate.

12. Analyze pellet by SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

DIGESTION OF PROTEINS WITH HEXOSAMINIDASE

Terminal GlcNAc and O-GlcNAc can be removed from proteins using commercially available hexosaminidases; these enzymes will also cleave terminal GalNAc residues. Unlike O-GlcNAcase, commercial hexosaminidases have low pH optima, typically pH 4.0 to 5.0.

Materials

Protein sample for digestion (include a positive control, e.g., ovalbumin)
2% (w/v) SDS
2 \times hexosaminidase reaction mixture (see recipe)

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and electroblotting (UNIT 10.8)

1. Mix sample 1:1 with 2% SDS and boil for 5 min.
2. Mix sample 1:1 with 2 \times hexosaminidase reaction mixture and incubate at 37°C for 4 to 24 hr.
3. To assess completeness of the digestion, separate an aliquot of the reaction by SDS-PAGE (UNIT 10.2A) and electroblot (UNIT 10.8) onto an appropriate membrane. Probe blots with carbohydrate-specific lectins or antibodies.

DETECTION OF PROTEINS MODIFIED BY O-GlcNAc USING GALACTOSYLTRANSFERASE

The enzyme β -1,4-galactosyltransferase (from bovine milk) will label any terminal GlcNAc residue with Gal, using uridine diphospho-D-Gal (UDP-Gal) as a donor substrate (Brew et al., 1968). Hart and colleagues have exploited this property, using the enzyme to label terminal GlcNAc residues on proteins with [^3H]Gal, forming a [^3H]- β Gal1-4 β GlcNAc (Torres and Hart, 1984; Roquemore et al., 1994; Greis and Hart, 1998). The labeled sugar can be chemically released (via β -elimination) and analyzed by size-exclusion chromatography on a BioGel-P4 column, using the ^3H radiolabel to detect the fraction of interest (Roquemore et al., 1994). Labeling the O-GlcNAc allows for the subsequent detection of the proteins and peptides of interest during SDS-PAGE, HPLC, protease digestion, and Edman degradation steps. Researchers have been able to identify glycosylation sites on as little as 10 pmol using these methods (Greis et al., 1996).

SUPPORT PROTOCOL 2

ALTERNATE PROTOCOL 1

Preparation and Analysis of Glycoconjugates

17.6.7

To achieve efficient labeling of some proteins, it is necessary to denature samples, for example by boiling in the presence of 10 mM DTT and 0.5% (w/v) SDS. Galactosyltransferase has been shown to be active in solutions containing 5 mM DTT, 0.5 M NaCl, up to 2% (v/v) Triton X-100, up to 2% (v/v) NP-40, and 1 M urea. Up to 0.5% (w/v) SDS can be used, if it is titrated with a 10-fold molar excess of either Triton X-100 or NP-40 in the final reaction mixture. Digitonin, which is commonly used to solubilize cells, should be used with caution, as it is a substrate for galactosyltransferase. The total ionic strength should be less than 0.2 M.

Galactosyltransferase requires 1 to 5 mM Mn^{2+} for activity, but is inhibited by Mg^{2+} and concentrations of Mn^{2+} >20 mM. EDTA (or analogs) should be avoided unless titrated with appropriate levels of Mn^{2+} . Note that 1 mol of EDTA binds 2 mol of Mn^{2+} .

Free UDP is also an inhibitor of galactosyltransferase. For studies where complete labeling of the GlcNAc is preferable, such as site mapping, calf intestinal alkaline phosphatase is included in the reaction, as it degrades UDP (Unverzagt et al., 1990). While this increases the efficiency of the reaction, it is important to add this to the control as some preparations of alkaline phosphatase contain proteins that will label with galactosyltransferase (R.N. Cole, pers. commun.).

NOTE: Protease inhibitors, such as PIC 1, PIC 2, and PMSF (see recipe for 1000× protease inhibitors in Reagents and Solutions), can be included (final concentrations, 1×), but GlcNAc and 1-amino GlcNAc should be removed prior to labeling by spin filtration or another method of desalting.

Materials

Protein sample(s)
Dithiothreitol (DTT)
Sodium dodecyl sulfate (SDS)
Label: 1.0 mCi/ml UDP-[³H]Gal, (17.6 Ci/mM; Amersham Pharmacia Biotech) in 70% v/v ethanol
Nitrogen source
25 mM 5'-adenosine monophosphate (5'-AMP), in Milli-Q water, pH 7.0
Buffer H (see recipe)
10× galactosyltransferase labeling buffer (see recipe)
Galactosyltransferase, autogalactosylated (see Support Protocol 3)
Calf intestinal alkaline phosphatase
Unlabeled UDP-Gal
Stop solution: 10% (w/v) SDS/0.1 M EDTA

100°C water bath
30 × 1-cm Sephadex G-50 column equilibrated in 50 mM ammonium formate/0.1% (w/v) SDS

Additional reagents and equipment for acetone precipitation of protein (*UNIT 17.10A*), PNGase F digestion of proteins (*UNIT 17.13A*), SDS-PAGE (*UNIT 10.2A*), and product analysis (see Basic Protocol 6)

Prepare the reaction

1. Denature protein sample by adding DTT to 10 mM and SDS to 0.5% (w/v), then boiling the sample for 10 min.
2. Decide how many reactions are going to be carried out and thus how much label will be needed (~1 to 2 μ Ci/reaction).

A positive control (ovalbumin, 2 µg), a negative control (because galactosyltransferase can label itself), and a sample-minus-enzyme control will be needed.

3. Remove solvent from label in a Speed-Vac evaporator or under a stream of nitrogen.

Ethanol can inhibit the galactosyltransferase reaction, but if <4 µl is required the label can be added directly to the reaction (final reaction volume, 500 µl).

4. Resuspend appropriate amount of label for each reaction, respectively, in 50 µl of 25 mM 5'-AMP.

The AMP is included to inhibit possible phosphodiesterase reactions, which might compete for label during the labeling experiment.

5. Set up reactions as follows:

Up to 50 µl protein sample (final concentration 0.5 to 5 mg/ml)
350 µl buffer H
50 µl 10× galactosyltransferase labeling buffer
50 µl UDP-[³H]Gal/5'-AMP mixture from step 4
30 to 50 µl autogalactosylated galactosyltransferase
1 to 4 U calf intestinal alkaline phosphatase
Milli-Q water to final volume of 500 µl

Reaction volumes can be scaled down to 50 µl.

6. Labeling at 37°C for 2 hr or at 4°C overnight.

These are the typical conditions. Galactosyltransferase is active over a range of temperatures.

7. Add unlabeled UDP-Gal to a final concentration of 0.5 to 1.0 mM and another 2 to 5 µl of galactosyltransferase.

For studies where complete labeling of the GlcNAc is required, such as site mapping, the reactions are chased with unlabeled UDP-Gal and fresh galactosyltransferase.

8. Add 50 µl of stop solution to each sample and heat to 100°C for 5 min in a water bath.

Isolate the product

9. Resolve the protein from unincorporated label using a Sephadex G-50 column equilibrated in 50 mM ammonium formate/0.1% w/v SDS. Collect 1-ml fractions.

Size-exclusion chromatography using Sephadex G-50 is traditionally used to desalt samples. However, TCA precipitation, spin filtration/buffer exchange, or other forms of size-exclusion chromatography (e.g., Pharmacia PD-10 desalting column) can be used. The addition of carrier proteins such as BSA (~67 kDa) and cytochrome c (~12.5 kDa) to samples and buffers will reduce the amount of protein lost due to nonspecific protein adsorption.

10. Count a 50-µl aliquot of each fraction using a liquid scintillation counter.

Approximately 2×10^6 dpm of [³H]Gal should be incorporated into 2 µg of ovalbumin.

11. Combine the void volume and lyophilize to dryness.

12. Resuspend samples in Milli-Q water and precipitate with acetone (UNIT 17.10A).

13. Treat samples with PNGase F (UNIT 17.13A), separate by SDS-PAGE (UNIT 10.2A) and detect by autoradiography (APPENDIX 3A). Alternatively, subject samples to “product analysis” to confirm that the label was incorporated onto O-GlcNAc (see Basic Protocol 6).

AUTOGALACTOSYLATION OF GALACTOSYLTRANSFERASE

As galactosyltransferase contains N-linked glycosylation sites, it is necessary to block these before using this enzyme to probe other proteins for terminal GlcNAc.

Materials

- 10× galactosyltransferase labeling buffer (see recipe)
- 10,000 U/ml aprotinin
- 2-mercaptoethanol
- UDP-Gal
- Saturated ammonium sulfate: >17.4 g (NH₄)₂SO₄ in 25 ml Milli-Q water
- 85% ammonium sulfate: 14 g (NH₄)₂SO₄ in 25 ml Milli-Q water
- Galactosyltransferase storage buffer (see recipe)
- 30- to 50-ml centrifuge tubes
- Refrigerated centrifuge

1. Resuspend 25 U of galactosyltransferase in 1 ml of 1× galactosyltransferase labeling buffer.
2. Transfer sample to 30- to 50-ml centrifuge tube.
The centrifuge tubes should be able to withstand a centrifugal force of 15,000 × g.
3. Remove a 5-μl aliquot for an activity assay.
This is the “Pre-Gal” sample to be used in Support Protocol 4.
4. Add 10 μl of 10,000 U/ml aprotinin, 3.5 μl of 2-mercaptoethanol, and 1.5 to 3.0 mg of UDP-Gal.
5. Incubate the sample on ice for 30 to 60 min.
6. Add 5.66 ml of prechilled saturated ammonium sulfate in a dropwise manner. Incubate on ice for 30 min.
7. Centrifuge 15 min at >10,000 × g, 4°C. Pour off supernatant.
8. Resuspend pellet in 5 ml cold 85% ammonium sulfate and incubate on ice for 30 min.
9. Centrifuge 15 min at >10,000 × g, 4°C, and pour off supernatant.
10. Resuspend pellet in 1 ml of galactosyltransferase storage buffer and divide into 50-μl aliquots, saving 5 μl for an activity assay as the “Auto-Gal” sample. Assay that aliquot for activity (see Support Protocol 4).
11. Store remaining aliquots up to 1 year at –20°C pending use in Alternate Protocol 1.

ASSAY OF GALACTOSYLTRANSFERASE ACTIVITY

As sample and activity may be lost during the autogalactosylation procedure, it is important to assess the activity of the enzyme.

Materials

- 1.0 mCi/ml UDP-[³H]Gal, (17.6 Ci/mM; Amersham Pharmacia) in 70% v/v ethanol
- Nitrogen source
- 1× galactosyltransferase dilution buffer: galactosyltransferase storage buffer (see recipe) supplemented with 5 mg/ml BSA
- 10× galactosyltransferase labeling buffer (see recipe)

25 mM 5'-adenosine monophosphate (5'-AMP) in Milli-Q water, pH 7.0
 "Pre-Gal" sample aliquot (see Support Protocol 3, step 3) and "Auto-Gal" sample aliquot (see Support Protocol 3, step 10)
 200 mM GlcNAc
 Dowex AG1-X8 resin (PO₄ form) slurry in 20% (v/v) ethanol
 Glass wool

1. Dry 40 µl of 0.1 µCi/µl of UDP-[³H]Gal in a Speed-Vac evaporator or under a stream of nitrogen.
2. Resuspend in 90 µl of 25 mM 5'-AMP.
3. Make 1/1000, 1/10,000, and 1/100,000 serial dilutions of the "Pre-Gal" and "Auto-Gal" sample aliquots, in 1× galactosyltransferase dilution buffer. Using these dilutions, 200 mM GlcNAc, and 10× galactosyltransferase labeling buffer, prepare reaction mixtures as described in Table 17.6.1.
4. Start the reaction by adding 10 µl of 0.05 µCi/µl UDP-[³H]Gal (see step 2) to each tube.
5. Incubate samples at 37°C for 30 min.
While the samples are incubating, prepare the columns.
6. Pour 1 ml of Dowex AG1-X8 slurry (PO₄ form) into 13 Pasteur pipets, each plugged with a small amount of glass wool.
The glass wool prevents the resin from flowing out of the column. If too much glass wool is used, it will reduce the flow rate of the column. The glass wool plug should be 0.3 to 0.5 mm long and should not be over-compressed.
7. Wash with at least 3 ml of Milli-Q water. Do not let the columns run dry.
8. When almost all the Milli-Q water has eluted, place each column over a separate 15-ml scintillation vial.
9. Stop the reaction (still incubating from step 5) by adding 500 µl of Milli-Q water.
10. Load each sample onto the corresponding column and add a 500 µl water wash of the tube. Collect eluate as fraction A.
11. Elute with two 1-ml additions of Milli-Q water. Collect eluates as fractions B and C, respectively.

Table 17.6.1 Reaction Mixtures for Assay of Galactosyltransferase Activity

Sample	Dilution	Vol. (µl) of diluted sample	Vol. (µl) of 200 mM GlcNAc	Vol. (µl) 10× Gal labeling buffer	Vol. (µl) Milli-Q water
Blank		0	10	10	70
Pre-Gal	1/1000	10	10	10	60
	1/10,000	10	10	10	60
	1/100,000	10	10	10	60
Auto-Gal	1/1000	10	10	10	60
	1/10,000	10	10	10	60
	1/100,000	10	10	10	60

12. Count 100 μl of the sample and 10 μl of the UDP-[^3H]Gal using a liquid scintillation counter.
13. Calculate activity.
 - a. Calculate the total moles of UDP-Gal transferred to GlcNAc as follows:

$$\{ \text{cpm}_{(\text{with GlcNAc})} - \text{cpm}_{(\text{no GlcNAc})} / \text{total cpm} \} \times 1.76 \text{ nmol}$$

Note, $\text{cpm}_{(\text{with GlcNAc})}$ represents counts in the sample, $\text{cpm}_{(\text{no GlcNAc})}$ represents counts in the no-enzyme control, and total cpm represents the total counts available to transfer. $\{ \text{cpm}_{(\text{with GlcNAc})} - \text{cpm}_{(\text{no GlcNAc})} / \text{total cpm} \}$ represents the portion of [^3H]Gal transferred in the reaction. This proportion is multiplied by the total number of moles of UDP-Gal in the reaction. If the specific activity of the UDP-[^3H]Gal is 17.6 Ci/mM and 10 μl of label was used, then there are 1.76 nmol of UDP-Gal in 10 μl .
 - b. Calculate the activity; one unit of activity (U) is defined as 1 μM of Gal transferred to GlcNAc per minute at 37°C.

**BASIC
PROTOCOL 5**

DETECTION OF PROTEINS MODIFIED BY O-GlcNAc USING METABOLIC LABELING

Metabolic labeling of O-GlcNAc-bearing proteins provides a useful means to test if a protein of interest is modified by O-GlcNAc, to observe the gross dynamic changes in O-GlcNAc levels and to study the subcellular localization in response to stimulation or during cell cycle. In the protocol described below, cells are labeled with [^3H]glucosamine, which is metabolized to UDP-[^3H]GlcNAc in the hexosamine synthetic pathway. For labeling, it is critical that the labeled sugar compete with glucose import; this ensures efficient uptake of the label. While glucosamine is a good competitor, N-acetylglucosamine is not. For further discussions on metabolic labeling of glycoconjugates, readers are encouraged to consult Varki (1994) for details.

Materials

Cells of interest, growing in culture
 Biosynthetic labeling medium (see recipe)
 Phosphate-buffered saline (PBS; APPENDIX 2)

Additional reagents and equipment for PNGase F digestion of proteins (UNIT 17.13A), SDS-PAGE (UNIT 10.2A), and autoradiography (APPENDIX 3A)

1. Replace growth medium with biosynthetic labeling medium. Label cells for 5 to 24 hr in an incubator.

The labeling is done in a glucose-free medium to maximize labeling efficiency. The addition of nonessential amino acids to the medium reduces the influx of glucosamine into the amino acid biosynthetic pathways (Medina et al., 1998).

2. Wash labeled cells twice, each time by resuspending in 5 ml of PBS and centrifuging 10 min at $500 \times g$, 4°C.
3. Extract as desired.

See Critical Parameters for a discussion on reducing O-GlcNAcase activity.

There are many types of cell fractionation and extraction techniques available. Those that minimize plasma membrane and organelle contamination are preferable. If a particular study concerns one or a few proteins, and specific antibodies are available, the protein(s) can be isolated by immunoprecipitation after metabolic labeling.

4. Treat sample with PNGase F (UNIT 17.13A).

5. Separate proteins by SDS-PAGE (UNIT 10.2A) and visualize labeled proteins by autoradiography (APPENDIX 3A).

CHARACTERIZATION OF LABELED GLYCANS BY β -ELIMINATION AND CHROMATOGRAPHY

BASIC
PROTOCOL 6

This protocol has three steps: (1) the release of carbohydrates as sugar alditols by reductive β -elimination; (2) desalting the sample, while confirming the size of the labeled sugar alditol(s); and (3) confirmation that the product is [^3H] β Gal1-4 β GlcNAcol (from galactosyltransferase labeling) or [^3H]GlcNAcol (from metabolic labeling).

Materials

Labeled proteins
 β -elimination reagent: 1 M NaBH_4 /0.1 M NaOH (prepare fresh)
4 M acetic acid
Screw-cap microcentrifuge tubes

Additional reagents and equipment for acetone or methanol precipitation of proteins (UNIT 17.10A), size-exclusion (gel-filtration) chromatography (UNIT 10.9), and Dionex chromatography (Townsend et al., 1990; Hardy and Townsend, 1994)

1. Acetone or methanol precipitate labeled proteins (UNIT 17.10A) in screw-cap microcentrifuge tubes.

The β -elimination reaction is performed in screw-cap microcentrifuge tubes to prevent the lids from popping open during the lengthy incubation, which would result in evaporation of the sample. The tubes should be tightly sealed. Take care in opening the tubes at the end of the reaction, as gas generated during the reaction will escape.

2. Resuspend sample in 500 μl of β -elimination reagent and incubate at 37°C for 18 hr.
After several hours check that the pH is >13. Add more β -elimination reagent if needed.
3. Cool the sample on ice.
4. Neutralize the reaction by adding 5 μl cold 4 M acetic acid in a stepwise manner. Check that the pH is between pH 6 and 7.

Samples can be desalted either by chromatography on a Sephadex G-50 column (1 \times 30 cm, equilibrated in 50 mM ammonium formate, 0.1% SDS) or by anion-exchange chromatography on a 1-ml Bio-Rad Dowex AG 50W-X2 200-400 mesh (H^+ form) column equilibrated in water. Fractions containing [^3H]GlcNAc or [^3H]Gal are pooled and lyophilized. Residual NaBH_4 is removed by washing the sample with methanol; NaBH_4 is volatile in the presence of methanol and is removed in a Speed-Vac evaporator or under a stream of nitrogen (Fukuda, 1990).

5. Resuspend the sugar alditols in Milli-Q water. Analyze by size-exclusion chromatography or by Dionex chromatography.

To determine the size of the oligosaccharide, labeled glycans released by β -elimination are subjected to size exclusion chromatography. Readers are referred to several standard methods using BioGel P4 (Kobata, 1994) or TSK Fractogel (Fukuda, 1990) chromatography. Alternatively, the Amersham Pharmacia Biotech Superdex Peptide column, equilibrated in 30% v/v CH_3CN , 0.1% v/v TFA, has been used to size oligosaccharides (R.N. Cole, pers. commun.).

To determine the nature of the monosaccharide alditol or disaccharide alditol generated from either metabolic labeling or galactosyltransferase labeling, samples released by β -elimination can be analyzed by high-voltage paper electrophoresis or high-pH anion exchange chromatography (HAPEC) with pulsed amperometric detection on a Dionex CarboPac PA100 column (Townsend et al., 1990; Hardy and Townsend, 1994).

Preparation and
Analysis of
Glycoconjugates

17.6.13

SITE MAPPING BY MANUAL EDMAN DEGRADATION

This protocol describes methods for mapping sites on peptides that have been labeled with [³H]Gal (see Alternate Protocol 1) or [³H]glucosamine (see Basic Protocol 5). Proteins of interest can be digested in solution or in gel (Riviere and Tempst, 1995; Stone and Williams, 1995) and the peptides separated by conventional reversed-phase HPLC (UNIT 10.14).

Glycopeptides are covalently attached to arylamine-derivatized PVDF disks via the activation of peptide carboxyl groups using water-soluble *N*-ethyl-*N'*-dimethylamine-nopropylcarbodiimide (EDC; Kelly et al., 1993). Note that both the C-terminus and any acidic residue will couple to the membrane and as such, cycles with acidic amino acids will yield blanks.

Some researchers have shown that glycosylated amino acids can be visualized during automated Edman degradation. However, this technique requires at least 20 pmol of starting material, where at least 20% of the sample is glycosylated. For more details, readers are referred to Zachara and Gooley (2000).

Materials

- Acetonitrile (CH₃CN; HPLC-grade)
- Trifluoroacetic acid (TFA; sequencing grade)
- Sequelon-AA Reagent Kit (Millipore) containing:
 - Mylar sheets
 - Carbodiimide
 - Coupling buffer
 - N*-ethyl-*N'*-dimethylamine-nopropylcarbodiimide (EDC)
- Labeled sample and control peptides (must contain ≥1000 dpm and not be in amine-containing buffers such as Tris)
- Methanol (HPLC-grade)
- Sequencing reagent (see recipe)
- 100 mM Tris·Cl, pH 7.4 (APPENDIX 2)
- Heating block
- Screw-capped polypropylene microcentrifuge tubes

Couple the sample to a PVDF disk

1. Resuspend peptide in 10% to 30% (v/v) CH₃CN and up to 0.1% (v/v) TFA.
2. Place disk on a Mylar sheet (from Sequelon kit) on a heating block at 55°C.
3. Wet disk with 10 μl of methanol and allow excess methanol to evaporate.
4. Apply sample in 10-μl aliquots, allowing the membrane to come to near-dryness between aliquots.
5. Dry the membrane after all of the sample has been applied. Place the disc in the lid of a screw-cap microcentrifuge tube for subsequent reactions.
6. Prepare coupling reagent by combining 1 mg carbodiimide per 100 μl of coupling buffer (both provided with Sequelon kit). Add ~1 mg of EDC per 100 μl of coupling reagent and carefully pipet ~50 μl onto each disk.
7. Incubate samples at 4°C for 30 min. At the end of the reaction, remove the coupling reagent to a microcentrifuge tube.

Incubation of the sample at 4°C increases the yield. The membrane should not be incubated for >30 min.

8. Place the membrane in a microcentrifuge tube. Wash the membrane alternately three times with 1 ml methanol and 1 ml Milli-Q water, vortexing briefly after each addition. Combine each wash with the coupling reagent from step 7.
9. Dry the membrane. Samples are stable at -20°C on disks for at least 6 months.
10. Count an aliquot of the pooled coupling reagent and washes (step 8) and determine the coupling efficiency.

Sequencing peptides

The times given in this procedure are critical. Steps 12 to 17 represent a “cycle.” This method is only efficient for 10 to 20 cycles.

11. Place disk in a screw-capped polypropylene microcentrifuge tube.
12. Add 0.5 ml of the sequencing reagent to the disk and incubate 10 min at 50°C in a heating block.

This step derivatizes the N-terminus of the peptide, forming the phenylthiocarbamyl derivative.

13. Wash disk five times in microcentrifuge tube, each time with 1 ml of methanol, vortexing after each addition. Dry disk in a Speed-Vac evaporator for 5 min.
14. Add 0.5 ml TFA and incubate at 50°C for 6 min. Remove and save the supernatant.

In this step, the derivatized amino acid is released from the peptide.

15. Wash the disk with 1 ml of methanol. Save the supernatant and combine the supernatant from step 14.
16. Wash disk five times, each time with 1 ml methanol.
17. Return to step 12 and repeat the cycle.

Steps 12 to 17 represent a “cycle,” with one amino acid being released per cycle from the N-terminus of the protein or peptide. This method is only efficient for 10 to 20 cycles. As each cycle represents the release of an amino acid, it is not necessary to perform 20 cycles if the peptide in question is 10 amino acids long. The authors usually perform 15 cycles, as the data become hard to interpret after this.

18. Dry the combined supernatants from steps 14 and 15 on a 50°C heating block, or on the bench overnight.
19. Add 0.5 ml of 100 mM Tris·Cl, pH 7.4 and 15 ml liquid scintillation fluid. Count on a liquid scintillation counter.

Edman degradation is a sequential process, with one amino acid being released from the N-terminus of the protein or peptide per cycle. In the method described here, glycosylated amino acids are being detected by following the [^3H]Gal label.

To interpret the data, plot the dpm per cycle as a bar graph. A cycle with a glycosylated amino acid should have much higher counts than either the preceding or following cycle, unless there are two sites in a row.

Manual Edman degradation is often performed in concert with other techniques that will identify the peptide being sequenced, e.g., conventional Edman degradation or MALDI-TOF MS (UNITS 10.21 & 10.22). When looking at data sets from several techniques, the cycle with the counts should line up with a Ser or Thr residue.

SITE MAPPING BY MASS SPECTROMETRY AFTER β -ELIMINATION

As mass spectrometry (MS; *UNITS 10.21 & 10.22*) has become more readily available, several MS techniques have been applied to the characterization of O-GlcNAc proteins and peptides (Reason et al., 1992; Greis et al., 1996; Haynes and Aebersold, 2000). When analyzing proteins or peptides modified by O-GlcNAc via mass spectrometry, several challenges need to be overcome. Some researchers have shown that when using matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF; *UNIT 10.22*) with a conventional matrix (such as α -cyano-4-hydroxycinnamic acid) the addition of a single GlcNAc to a peptide may reduce the signal by approximately five-fold. In addition, the presence of the unglycosylated peptide further suppresses the signal (Hart et al., 2000). Secondly, the β -O-GlcNAc bond is more labile in the mass spectrometer than other bonds formed by protein glycosylation. Thus, in conventional electrospray ionization-MS, O-GlcNAc is released at lower orifice potentials and collision energies than is required to sequence peptides.

Greis et al. (1996) developed a technique where peptides are analyzed before and after β -elimination. During β -elimination Ser (89 atomic mass units) and Thr (101 atomic mass units) residues are converted to 2-aminopropenoic acid (69 atomic mass units) and α -aminobutyric acid (83 atomic mass units), respectively. These amino acids have different masses than their parent amino acids and can be used to map the site of attachment. It should be noted that this method will also release phosphate linked to Ser and Thr residues. In the protocol described here, glycans are released from peptides by β -elimination, and then analyzed using conventional MS-MS strategies.

Materials

Samples from β -elimination (see Basic Protocol 7)

200 mM NaOH

300 mM acetic acid

Screw-cap polypropylene microcentrifuge tubes

45°C heating block

Additional reagents and equipment for ESI-MS (*UNIT 10.21*), reversed-phase HPLC of peptides (*UNIT 10.14*), and MALDI-TOF MS (*UNIT 10.22*)

1. Combine the following in a screw-cap polypropylene microcentrifuge tube:

≤ 25 μ l sample from β -elimination

25 μ l 200 mM NaOH

Milli-Q water to a final volume of 50 μ l

2. Incubate at 45°C for 4 hr in a heating block.

Time is critical, as increased incubation times will result in the peptide backbone hydrolyzing.

3. Place sample on ice and add 25 μ l of 300 mM acetic acid in 5- μ l increments.

The reaction mixture will boil over unless the acetic acid is added in a stepwise manner.

4. Dry sample in a Speed-Vac evaporator and store at -80°C until analyzed by ESI-MS (*UNIT 10.21*). Alternatively, analyze peptides by MALDI-TOF MS (*UNIT 10.22*) after desalting using reversed-phase chromatography (*UNIT 10.14*).

Zip-Tips (Millipore) are ideal for desalting small quantities of peptide before MALDI-TOF MS.

ASSAY FOR OGT ACTIVITY

The detection and analysis of O-GlcNAc on proteins is only the first step in the analysis of O-GlcNAc and the protein(s) of interest. More important is determining the function of the modification. Protocols for the analysis of the enzymes that add and remove O-GlcNAc have been included, as they may aid in understanding the role of O-GlcNAc. Recent examples where studies such as this have been critical include those which have shown the reciprocity between O-GlcNAc and O-phosphate on the C-terminal domain of RNA Pol II; studies showing elevated activity of enzymes in certain tissue/cell lines and tissue fractions; and, finally, studies which have indicated that the enzymes responsible for the addition and removal of O-GlcNAc copurify with kinases and phosphatases.

O-GlcNAc transferase (OGT), or uridine diphospho-*N*-acetylglucosamine:polypeptide β -*N*-acetylglucosaminyltransferase, transfers GlcNAc to the hydroxyl groups of Ser and Thr residues of proteins and peptides using UDP-GlcNAc as a donor substrate (Haltiwanger et al., 1992; Kreppel et al., 1997). OGT activity is assayed by determining the rate at which [³H]GlcNAc is transferred to an acceptor peptide. A number of peptides have been identified as substrates for OGT in vitro, but a peptide (³⁴⁰PGGSTPVSSANMM³⁵²) from the α -subunit of casein kinase II (CKII) is the most efficient in vitro substrate known to date (Kreppel and Hart, 1999).

OGT activity can be assayed in crude preparations (Haltiwanger et al., 1992) or using recombinant protein (Kreppel and Hart, 1999). OGT activity is sensitive to salt inhibition, so it is important to desalt the preparation before assaying if high salt concentrations are present (see Support Protocol 5). For pure preparations 0.2 to 1 μ g is typically used per assay, in crude preparations 20 to 50 μ g, though the latter is precipitated using ammonium sulfate (40% to 60%).

Materials

0.1 mCi/ml UDP-[³H]GlcNAc (20 to 45 Ci/mmol; NEN Life Science Products) in 70% ethanol

25 mM 5'-adenosine monophosphate (5'-AMP), in Milli-Q water, pH 7.0

Nitrogen source

Crude or purified OGT sample, desalted (see Support Protocol 5)

10 \times OGT assay buffer (see recipe)

CKII peptide substrate (⁺H₂N-PGGSTPVSSANMM-COO⁻): dissolve in H₂O to 10 mM and adjust to pH 7 if necessary

50 mM formic acid

Methanol (HPLC-grade)

Waters Sep-Pak C₁₈ cartridges

1. Dry down an aliquot of UDP-[³H]GlcNAc in a Speed-Vac evaporator or under a stream of nitrogen just prior to use. Resuspend in an appropriate volume of 25 mM 5'-AMP, so that the concentration is 0.02 μ Ci to 0.1 μ Ci/ μ l.

AMP is included in the assay to competitively inhibit any pyrophosphatase in the sample that will hydrolyze the UDP-GlcNAc.

2. Set up assay reactions as follows:

5 μ l of 10 \times OGT assay buffer

10 μ l of 10 mM CKII peptide substrate

5 μ l of 0.02 to 0.1 μ Ci/ μ l UDP-[³H]GlcNAc (from 0.1 to 0.5 μ Ci total)

\leq 25 μ l of desalted OGT to be analyzed

H₂O to 50 μ l

It is critical to include a negative control. A mimic of the CKII peptide where the Ser and Thr residues are replaced with Ala is appropriate, or, simply, a “no-enzyme” control can be included.

The results generated are variable and the reactions should be set up in duplicate.

3. Incubate at room temperature for 30 min.

An incubation time of 15 to 30 min at room temperature is usually sufficient.

4. Stop reaction by adding 450 μl of 50 mM formic acid.
5. Wet a Waters Sep-Pak C_{18} cartridge with methanol, then wash the cartridge with 5 ml H_2O .
6. Load the reaction (500 μl total) onto the cartridge with a syringe. Wash with 5 ml H_2O .

The CKII peptide binds to the matrix of the C_{18} cartridge. Unincorporated UDP- ^3H GlcNAc is eliminated by the wash.

7. Elute the peptide with 2 to 4 ml methanol, directly into a 15-ml liquid scintillation counter tube.
8. Add 10 ml scintillation fluid and count ^3H . Calculate OGT activity according to the following equations.

$$\mu\text{Ci of GlcNAc incorporated} = (\text{dpm in sample} - \text{dpm in blank}) / (2.22 \times 10^6 \text{ dpm} \cdot \mu\text{Ci}^{-1})$$

$$\text{mmol of GlcNAc incorporated} = (\mu\text{Ci of GlcNAc incorporated}) / (\text{specific activity in } \mu\text{Ci/mmol})$$

This number should be expressed in terms of mg of OGT or cell extract. If the assay is done at several time points, it can be expressed as mmol/min.

The activity can be expressed either as dpm ^3H incorporation into the peptide, or as $\mu\text{mol } ^3\text{H}$ incorporation ($1 \mu\text{Ci} = 2.22 \times 10^6 \text{ dpm}$).

SUPPORT PROTOCOL 5

DESALTING THE O-GlcNAc TRANSFERASE

OGT activity is sensitive to salt inhibition ($\text{IC}_{50} = 40$ to 50 mM NaCl). It is important to desalt the enzyme preparation before assay if high concentration of salt is present.

Materials

- Sephadex G-50 slurry (Pharmacia Biotech)
- OGT desalting buffer (see recipe)
- Protein sample for OGT assay in volume $\leq 200 \mu\text{l}$
- 1-ml tuberculin syringe
- 1.5-ml tubes, prechilled

1. Pack a column containing exactly 1 ml of Sephadex G-50 slurry in a 1-ml tuberculin syringe. Wash the column with 5 ml of OGT desalting buffer.

Sephadex G-50 is usually supplied in 20% (v/v) ethanol.

2. Load protein sample onto column.

The volume of sample can be up to $200 \mu\text{l}$.

3. Wash column with desalting buffer so that the total volume of this wash and the protein sample is $350 \mu\text{l}$. For example, if sample volume is $150 \mu\text{l}$, add $200 \mu\text{l}$ desalting buffer to the column at this step.

4. Transfer the syringe column to a clean, prechilled 1.5-ml tube. Elute protein with 200 μ l desalting buffer. Keep on ice.

This is the desalted sample.

Alternatively, PD-10 desalting columns (Amersham Pharmacia Biotech) can be used if O-GlcNAc transferase is in larger volume (1 to 2.5 ml).

ASSAY FOR O-GlcNAcase ACTIVITY

O-GlcNAcase, also known as N-acetylglucosaminidase or hexosaminidase C (EC 3.2.1.52), is a cytosolic glycosidase specific for O-linked β -GlcNAc. The activity of O-GlcNAcase can be conveniently assayed in vitro with a synthetic substrate, *p*-nitrophenol N-acetylglucosaminide (*p*NP- β -GlcNAc). The cleavage product, *p*NP, has an absorbance peak at 400 nm.

Materials

Partially purified O-GlcNAcase (0.2 to 1 μ g) or cell extract sample (20 to 50 μ g, precipitated with 30% to 50% ammonium chloride)

10 \times O-GlcNAcase assay buffer (see recipe)

100 mM (50 \times) *p*-nitrophenol N-acetylglucosaminide (*p*NP-GlcNAc) in DMSO

500 mM Na₂CO₃

96-well flat bottom plates or 1.5 ml microcentrifuge tubes

Plate reader or spectrophotometer

1. Prepare O-GlcNAcase.

Native or recombinant O-GlcNAcase can be partially purified from animal tissues or cultured cells by several chromatographic steps (Dong and Hart, 1994; Gao et al., 2001). Alternatively, a crude enzyme preparation can be generated by passing cell extract over a 1-ml Con-A column. Most of the interfering acidic hexosaminidases are modified by N-linked sugars and bind to Con-A, while neutral O-GlcNAcase is in the flow-through (Izumi and Suzuki, 1983).

2. Precool 96-well plate or microcentrifuge tubes on ice.

3. Set up reactions in the precooled plate wells or tubes as follows:

1 to 50 μ l partially purified O-GlcNAcase enzyme or cell extract

10 μ l 10 \times O-GlcNAcase assay buffer

2 μ l 100 mM *p*NP-GlcNAc

H₂O to 100 μ l

The total reaction volume can be scaled up to 500 μ l in microcentrifuge tubes.

**p*NP-GlcNAc breaks down chemically. A blank reaction without enzyme should be included to determine the background.*

50 mM GalNAc is included in the reaction to inhibit lysosomal hexosaminidases A and B which may be present in the enzyme preparation. O-GlcNAcase is not inhibited by 50 mM GalNAc.

4. Mix well and cover.

5. Incubate at 37°C for 30 min to 4 hr.

*Yellow color will develop as *p*NP-GlcNAc is hydrolyzed by O-GlcNAcase. Reactions should be optimized to keep the absorbance within the linear range of the spectrophotometer. The authors find that 20 to 50 μ g of cell extract used in a reaction of 100 μ l, with a 1 to 2 hr incubation time is appropriate.*

6. At the end of incubation, add an equal volume of 500 mM Na₂CO₃ to each well (100 μl or 500 μl).

Na₂CO₃ raises the pH to >pH 9.0, intensifying the yellow color and stopping the reaction, as O-GlcNAcase has little activity at pH 9 to 10.

7. Read the absorbance at 400 nm on a plate reader or spectrophotometer.
8. Calculate O-GlcNAcase activity according to the following equation:

$$\text{mM of GlcNAc released} = A_{400} / (17.4 \times 10 \text{ mM}^{-1} \cdot \text{cm}^{-1} \times \text{pathlength})$$

One unit is the amount of enzyme catalyzing the release of 1 μmol/min of pNP from pNP-GlcNAc.

The molar extinction coefficient for pNP is 17.4 × 10 mM⁻¹·cm⁻¹ at pH 10. The path length for 200 μl on a 96-well plate is 0.71 cm.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Biosynthetic labeling medium

Glucose-free culture medium containing:

50 μCi/ml D-[6-³H]glucosamine (22 Ci/mmol; Amersham Pharmacia Biotech)

10% (v/v) FBS

Prepare fresh

Buffer H

50 mM HEPES, pH 6.8

50 mM NaCl

2% (v/v) Triton X-100

Store up to 1 month at room temperature

Citrate-phosphate buffer, pH 4.0, 2×

Dissolve 12.9 g citric acid monohydrate (mol. wt. 210) and 20.6 g disodium hydrogen phosphate heptahydrate (Na₂HPO₄·6H₂O) in 300 ml Milli-Q water. Bring volume to 500 ml.

Galactosyltransferase labeling buffer, 10×

100 mM HEPES, pH 7.5

100 mM galactose

50 mM MnCl₂

Store up to 1 month at 4°C

Galactosyltransferase storage buffer

2.5 mM HEPES, pH 7.4

2.5 mM MnCl₂

50% (v/v) glycerol

Store up to 1 month at room temperature

Hexosaminidase reaction mixture, 2×

Per reaction:

25 μ l 2 \times citrate-phosphate buffer (see recipe)
1 U *N*-acetyl- β -D-glucosaminidase (V-Labs)
0.01 U aprotinin
1 μ g leupeptin
1 μ g α_2 -macroglobulin

O-GlcNAcase assay buffer, 10×

500 mM sodium cacodylate, pH 6.4
500 mM *N*-acetylgalactosamine (GlcNAc)
3% (w/v) bovine serum albumin (BSA)
Prepare fresh

OGT assay buffer, 10×

500 mM sodium cacodylate, pH 6.0
10 mg/ml bovine serum albumin (BSA)
10 mM 1-amino-GlcNAc (2-acetamido-1-amino-1,2-dideoxy- β -D-glucopyranose;
Sigma)
Prepare fresh

OGT desalting buffer

20 mM Tris·Cl, pH 7.8 (APPENDIX 2)
1 mg/ml bovine serum albumin (BSA)
20% (v/v) glycerol
0.02% (w/v) NaN₃
Store up to 1 week at 4°C

Protease inhibitors, 1000×

PIC 1, 1000 \times :

Dissolve the following in 10,000 U/ml aprotinin solution (Sigma)
1 mg/ml leupeptin
2 mg/ml antipain
10 mg/ml benzamide

PIC 2, 1000 \times :

Prepare in DMSO
1 mg/ml chemostatin
2 mg/ml pepstatin

PMSF, 1000 \times :

0.1 M phenylmethylsulfonyl fluoride in 95% ethanol

Sequencing reagent

7 ml methanol (HPLC-grade)
1 ml triethylamine (TEA; sequencing grade)
1 ml phenylisothiocyanate (PITC; sequencing grade)
1 ml Milli-Q water
Stable 24 hr at 4°C

sWGA Gal elution buffer

Phosphate-buffered saline (PBS; APPENDIX 2) containing:
0.2% (v/v) NP-40
1 M D-(+)-galactose (Gal)
Store up to 1 week at 4°C

sWGA GlcNAc elution buffer

Phosphate-buffered saline (PBS; *APPENDIX 2*) containing:

0.2% (v/v) NP-40

1 M N-acetylglucosamine (GlcNAc)

Store up to 1 week at 4°C

TBS-HD

10 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

150 mM NaCl

1% (v/v) Triton X-100

0.1% (w/v) SDS

0.25% (w/v) deoxycholic acid

Store up to 1 month at 4°C

TBS-HT

10 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

150 mM NaCl

0.3% (v/v) Tween 20

Store up to 1 month at room temperature

TBST

10 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

150 mM NaCl

0.05% (v/v) Tween 20

Store up to 1 month at room temperature

Tris-buffered saline (TBS)

10 mM Tris-Cl, pH 7.5 (*APPENDIX 2*)

150 mM NaCl

Store up to 1 month at room temperature

COMMENTARY

Background Information

(β)-D-1-4-galactosylaminyltransferase from bovine milk recognizes terminal N-acetylglucosamine (GlcNAc) residues and modifies them by the addition of a single Gal residue. Torres and Hart (1984) first used this enzyme in combination with UDP-[3 H]Gal to demonstrate that bovine lymphocytes contain proteins modified by O-linked GlcNAc. Further refinements of this experiment led them to propose that the product, β Gal1-4 β GlcNAc, was the result of the galactosyltransferase recognizing and modifying a single GlcNAc residue O-linked to Ser/Thr residues of nuclear and cytoplasmic proteins (Holt and Hart, 1986). Since this report, many cytosolic and nuclear proteins from mammalian cells were shown to be modified by O-GlcNAc. This method has remained the “gold standard” technique for the detection of O-GlcNAc-modified proteins, as the label provides a “tag” for subsequent analyses, such as those described under Product Characterization, below (see Critical Parameters and Troubleshooting).

In subsequent years, methods such as WGA affinity and western blotting with GlcNAc-specific lectins and antibodies have become popular as simple techniques for the initial characterization of target proteins.

Critical Parameters and Troubleshooting

Extraction of proteins from cells

The O-GlcNAc modification can be removed from proteins either by cytosolic O-GlcNAcase or lysosomal hexosaminidases. The inclusion of inhibitors during the extraction and purification process will preserve the levels of O-GlcNAc on proteins. Commonly used inhibitors (Dong and Hart, 1994) include 1-amino-GlcNAc (1 mM), GlcNAc (100 mM), and PUGNAc (5 μ M). Note that these may have to be removed, as they will act as inhibitors in other methods.

Product characterization

Product characterization is a critical step showing that a protein is modified by O-GlcNAc, and not other glycans. While many proteins modified by O-GlcNAc have been identified, there is evidence based on metabolic labeling (Medina et al., 1998) and lectin labeling studies (Hart et al., 1989) that indicate that O-GlcNAc is not the only intracellular carbohydrate post-translational modification. In addition, at least one peptide mimic of O-GlcNAc has been identified in cytokeratins (Shikhman et al., 1994).

Moreover, many techniques used for breaking open cells also release proteins that are modified by complex N- and O-linked sugars, which may contain terminal GlcNAc. Many of the techniques described in this unit will recognize any GlcNAc residue, and it is important to perform the described controls such as PNGase F digestion to show specificity.

Product analysis is critical for metabolic labeling with glucosamine. While UDP-GlcNAc is the major product, glucosamine can enter other biosynthetic pathways, such as those used for amino acid synthesis. This issue was highlighted by studies of the SV40 large T-antigen. Some researchers have found that the SV40 large T-antigen labels with a number of different tritiated carbohydrates. However, O-GlcNAc is the only carbohydrate post-translational modification of the SV40 large T-antigen. The incorporation of glucosamine into amino acid biosynthetic pathways could be reduced by growing cells in the presence of excess nonessential amino acids (Medina et al., 1998).

Lastly, while galactosyltransferase is specific for terminal GlcNAc residues, researchers (Elling et al., 1999) have shown that galactosyltransferase will modify GlcNAc linked in either the α - or β -anomeric conformation. The authors of this unit have shown that proteins modified by α -O-GlcNAc will be labeled using the procedure described (N. Zachara, unpub. observ.). While α -O-GlcNAc has not been identified in complex eukaryotes, it is a common modification of cell surface proteins of simple eukaryotes such as trypanosomes and *Dictyostelium*. Product analysis, such as HPAEC of the sugar alditols, will resolve many of the issues discussed.

Time Considerations

Detection of O-GlcNAc proteins using antibodies (see Basic Protocol 2) and lectins (see

Basic Protocol 3) will take approximately 2 to 3 days after the extraction of the proteins from cells. Samples and controls must be treated with PNGase F and/or hexosaminidase (1 hr to overnight), before SDS-PAGE and blotting. In either case, overnight incubation at 4°C provides the best signal-to-noise ratio.

WGA affinity chromatography of low-copy-number proteins will take 2 to 3 days. The ITT and WGA affinity chromatography can be completed in 1 day; subsequent analysis of the product by SDS-PAGE will take 1 to 2 days depending on the label used and the amount of label incorporated into proteins eluting from the WGA-agarose.

Autogalactosylation of the galactosyltransferase and subsequent analysis of the activity will take 1 to 2 days. As the enzyme is stable for 6 to 12 months at -20°C , autogalactosylation does not need to be repeated for each analysis. Labeling of the proteins can take several hours to overnight, though optimization of the conditions may take a few days. The subsequent analysis, as well as desalting (dependent on the technique used), PNGase F digestion (1 hr to overnight), precipitation of protein (3 hr to overnight), SDS-PAGE, and autoradiography (1 to 10 days), can take up to 2 weeks. The length of time allotted to product analysis is dependent on the methods chosen, but will almost certainly require 7 to 10 days. Further analysis, including digestion of labeled proteins and subsequent purification of peptides, will take at least 3 days.

Lectin Analysis of Proteins Blotted onto Filters

UNIT 17.7

Lectins are proteins that bind with great specificity to certain carbohydrate structures. Plant lectins are widely used for investigations of carbohydrate structure (UNIT 17.3) and for fractionation and purification of individual oligosaccharides and glycopeptides (UNIT 17.18). This unit describes the use of lectins as sensitive indicators for the presence of certain carbohydrate structures linked to proteins blotted onto filters. A tagged lectin is incubated with a blot containing the target protein and binding of the lectin is detected by one of several different procedures. Direct approaches include using lectins labeled with ^{125}I or conjugated to horseradish peroxidase or alkaline phosphatase, which can be detected by chromogenic or luminescent visualization systems. Indirect approaches involve using lectins conjugated to biotin or digoxigenin followed by a second incubation with alkaline phosphatase–conjugated avidin or antibodies specific for the haptenic digoxigenin group and then by visualization. Several commercial kits are available that provide labeled lectins, control proteins, and developing reagents needed for visualization. These systems can also be adapted for use with lectins other than those supplied with kits. The following protocol is easy to perform with or without a kit. However, the results, while suggestive of carbohydrate structure, are not definitive.

Materials

- Purified protein sample containing 1 to 10 μg of target protein
- Lectin blot kit (e.g., E-Y Laboratories Lectin Staining Kit; Genzyme Lectin Link Kit; Boehringer Mannheim Glycan Differentiation Kit) *or* equivalent materials:
 - Glycoprotein known to bind with the chosen lectins (positive control; Table 17.7.1)
 - Blocking solution: e.g., 1% to 2% (w/v) gelatin in TTBS or 3% periodate-oxidized bovine serum albumin (BSA)
 - Incubation buffer: e.g., 0.1% (v/v) Tween 20 in Tris-buffered saline (TTBS; UNIT 10.8)
 - Labeled or conjugated lectin (Tables 17.7.2 & 17.7.3) in TTBS or other appropriate incubation buffer
 - Enzyme- or antibody-linked antibody (secondary reagent), if needed
 - Chromogenic or luminescent visualization reagent for detecting tagged lectin or antibody (Table 10.8.1)
- Additional reagents and equipment for SDS-PAGE (UNIT 10.2), immunoblotting and immunodetection (UNIT 10.8), and autoradiography (APPENDIX 3)

**BASIC
PROTOCOL**

Table 17.7.1 Lectin-Binding Glycoproteins^a

Glycoprotein	Molecular weight (kDa)	Lectin bound ^b
RNase B	17	Con A
Ovalbumin	45	Con A
Transferrin	80	SNA
Fetuin	68	SNA, MAA
Asialofetuin	61	RCA I
α 1-acid glycoprotein	45	DSA

^aGlycoproteins known to bind with the chosen lectins are used as positive controls and as standards for quantitative analysis. They are supplied with some lectin blot kits (e.g., Boehringer Mannheim's) or available separately from Sigma.

^bAbbreviations: Con A, concanavalin A; SNA, *Sambucus nigra* agglutinin; MAA, *Maackia amurensis* agglutinin; RCA I, *Ricinus communis* agglutinin I; DSA, *Datura stramonium* agglutinin.

Supplement 23

Table 17.7.2 Lectins Suitable for Analysis of Proteins Blotted onto Filters

Lectin	Specificity ^a	Notes	Kit ^b
Con-A (Concanavalin A)	α Man, α Glc	Strongly indicates N-linked oligosaccharide chains. Binds high mannose, hybrid, or biantennary complex chains	EY-L GN-LL
GNA (<i>Galanthus nivalis</i> agglutinin)	Man α Man	Binds terminal mannose-linked, α 1-3, α 1-6 or α 1-2 linked to mannose. It will identify "high mannose" N-glycan chains or O-glycosidically linked mannose chains in yeast glycoproteins	BM-GD
WGA (Wheat germ agglutinin)	β -GlcNAc or sialic acid	Binds terminal β GlcNAc or sialic acids on various glycans	GN-LL, EY-L
RCA I (<i>Ricinus communis</i> agglutinin)	β Gal	Binds Gal-terminated N-linked oligosaccharides, but not exclusive	GN-LL
DSA (<i>Datura stramonium</i> agglutinin)	Gal β 1-4GlcNAc	Binds Gal β -1-4GlcNAc in complex and hybrid N-glycans and GlcNAc in O-glycans, also polylectosamines	BM-GD GN-LL
MAA (<i>Maackia amurensis</i> agglutinin)	SA α 2-3 Gal- β -GlcNAc	Binds sialic acid linked α 2-3 to galactose in N- and O-linked glycans	BM-GD GN-LL
SNA (<i>Sambucus nigra</i> agglutinin)	SA α 2-6 Gal or GalNAc	Binds sialic acid linked α 2-6 to Gal or GalNAc; identifies sialylated O-glycan, N-glycan chains	BM-GD GN-LL
PNA (Peanut agglutinin)	Gal β 1-3 GalNAc	Recognizes the core disaccharide galactose β 1-3 N-acetylgalactosamine O-glycosidically linked chains (except of yeast glycoproteins)	BM-GD

^aAbbreviations: Man, mannose; Glc, glucose; GlcNAc, N-acetylglucosamine; Gal, galactose; SA, sialic acid; GalNAc, N-acetylgalactosamine.

^bEY-L, E-Y Laboratories Lectin Staining Kit; BM-GD, Boehringer Mannheim Glycan Differentiation Kit; GN-LL, Genzyme Lectin Link Kit.

1. Separate the proteins in the sample by one-dimensional SDS-PAGE and transfer onto nitrocellulose by electroblotting. Include positive control (a glycoprotein known to bind to the lectins) and extra sample lanes for incubation controls (see step 5 annotation).

Inclusion of a positive control is particularly important in early experiments when incubation conditions are being optimized. These procedures are useful for relatively pure proteins. Crude mixtures of proteins are not suitable for these tests.

If some samples are to be digested with exo- or endoglycosidases to facilitate interpretation of results (see critical parameters), digestions should be carried out prior to running the sample on the gel. In this case a gel with separate wells must be used and a glycosidase-only control lane included for each digestion. Many of the glycosidases are themselves glycoproteins and will bind lectins.

2. Incubate nitrocellulose blot in blocking solution with agitation \geq 30 min at room temperature.

Table 17.7.3 Commercial Sources of Lectins for Detecting Blotted Glycoproteins

Supplier	Conjugate				
	Biotin	Peroxidase	Alkaline phosphatase	Digoxigenin	Lectin conjugates in kits
E-Y Labs	+	+	+	—	Avidin/horseradish peroxidase Avidin/alkaline phosphatase
Boehringer Mannheim	+	—	—	+	Anti-digoxigenin Alkaline phosphatase
Genzyme	+	—	—	—	Avidin/alkaline phosphatase
Sigma	+	+	—	—	—
ICN	+	+	—	—	—

Gelatin is used as the blocking reagent because it is not a glycoprotein. Blocking reagents that contain even small amounts of glycoproteins (e.g., nonfat dry milk) may bind to the lectins, potentially depleting the available lectin or producing a high background signal. Alternatively, periodate oxidized BSA (3%) can be used as a blocking reagent (Glass et al., 1981).

3. Wash each filter three times in 50 ml TTBS or other buffer appropriate for incubation with the labeled lectin, 15 min per wash.

Other buffers and washing conditions may be suitable, as discussed in the literature accompanying lectin blot kits, but TTBS is routinely used.

4. Place the blot on a smooth, clean surface, such as a glass plate, and use a clean razor blade to cut the nitrocellulose into multiple strips approximately the width of a single lane.

It is not necessary to cut the strips exactly along the interlane boundaries. If photographs are required, the lane can be trimmed to a desirable width later.

5. Place each strip in a separate container and add sufficient TTBS or other appropriate buffer containing ~1 µg/ml labeled lectin to cover and suspend strip. Incubate 1 hr at room temperature with gentle shaking.

Incubation conditions must be optimized for each lectin and for each detection method. This information is available in kit instructions or from the supplier. Chelators such as EDTA should be avoided, as some lectins (e.g., Con A) require tightly bound metal ions for activity.

A sample incubated without lectin should be prepared as a control. Regardless of the method used to detect lectin binding, it is also important to include controls in which either the primary or secondary reagents are eliminated. If a sufficient amount (50 to 100 mM) of the appropriate competing sugar is available, lectin binding should be carried out in the presence of the sugar as a negative control (the sugar should eliminate specific binding).

6. Remove the lectin solution and store it at 4°C. Wash filter three times in 50 ml TTBS, 10 min each time.

Lectin solutions may be reused several times within one week of their first use if they are stored at 4°C. If a lectin solution is reused, the positive control will detect whether the lectin is still active.

- 7a. For lectins directly tagged with ^{125}I , biotin, horseradish peroxidase, or alkaline phosphatase: Visualize by autoradiography or using the appropriate chromogenic or luminescent visualization solution.
- 7b. For lectins conjugated to biotin or digoxigenin: Incubate filter in the appropriate secondary reagent 1 hr at room temperature. Wash filter 3 times with 50 ml TTBS, 10 min each time. Detect bound lectin using the appropriate chromogenic or luminescent visualization solution.

Lectins conjugated to these groups are detected by incubation with avidin–alkaline phosphatase conjugates or anti-digoxigenin–alkaline phosphatase.

COMMENTARY

Background Information

Lectins have been used for many years to detect the presence of various types of sugar chains. Lectin blots provide quick glimpses of the types of sugars attached to purified proteins. Even though the blots provide useful information, they cannot provide proof of a sugar structure and hence cannot substitute for the more specific and quantitative analytical approaches presented in this chapter. This is because lectin binding and its quantitation depend upon many factors that vary with different individual proteins. The advantage of using lectins is that many different ones are available and analysis requires only modest amounts of protein and routine laboratory equipment. Also, many detection methods are available. In order to have confidence in the results of lectin-binding studies, it is necessary to show that their binding specificity is abolished by coincubation with a competing sugar (usually a monosaccharide) or by prior enzymatic digestion to remove some or all of the protein-linked sugar chains. Lectins labeled with fluorescent indicators can be used to visualize glycoconjugates directly in hydrated gels (West and McMahon, 1977). However, this approach requires several days. This unit describes a less time-consuming method (based on Tanner and Anstee, 1976) in which the proteins are blotted onto filters prior to detection by one of several methods.

Critical Parameters and Troubleshooting

Information concerning critical parameters and troubleshooting for protein blotting, immunoprobeing, and chromogenic and luminescent detection is provided in *UNIT 10.8*.

Experimental design

Two points are especially important in designing lectin-binding experiments: the choice of lectin and the choice of method for detecting

lectin bound to glycoprotein. If the goal of the experiment is to obtain preliminary evidence that a protein contains carbohydrate groups, a battery of lectins should be used along with appropriate controls (e.g., competition by appropriate sugars). If the experiment is meant to serve as a guide to further structural analysis, the effects of various chemical or enzymatic treatments must be combined with analysis using one or more lectins known to bind to the glycoconjugate. Table 17.7.2 shows the specificity of the most popular lectins, some of which are supplied in the various kits.

The choice of detection method is affected by the amount of protein available and the extent of glycosylation. If the sample contains 1 to 10 μg of target protein or if the material is extensively glycosylated, lectins labeled directly with ^{125}I , alkaline phosphatase, or horseradish peroxidase can be used. If either the protein quantity or extent of glycosylation is minimal, an indirect system using lectins that are biotinylated or coupled to digoxigenin and a secondary enzyme- or antibody-linked reagent has the advantage of signal amplification.

Kits

The various reagents can be purchased separately or as prepackaged kits from the suppliers listed in Table 17.7.3. E-Y Laboratories offers the largest selection of purified lectins and lectins tagged with various conjugates.

The E-Y Laboratories kit uses lectins coupled to horseradish peroxidase. The Genzyme and Boehringer Mannheim kits use alkaline phosphatase-coupled molecules to detect the tagged lectins. Alternatively, tagged lectins can easily be prepared in the laboratory (*UNIT 11.1*). The major advantages of using kits are that they are self-sufficient, containing all of the reagents and positive controls needed, and that the lectins they employ are among those with the best characterized specificities. When coupled

with glycosidase digestions, the kits probably provide the most information about the sugar chains in the least amount of time for the least amount of money. Because there are limitations to the information that can be obtained, the decision about which individual lectins or kits to buy will depend upon the precision of information required.

The Glycan Differentiation Kit (Boehringer Mannheim) supplies lectins that are coupled to the steroid digoxigenin using an *N*-hydroxy-succinimide ester. An alkaline phosphatase-conjugated antiserum against this steroid is used to visualize bound lectin on target glycoproteins (Haselbeck et al., 1990). Digoxigenin is a naturally occurring steroid found only in plants of the *Digitalis* family and not in animals, which minimizes background. The sheep Fab fragment to the hapten is affinity purified and coupled to alkaline phosphatase. The company has used the digoxigenin system extensively in different types of kits to detect proteins, glycoproteins, and nucleic acids (UNIT 3.18). Lectin binding is simply an extension of this technology. The system has also been adapted to visualize glycoconjugates by light and electron microscopy (Sata et al., 1990).

The Lectin Link Kit (Genzyme) uses a biotinylated lectin and an alkaline phosphatase-avidin conjugate to visualize glycoproteins on the blot. The basic ABC (avidin-biotin conjugate) technology is well established in the literature for many assays. This kit as presented is primarily intended to identify and differentiate between various types of N-linked oligosaccharides. The conclusion that binding of any lectin is exclusively due to the presence of a particular structure on an N-linked oligosaccharide chain is valid only if all lectin binding is destroyed by PNGase F digestion (UNIT 17.13), because, except for Con A, no lectin is specific for N-linked oligosaccharides. It is important to note that not all N-linked oligosaccharides are sensitive to PNGase F (UNIT 17.13); resistance to PNGase F does not prove that a glycan is, by elimination, O-linked.

Anticipated Results

Even though lectins are quite specific, results are more qualitative than quantitative. The results obtained using lectins should be regarded as guides and preliminary indications of likely structures. Lectin-binding studies, especially when combined with a battery of enzymatic digestions, are useful experiments for preliminary characterization of glycoprotein structure because they are quick, reasonably

priced, and use only a few micrograms (or less) of purified sample material. However, they cannot substitute for the more precise structural and chemical analyses presented in other units in Chapter 17.

Inclusion of a positive control provides a qualitative and rough quantitative estimate for the amount of reactive material in the sample relative to the standards. This may be especially important in assessing the effects and completeness of exo- or endoglycosidase digestions. The problem with attempting accurate quantitation is that the intensity of staining will depend upon the binding affinity, the amount of protein, and the number of accessible glycans on the protein. All of these factors are important, and a high number of low-affinity binding sites present on a large quantity of protein can give an intensity on a blot similar to that of a single high-affinity binding site on a smaller amount of protein.

Two examples illustrate useful approaches for maximizing the information from lectin binding. In both, lectin-binding results first suggest the presence of certain types of carbohydrate chains on the protein. This information is used to design glycosidase digestions (UNIT 17.13) that should alter the binding of some or all of the lectins. Digested glycoproteins are probed with the lectins to confirm the predictions. All of the data are combined into a composite picture of the sugar chains present. To be conclusive, results of lectin binding and glycosidase digestions should be internally consistent. Because some of the glycosidases are themselves glycoproteins, controls should include a lane with glycosidase alone to identify bands due to the presence of glycosidase in the digested sample.

Example 1

A hypothetical purified glycoprotein reacts with wheat germ agglutinin (WGA) and *Sambucus nigra* agglutinin (SNA; see Table 17.7.2). WGA binds to terminal GlcNAc residues or sialic acids. Terminal GlcNAc may occur in complex N-linked oligosaccharides, such as those in ovomucoid, or as multiple residues of O- β -GlcNAc or GlcNAc-1-P directly bound to protein. Sialic acid could be present in α 2-3 or α 2-6 linkages to underlying β Gal residues on N- or O-linked chains. SNA binds to sialic acid linked α 2-6 to β Gal. One way to distinguish among the possibilities is to treat the sample with sialidase. Loss of WGA binding following sialidase treatment indicates that WGA binding is due to sialic acid and not terminal GlcNAc.

If both WGA binding and SNA binding are lost with PNGase F digestion, all of the WGA and SNA binding are due to the presence of sialic acids linked α 2-6 to β Gal residues on N-linked oligosaccharides.

Example 2

Experimental results from lectin and glycosidase digestion analysis of a hypothetical pu-

rified glycoprotein, glycoprotein, are shown in Figure 17.7.1. Undigested glycoprotein (panel A) produces a diffuse band when incubated with *Datura stramonium* agglutinin (DSA), *Ricinus communis* agglutinin (RCA I), and *Maackia amurensis* agglutinin (MAA) and a less diffuse band with SNA, but no band when incubated with Con A. Thus, all the lectins but Con A bind to glycoprotein. These data sug-

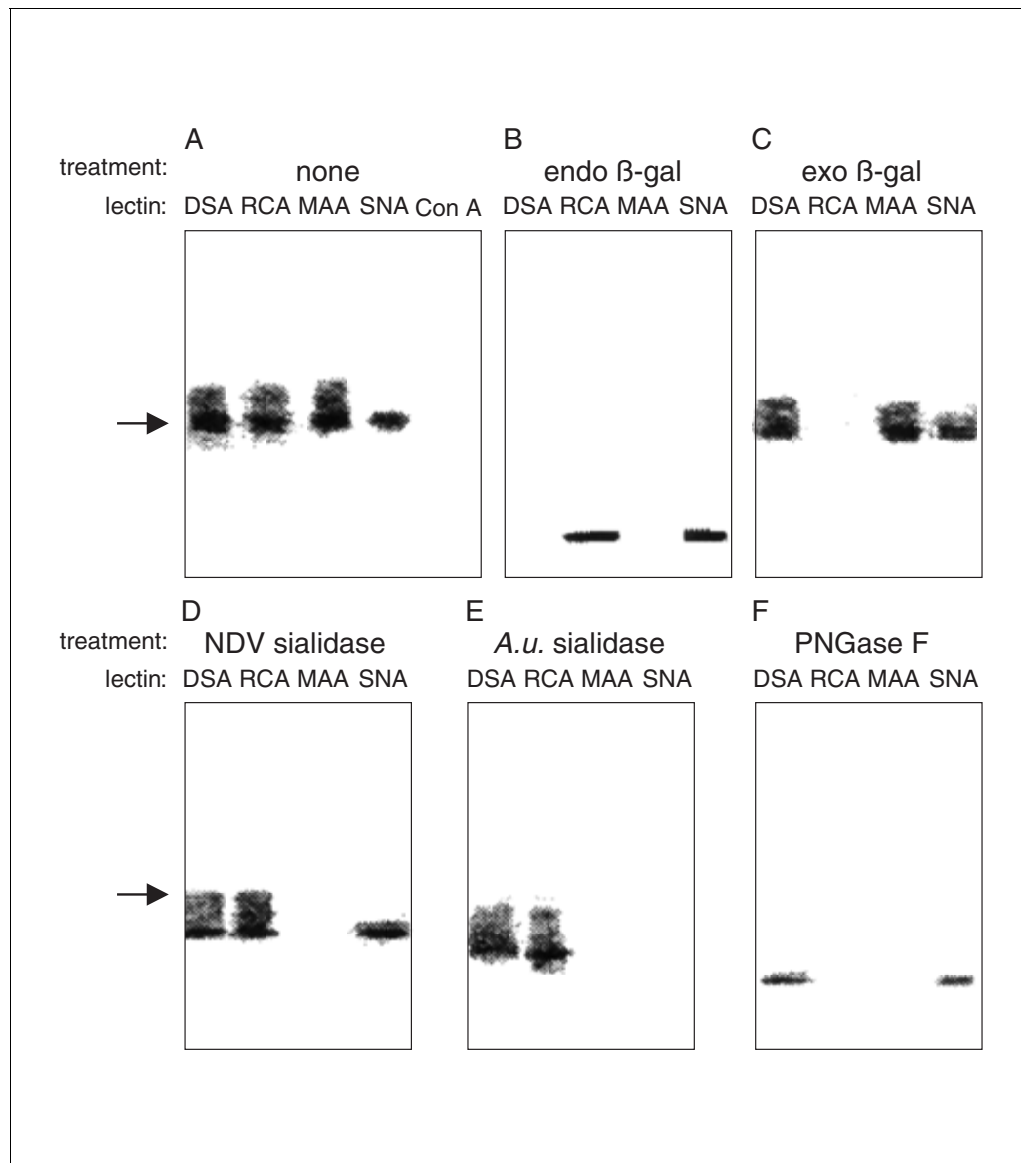

Figure 17.7.1 Example: Lectin blot analysis of a hypothetical purified glycoprotein, glycoprotein, using one of the procedures or kits described in this unit. All enzymatic digestions were conducted prior to lectin binding, and each lectin was previously tested on a positive control protein to check the reagents, developing conditions, etc. All samples of the test protein were run on SDS-PAGE, blotted onto nitrocellulose filters, blocked, and probed with the indicated lectins after the enzymatic treatment. Control lanes with glycosidase only control are not shown, but would normally be run. **(A)** Undigested glycoprotein. **(B)** Glycoprotein digested with endo- β -galactosidase. **(C)** Glycoprotein digested with exo- β -galactosidase. **(D)** Glycoprotein digested with Newcastle Disease Virus (NDV) sialidase. **(E)** Glycoprotein digested with the broad-spectrum sialidase from *Arthrobacter ureafaciens* (A.U.). **(F)** Glycoprotein digested with PNGase F. Arrow indicates the densest portion of the band for undigested glycoprotein.

gest that the glycoprotein may contain poly-lactosamine chains (DSA), terminal β -Gal residues (RCA I), and both α 2-3- and α 2-6-linked sialic acids (MAA and SNA, respectively). High-mannose type chains are probably absent (Con A).

This is useful information, but performing a few enzyme digestions and then probing with all of the lectins will provide much more. First, specific enzyme digestions should be done to show that each of the lectins is, in fact, binding to the expected sugar structure. Digestion with endo- β -galactosidase (panel B), which removes poly-lactosamine chains (UNIT 17.13), abolishes all bands in the DSA lane, showing that binding to DSA was due entirely to poly-lactosamine chains. The apparent M_r of the band has dropped and its boundaries have sharpened, showing that the poly-lactosamines contributed to the diffuse appearance of the original band. Glycoproteins often produce diffuse bands in gels and on blots because of microheterogeneity in the carbohydrate chains (UNIT 17.1). This digestion also destroys all of the MAA binding, suggesting that the poly-lactosamine chains, and only those chains, were terminated by α 2-3-linked sialic acids (UNIT 17.12). Bands are still observed in the RCA I lane, showing that terminal β -Gal residues were not digested, and in the SNA lane, showing that the poly-lactosamine chains do not terminate in α 2-6 sialic acids. If the digestion is done with exo- β -galactosidase (panel C), which removes terminal β -Gal residues (UNIT 17.18), it destroys the band in the RCA I lane but has minimal effects on the position and appearance of the other bands. This shows that the lectin was bound to the predicted terminal sugar residues. There are probably only a small number of these and they did not contribute much to the heterogeneity of the protein. Digestion with Newcastle Disease Virus (NDV) sialidase (panel D), which specifically removes α 2-3-linked sialic acids, abolished the binding of MAA, showing that MAA bound the α 2-3 sialic acid, as predicted. The significant reduction in the apparent size of the protein size shows that the sialic acids make a large contribution to the apparent size. Digestion with *Arthrobacter ureafaciens* sialidase (panel E), a broad-spectrum sialidase (UNIT 17.12), abolishes the bands in both the MAA and SNA lanes. Diffuse bands are still seen in the DSA and RCA I lanes; the apparent protein size is slightly smaller than in panel D, showing that the α 2-6-linked sialic acids make a relatively small contribution to the apparent size compared to those linked α 2-3. For each digestion

the bands are reduced in M_r and/or become sharper compared to those in the undigested glyco-biologin.

The final digestion (panel F) is with peptide N:glycosidase F (PNGase F), which removes essentially all N-linked chains; however, some are resistant (UNIT 17.13). Any lectin binding that is completely destroyed by this digestion is due only to components found on N-linked chains. PNGase F digestion of glyco-biologin completely abolishes the bands in the RCA I and MAA lanes but only partially reduces the intensity of the bands in the DSA and SNA lanes. The lack of binding to RCA I and MAA indicates that all of the β -Gal-terminated chains and those with α 2-3 sialic acids are exclusively N-linked (RCA I and MAA). Reduced binding to SNA indicates that some of the N-linked chains also contain α 2-6 sialic acid, which may also be found on O-GalNAc-linked chains. Reduced binding to DSA suggests either that the protein also contains poly-lactosamine units on both N- and O-linked chains or possibly that the PNGase F digestion was incomplete. The band is still diffuse because of residual poly-lactosamine chains. The apparent protein size is considerably smaller, showing that most of the heterogeneity was due to poly-lactosamine chains on N-linked oligosaccharides.

It is important to stress again that lectin blots give only preliminary evidence for the presence of the suggested structures. The results should be viewed as useful guides.

Time Considerations

Most enzymatic digestions are carried out overnight. If the proteins are separated on minigels, the entire analysis including blotting and development can be done in a single day. The procedure can be interrupted following protein transfer to nitrocellulose. Incubation in blocking buffer can be extended to overnight at 4°C.

Literature Cited

Detailed references regarding detection of the various types of conjugates are given in UNIT 10.8. Kit manufacturers will supply relevant references upon request. Much of their information may have been obtained exclusively from data produced in company laboratories, although some has also appeared in the peer-reviewed literature.

Detection of Glycophospholipid Anchors on Proteins

Many eukaryotic proteins are tethered to the plasma membrane by glycosyl phosphatidylinositol (GPI) membrane anchors. Figure 17.8.1 schematically depicts the minimal (core) structure common to all GPI protein anchors characterized to date. Detailed structural information is described in reviews by Cross (1990) and Ferguson (1991).

This unit provides a general approach for detecting GPI-anchored proteins. First, the detergent-partitioning behavior of a protein of interest is examined for characteristics of GPI-linked species. The partitioning of total cellular and isolated proteins with Triton X-114 is described in the first basic and alternate protocols, respectively. Precondensation of Triton X-114, necessary to remove hydrophilic contaminants before partitioning, is outlined in the first support protocol.

The protein may also be subjected to specific enzymatic or chemical cleavages to release the protein from its GPI anchor. Phospholipase cleavage is detailed in the second basic and alternate protocols, and chemical cleavage with nitrous acid is described in the third basic protocol.

If GPI-anchored proteins are radiolabeled with fatty acids, it facilitates the detection of the GPI protein products following the cleavage reactions. Separation of lipid moieties is described in the third support protocol and base hydrolysis of proteins is presented in the fourth basic protocol. Figure 17.8.2 is a flowchart depicting the relationships between the various protocols.

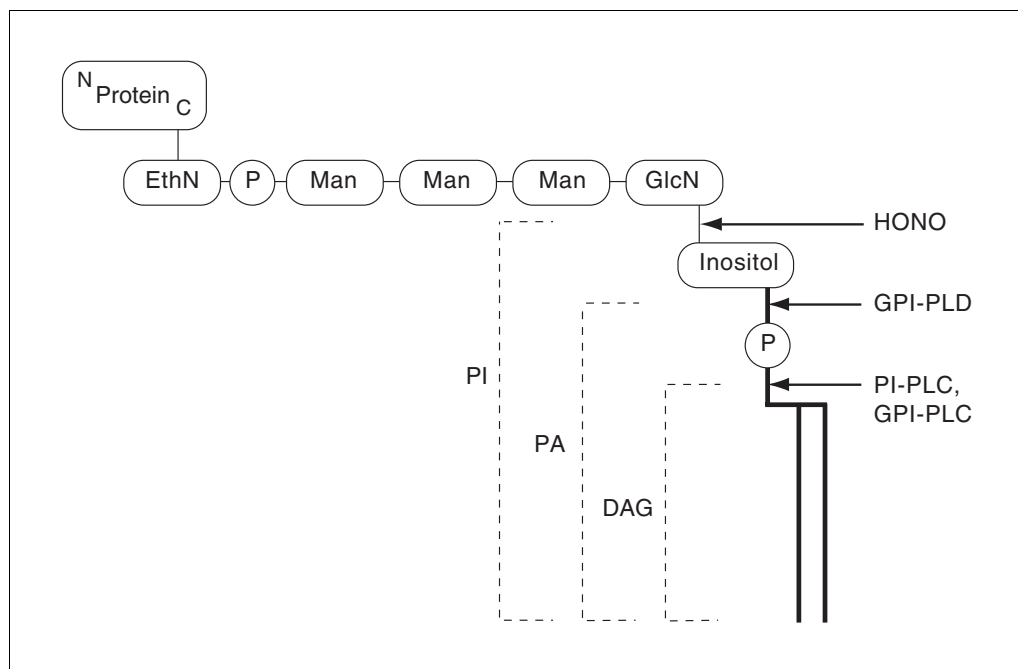

Figure 17.8.1 Schematic representation of the glycan core structure common to all GPI anchors. The sites of cleavage of phospholipase C enzymes (PI-PLC, GPI-PLC), phospholipase D (GPI-PLD), and nitrous acid (HONO) are indicated, as are lipid products resulting from these cleavages: PI (phosphatidylinositol), PA (phosphatidic acid), DAG (diacylglycerol). Other abbreviations: Man, mannose; GlcN, glucosamine; EthN, ethanolamine; P, phosphate group. Phospholipase C treatment generates inositol cyclic phosphate, the major epitope contributing to the cross-reacting determinant (CRD). Lipid products may vary from those depicted, depending on features of the anchor (see background information).

Preparation
and Analysis of
Glycoconjugates

17.8.1

Supplement 22

Strategic Planning

The techniques described below require that a method for identifying the protein of interest be available. Proteins may be visualized after one-dimensional gel electrophoresis (UNIT 10.2) and Coomassie blue or silver staining (UNIT 10.6), or they may be identified by immunoprecipitation (UNIT 10.16), or immunoblotting (UNIT 10.8) using available specific antibodies. Enzymes may also be detected by their known activities (e.g., see Kodukula et al., 1992).

It is extremely convenient, particularly for low-abundance species, to use proteins that are labeled with radioactive amino acids (UNIT 10.18) or GPI components (see Fig. 17.8.1). The ability to radiolabel proteins with GPI precursors such as fatty acids, ethanolamine, *myo*-inositol, and certain monosaccharide precursors (UNIT 17.4) is in itself suggestive of GPI anchorage. Because GPI-anchored proteins commonly represent a small fraction of eukaryotic glycoconjugates, metabolic radiolabeling may be inefficient. Tunicamycin (UNIT 17.10) may be used to increase relative incorporation of monosaccharide precursors into GPIs.

Rigorous identification of specific GPI anchor structures requires detailed analysis. These methods, which are beyond the scope of this unit, are described in Ferguson (1992).

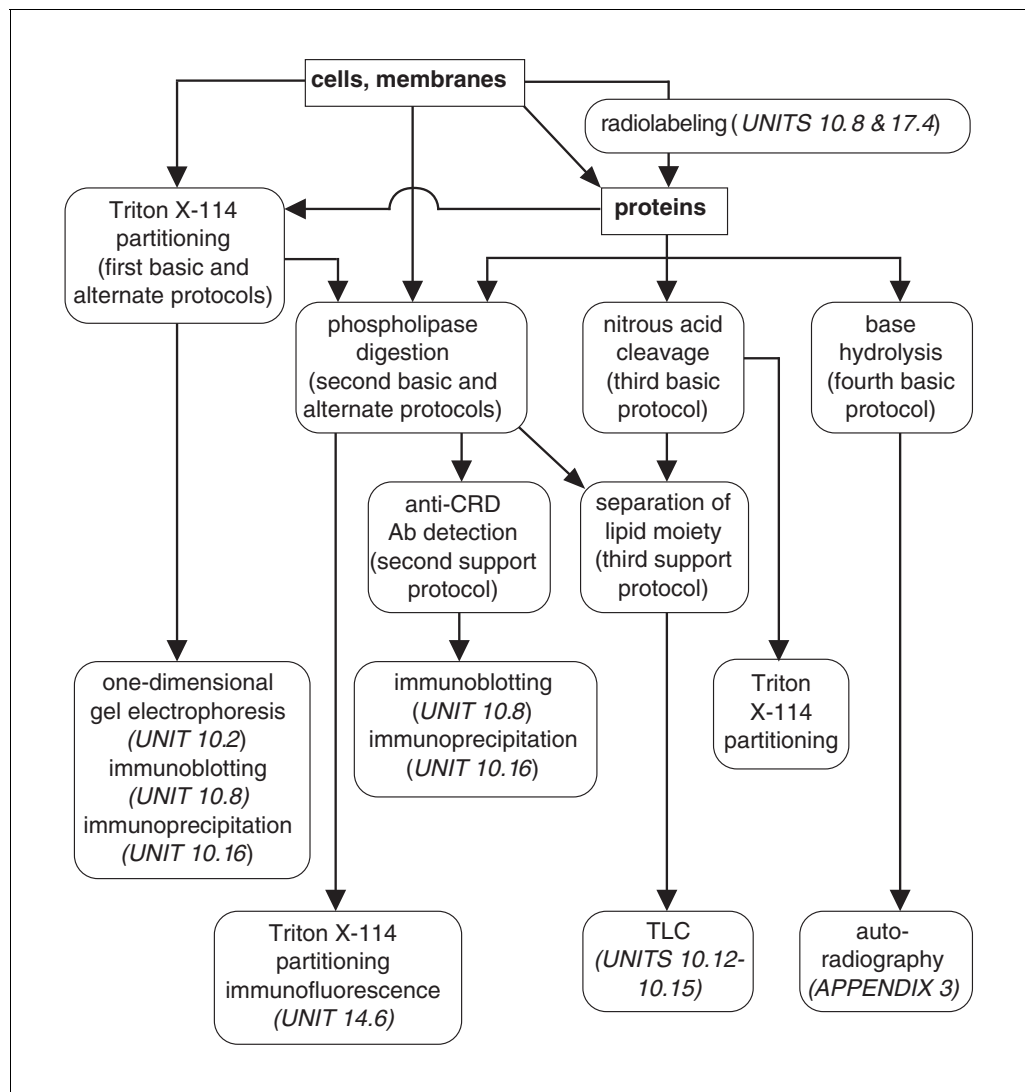

Figure 17.8.2 Flowchart for the detection of GPI-anchored proteins.

EXTRACTION AND PARTITIONING OF TOTAL PROTEINS FROM CELLS OR MEMBRANES WITH TRITON X-114

BASIC PROTOCOL

Extraction of cells or tissues with the detergent Triton X-114 provides a profile (and potentially an initial purification) of amphiphilic proteins, including integral membrane proteins and species bearing GPI anchors. Once a GPI-containing protein is released from the lipid component of its anchor, it will no longer partition into the detergent-enriched phase. This alteration of partitioning behavior provides a rapid assay for presence or absence of anchors. It may be used to monitor the changes in proteins produced by the other procedures.

In this protocol, cells or membrane fractions are first resuspended in TBS, then extracted with a Triton X-114 incubation on ice. The mixture is then warmed and separates into two protein-containing phases due to aggregation of detergent micelles (see background information). The upper (detergent-depleted) phase contains hydrophilic proteins; amphiphilic proteins (including those with GPI anchors) partition to the lower (detergent-enriched) phase. Both phases are then analyzed to clarify the group to which each protein belongs.

Materials

Cells, membrane fraction, or other source of protein
Tris-buffered saline (TBS), ice-cold
Precondensed Triton X-114 stock solution in TBS (support protocol), ice-cold
15-ml polypropylene centrifuge tubes
Centrifuges: low-speed (tabletop) and equipped with appropriate rotor (e.g., SS-34), at 4°C and room temperature

1. Resuspend cells (or membranes) in ice-cold TBS to a final protein concentration of ≤ 4 mg/ml in a 15-ml tube.

The amount of protein required is that which will give detectable levels at the end of the procedure and will depend on the system the individual researcher is using. As a guideline, use several times the amount of protein that is believed to be needed, to account for partitioning and losses (see critical parameters).

2. Add $\frac{1}{5}$ vol precondensed Triton X-114 stock solution ($\sim 2\%$ final concentration).
3. Extract cells by incubating 15 min on ice with occasional mixing.

At this point in the procedure there will only be one phase.

4. Centrifuge cell mixture 10 min at $10,000 \times g$ (9000 rpm in an SS-34 rotor), 4°C, and transfer supernatant to a fresh tube. Resuspend pellet in ice-cold TBS and save on ice for analysis in step 7.

The cold supernatant fraction contains both soluble and detergent-extracted proteins; the latter group includes proteins anchored by GPI structures or by transmembrane polypeptide domains. The pellet contains additional GPI species, as well as cell elements insoluble in nonionic detergents.

5. Warm supernatant fraction to 37°C in a water bath until the solution becomes cloudy.
6. Centrifuge the solution in a tabletop centrifuge 10 min at $1000 \times g$, room temperature. Collect upper and lower phases in separate tubes.

The upper phase (detergent-depleted) contains soluble proteins; the lower (detergent-enriched) phase contains proteins anchored by GPI structures or by transmembrane domains.

7. Analyze the resuspended pellet from step 4 and each phase from step 6 for the proteins of interest.

Preparation and Analysis of Glycoconjugates

17.8.3

As discussed in strategic planning, analysis may be by an activity assay, one-dimensional gel electrophoresis and staining of proteins (UNITS 10.2 & 10.6), or immunoprecipitation (UNIT 10.16) or immunoblotting (UNIT 10.8) using specific antibodies.

**ALTERNATE
PROTOCOL**

PARTITIONING OF ISOLATED PROTEINS WITH TRITON X-114

A modification to the basic protocol for Triton X-114 extraction of proteins from whole cells or membranes is used to partition isolated proteins.

1. Dilute or dissolve the protein in 1 ml ice-cold TBS in a 1.5-ml microcentrifuge tube. Add 0.2 ml Triton X-114 and mix.

See critical parameters for guidelines on the total amount of protein to use.

2. Warm protein mixture 15 min (or until it becomes cloudy) in a 37°C water bath. Microcentrifuge 5 min at maximum speed.
3. Collect the upper and lower phases and analyze each phase for the protein(s) of interest.

**SUPPORT
PROTOCOL**

PRECONDENSATION OF TRITON X-114 DETERGENT

Triton X-114 often contains hydrophilic contaminants, and must be precondensed by several rounds of phase separation before use.

Materials

Triton X-114 detergent
Tris-buffered saline (TBS)
50-ml centrifuge tubes
Tabletop centrifuge

1. Dissolve 1.5 g Triton X-114 in 50 ml TBS, place in a 50-ml centrifuge tube, then chill on ice.

At this point, the solution will be clear.

2. Warm the solution to 37°C in a water bath.

Following this warming, the solution will be turbid.

3. Centrifuge the solution in a tabletop centrifuge 10 min at 1000 × g, room temperature.
4. Remove and discard the upper (detergent-depleted) phase and redissolve the lower (detergent-enriched) phase in an equal volume of ice-cold TBS.

Hydrophilic contaminants partition into the upper phase.

5. Repeat partitioning (steps 2 to 4) three times.

The final detergent-enriched phase contains ~12% detergent. It may be stored at 4°C for routine use or frozen for long-term storage.

IDENTIFICATION OF GPI-ANCHORED PROTEINS BY PI-PLC DIGESTION OF INTACT CELLS

BASIC PROTOCOL

Phospholipase C (PLC) cleaves within the GPI membrane anchors (see Fig. 17.8.1) of glycoproteins, causing the release of protein from cell membranes. In this protocol, intact cells are digested with phosphatidylinositol-specific phospholipase C (PI-PLC). Following incubation with the enzyme, the cell mixture is centrifuged and both the resulting pellet and supernatant are analyzed for the presence of the protein of interest. Proteins released from GPI anchors are found in the supernatant; lack of release may indicate absence of a GPI anchor, modification of the GPI protein, or other factors (see background information).

Materials

- Cells (or membrane preparation)
- Bacterial phosphatidylinositol-specific phospholipase C (PI-PLC; e.g., from *Bacillus thuringiensis*, Oxford Glycosystems)
- Hanks balanced salt solution (HBSS; GIBCO/BRL), buffered saline, or culture medium
- Tabletop centrifuge and appropriate centrifuge tubes

1. Obtain cells (or membranes) of interest in dispersed suspension. Wash duplicate aliquots twice in HBSS, buffered saline, or culture medium, then resuspend in any of these solutions.

The final protein concentration of the samples (typically 0.1 to 0.5 mg/ml) should be based on supplier specifications for the enzyme preparation used. See critical parameters for guidelines on the total amount of protein to use.

2. Add bacterial PI-PLC to one aliquot. Add no enzyme to the second aliquot (control). Incubate tubes 1 hr at 37°C.

The amount of enzyme should be determined by supplier recommendations.

3. Centrifuge cells in a tabletop centrifuge 5 min at 1000 × g. Remove each supernatant to a fresh tube and save for analysis in step 4. Resuspend pellet in a volume of buffered saline equal to the volume of supernatant removed.

4. Assay supernatant and pellet fractions for protein(s) of interest.

The proteins may be assayed by Triton X-114 detergent partitioning (first basic protocol), one-dimensional gel electrophoresis (UNIT 10.2) followed by Coomassie blue or silver staining (UNIT 10.6), immunoprecipitation (UNIT 10.16) or immunoblotting (UNIT 10.8)

IDENTIFICATION OF GPI ANCHORAGE BY PHOSPHOLIPASE TREATMENT OF ISOLATED PROTEINS

ALTERNATE PROTOCOL

Several specific phospholipases that effectively degrade only GPI species are useful for analyzing GPI anchorage of isolated proteins (see background information). In this protocol, aliquots of the protein are digested in parallel with the following phospholipases: bacterial phosphatidylinositol-specific phospholipase C (PI-PLC), a GPI-specific phospholipase C (GPI-PLC) from *Trypanosoma brucei*, and a GPI-specific phospholipase D (GPI-PLD) from mammalian serum (rat, rabbit, or human). Proteins are partitioned by Triton X-114 extraction (first alternate protocol), then analyzed. Specific cleavage of proteins by phospholipase treatment strongly indicates GPI anchorage.

Preparation and Analysis of Glycoconjugates

17.8.5

Materials

Isolated protein

Acetone, -20°C

Appropriate enzyme buffer: GPI-PLD buffer, GPI-PLC buffer, and PI-PLC buffer

Phospholipase enzyme: GPI-PLD from rat, rabbit or human whole serum, GPI-PLC from *Trypanosoma brucei* (Oxford GlycoSystems), and PI-PLC from *Bacillus thuringiensis* (Oxford GlycoSystems) or *B. cereus* (Boehringer Mannheim or Sigma)

Tris-buffered saline (TBS)

Precondensed Triton X-114 solution (first support protocol)

Centrifuge and rotor (e.g., SS-34)

1. If the protein sample is lyophilized or concentrated in a buffer similar to the phospholipase buffers, begin at step 3. If it is not, acetone-precipitate the protein by adding 8 vol cold (-20°C) acetone to the protein solution and incubating it ≥ 3 hr at -20°C .

See critical parameters for guidelines on the total amount of protein to use. For low-abundance material, efficiency of precipitation may be increased by including 15 μg of a carrier protein (e.g., cytochrome c or bovine serum albumin).

2. Centrifuge the sample 20 min at $15,000 \times g$ ($\sim 11,000$ rpm in an SS-34 rotor), 4°C . Aspirate supernatant and allow pellet to air dry.
3. For each enzyme to be tested, dissolve two aliquots of the protein in 100 μl of the appropriate enzyme buffer in microcentrifuge tubes.
4. To one aliquot from each pair add the appropriate enzyme. Add an equal volume of the appropriate enzyme buffer to the second aliquot (control). Mix tubes and incubate 1 hr at 37°C .

The amount of enzyme added should be based on the activity of the lipase preparation (see supplier specifications) and the estimated amount of protein present. It may be desirable to titrate the enzyme, using various amounts in parallel reactions, to be sure that all sensitive proteins are completely digested.

GPI-PLD is not generally available, but whole serum (rat, rabbit or human) may serve as a source of this activity. Aliquots of serum may be stored frozen and thawed before use. For the assay, use 2 μl whole serum in a 100- μl reaction.

5. Dilute reaction with 200 μl ice-cold TBS, then add 60 μl Triton X-114. Chill 15 min on ice.
6. Partition the proteins as in steps 2 and 3 of the first alternate protocol.

GPI-anchored proteins partition into the detergent-enriched phase of Triton X-114 in the control reaction (uncleaved) and into the detergent-depleted phase after cleavage of the GPI anchor by phospholipase.

7. Analyze each phase for the presence of protein(s) of interest as in step 7 of the first basic protocol.

Alternatively, cleavage products can be detected by reactivity with α -CRD antibody (second support protocol) and, if the anchor is radiolabeled with fatty acids (UNIT 17.4), by separation of radiolabeled lipid products.

Migration of phospholipase-digested proteins on gel electrophoresis is not predictable and should not be used alone to assess cleavage. No shift, or a shift in either direction (relative to uncleaved protein migration) may be observed upon GPI anchor removal, depending on the properties of the protein.

DETECTION OF PRODUCTS AFTER PHOSPHOLIPASE TREATMENT BY REACTIVITY WITH ANTI-CRD ANTIBODY

SUPPORT
PROTOCOL

Cleavage of GPI structures with phospholipase C reveals a cryptic antigen termed the cross-reacting determinant (CRD). The major epitope contributing to the CRD is an inositol 1,2-(cyclic) monophosphate formed during phospholipase C cleavage; other structural features may also contribute to the antigenicity. Reactivity of a protein with anti-CRD antibody after solubilization by phospholipase C strongly indicates the presence of a GPI anchor. Anti-CRD antibody (Oxford GlycoSystems) may be used after phospholipase C treatment to immunoprecipitate (UNIT 10.16) or immunoblot (UNIT 10.8) proteins of interest. It should be noted that phospholipase D cleavage does not create the epitope required for α CRD activity (see Fig. 17.8.1).

NITROUS ACID CLEAVAGE OF GPI-ANCHORED PROTEINS

BASIC
PROTOCOL

An unusual property common to all GPI structures is the presence of a nonacetylated glucosamine that is glycosidically linked to inositol. The glycosidic bond is specifically cleaved when the glucosamine undergoes nitrous acid deamination, thereby cleaving the GPI anchor (see Fig. 17.8.1). Because nonacetylated glucosamine rarely occurs outside of GPIs, nitrous acid deamination may be used to identify GPI linkage to protein. Due to side reactions, deamination is not always quantitative or precisely reproducible, but it does serve a useful diagnostic purpose.

In this protocol, the protein is incubated in nitrous acid to cleave the GPI anchors. Cleaved and uncleaved proteins are then separated by Triton X-114 partitioning.

Materials

Protein(s)
0.1 M acetate buffer, pH 3.5
0.5 M NaNO₂, made fresh
0.5 M NaCl

1. Dry two aliquots of the protein of interest in microcentrifuge tubes and dissolve each in 0.1 ml of 0.1 M acetate buffer, pH 3.5.

See critical parameters for guidelines on the total amount of protein to use.

Nonidet P-40 (NP-40) detergent (0.1% v/v final) may be added to aid solubilization.

2. Add 0.1 ml of 0.5 M NaNO₂ to one tube. To the second tube (control), add 0.1 ml of 0.5 M NaCl. Incubate 3 hr at room temperature.
3. Detect the release of protein from GPI anchor by partitioning and analyzing the reaction products as in the first alternate protocol (Triton X-114 partitioning of isolated proteins).

If the anchor is radiolabeled with fatty acids (UNIT 17.4), the support protocol for separation of lipid moiety may be used.

Preparation
and Analysis of
Glycoconjugates

17.8.7

**SEPARATION OF LIPID MOIETY TO DETECT CLEAVAGE OF
GPI-ANCHORED PROTEINS**

If GPI-anchored proteins are radiolabeled with fatty acids, the efficacy of GPI anchor cleavage may be conveniently assessed by examining the released radiolabeled lipid products (see Fig. 17.8.1). In this protocol, radiolabeled proteins that have been cleaved by phospholipase or nitrous acid treatment are extracted with butanol. Released lipid moieties are extracted into the butanol phase and are analyzed and quantitated.

Materials

Radiolabeled protein, cleaved by phospholipase or nitrous acid treatment (second alternate and third basic protocols)

Water-saturated *n*-butanol

1. Add 100 μ l water to each of two 1.5-ml microcentrifuge tubes. To one tube, add 100 μ l cleaved radiolabeled protein. To the second, add 100 μ l control (uncleaved) protein.
2. Add 200 μ l water-saturated *n*-butanol to each tube and vortex vigorously.
3. Microcentrifuge 30 sec at maximum speed, room temperature, to separate the two phases.
4. Remove the upper (butanol) phase to a fresh tube, and set aside. Add another 200 μ l of water-saturated butanol to the original tubes.
5. Vortex and centrifuge as in steps 2 and 3 above.
6. Remove the second butanol phase and pool it with the first, retaining the lower (aqueous) phase for analysis.
7. Quantitate the percentage of lipid moieties released by the cleavage reactions by liquid scintillation counting of both butanol and aqueous phases. Compare counts recovered in butanol phases of the cleaved material with those recovered from control reactions to assess specific release.

To characterize released products fully, examine the butanol-extracted products by thin layer chromatography; compare to standards (Doering et al., 1990b). Products of phospholipase C digestion include diacylglycerol, alkyl-acyl glycerol, or ceramide, depending upon the original structure. Phosphatidylinositol (from nitrous acid treatment) or phosphatidic acid (released by phospholipase D) may also be analyzed and quantitated. This assay has been used for purification of phospholipase activity (Hereld et al., 1986).

BASE HYDROLYSIS OF RADIOLABELED PROTEINS

For proteins radiolabeled with fatty acids, it is useful to ascertain whether incorporated fatty acids are actually part of a GPI structure or are present in amide linkage (N-myristoylation) or thioester linkage (as in palmitoylation of cysteine residues). This can be characterized by assessing the lability of the fatty acid linkage to various chemical treatments.

In this protocol, aliquots of radiolabeled proteins are resolved by electrophoresis and the various lanes are treated with KOH in methanol or hydroxylamine. Methanol and Tris buffer are used to treat the control lanes. The lanes are then processed for fluorography. If the chemical bonds in the protein are susceptible to these treatments, a radiolabeled signal will no longer be produced at the protein band of interest.

Materials

Protein radiolabeled with fatty acid
0.2 M KOH in methanol
Methanol
1 M hydroxylamine-HCl, pH 7.5, made fresh
1 M Tris·Cl, pH 7.5 (APPENDIX 2)

Additional reagents and equipment for one-dimensional gel electrophoresis (UNIT 10.2), staining of gels (UNIT 10.6), and autoradiography (APPENDIX 3)

1. Resolve five identical samples of protein radiolabeled with fatty acid by SDS-PAGE electrophoresis. Include appropriate markers.
2. Cut apart the five gel lanes, and stain one to visualize protein and markers.
3. Soak the other four lanes in one of the following solutions for 1 hr at room temperature:
 - Lane 1: 0.2 M KOH in methanol
 - Lane 2: methanol alone
 - Lane 3: 1 M hydroxylamine-HCl, pH 7.5
 - Lane 4: 1 M Tris·Cl, pH 7.5
4. Soak the treated gel slices in three washes (10 min each) of water.
5. Process gel pieces for autoradiography.

If bonds are susceptible to the treatments above, radiolabel from fatty acids will no longer produce a signal at the position of the protein band of interest. KOH in methanol cleaves thio- and oxyesters but not amide linkages. Hydroxylamine treatment cleaves thioesters only. Fatty acids that are part of a GPI moiety will be released by KOH in methanol, but not by hydroxylamine treatment. The methanol and Tris·Cl treatments serve as controls. Ceramide-containing anchors are not sensitive to mild base treatment (see anticipated results and Conzelmann et al., 1992).

REAGENTS AND SOLUTIONS

0.1 M acetate buffer, pH 3.5

Dissolve 0.82 g sodium acetate in 95 ml distilled water. Adjust pH to 3.5 with acetic acid, then bring volume to 100 ml with distilled water. Store indefinitely at room temperature.

GPI-PLC buffer

50 mM Tris·Cl, pH 8.0
5 mM EDTA
1% NP-40
Store indefinitely at 4°C

GPI-PLD buffer

50 mM Tris·Cl, pH 7.4
10 mM NaCl
2.5 mM CaCl₂
0.1 % NP-40
Store indefinitely at 4°C

1 M hydroxylamine-HCl, pH 7.5

Dissolve 6.95 g hydroxylamine-HCl in 95 ml distilled water. Adjust pH to 7.5 with NaOH, then increase volume to 100 ml with water. Make fresh for each use.

PI-PLC buffer (for *B. thuringiensis* enzyme)

25 mM Tris acetate, pH 7.4
0.1% (w/v) sodium deoxycholate (Na-DOC)
Store indefinitely at 4°C

Tris-buffered saline (TBS)

10 mM Tris-Cl, pH 7.5
150 mM NaCl
Store indefinitely at room temperature

Water-saturated n-butanol

Mix equal volumes of distilled water and *n*-butanol. Cap tightly and shake vigorously. Let stand to allow phases to separate; the upper phase is the butanol. Store indefinitely at room temperature.

COMMENTARY

Background Information

Glycosyl phosphatidylinositol (GPI) membrane anchors are one mode of anchoring proteins to cell surfaces. These structures consist of a glycan bridge between phosphatidylinositol and phosphoethanolamine; the phosphoethanolamine is in amide linkage to the C-terminus of the protein (see Fig. 17.8.1). The glycan core of GPIs (shown schematically in Fig. 17.8.1) is remarkably conserved throughout evolution, although it is modified in many cell types by the addition of side chains. The lipid moieties of GPIs, however, are quite heterogeneous. This portion may consist of diacyl glycerol, alkyl acyl glycerol, *lyso*-acyl compounds, or ceramide. The hydrocarbon chains also vary in length and degree of saturation, and may be present as mixtures of species. GPI structures are reviewed in Ferguson (1991).

Much of our understanding of GPI anchors is derived from studies of the variant surface glycoprotein (VSG) of trypanosomes. Early work showed that VSG is associated with the membrane via a lipid moiety that contains dimyristoyl phosphatidylinositol (Cardoso de Almeida and Turner, 1983; Ferguson and Cross, 1984; Ferguson et al., 1985, 1986). Other investigations had shown that bacterial phospholipase C releases certain proteins from cell membranes (reviewed by Low, 1989). Together, these studies led to the definition of a class of proteins bearing a C-terminal glycolipid anchor.

Further investigations in this field have led to the elucidation of the pathway of GPI biosynthesis (reviewed by Doering et al., 1990a; Field and Menon, 1991), the purification of a GPI-specific phospholipase C (GPI-PLC), and the development of anti-cross-reacting determinant (anti-CRD) antibodies as probes for

GPIs. Phosphatidylinositol-specific phospholipase C (PI-PLC) and GPI-specific phospholipase D (GPI-PLD) are also useful in identification of GPI-anchored proteins.

The protocols included here are designed to allow identification of GPI-anchored proteins without detailed structural analysis. Because these techniques are rather diverse, further explanatory information is outlined below.

Triton X-114 partitioning. Triton X-114 forms a clear micellar solution at low temperatures; the solution separates into two phases when warmed above 20°C, due to aggregation of detergent micelles (Bordier, 1981). When cellular material is extracted in Triton X-114 at low temperatures, the solution contains soluble proteins, integral membrane proteins, and GPI-anchored proteins. Centrifugation results in a pellet containing some of the GPI-anchored species as well as cellular components that are insoluble in nonionic detergents (Hooper and Bashir, 1991). When the detergent solution is warmed, amphiphilic proteins (including those with GPI anchors) associate with the detergent-enriched phase, while hydrophilic ones partition to the detergent-depleted phase. Some GPI-anchored proteins exhibit detergent insolubility that develops shortly after synthesis (Brown and Rose, 1992); this is thought to be due to aggregation of the anchored proteins with glycosphingolipids, possibly as a step in directed protein transport.

Once a GPI-containing protein is released from the lipid component of its anchor, it will no longer partition into the detergent-enriched phase. This alteration of partitioning behavior provides a rapid assay for the presence or absence of anchors. It may be used to monitor the changes in proteins produced by the other procedures.

Phospholipase digestion. Bacterial phosphatidylinositol-specific phospholipase C (PI-PLC) efficiently cleaves GPI anchors, releasing proteins in aqueous soluble forms. This enzyme also cleaves phosphatidylinositol (PI), *lyso*-PI, and PI-linked glycans. Proteins specifically released from membranes by PI-PLC have all been found to be GPI-anchored, making this an extremely reliable mode of analysis (for review see Ikezawa, 1991).

Several other specific phospholipases that effectively degrade only GPI species are also useful for analysis. These enzymes are generally more expensive than PI-PLC. One of these, initially purified from *Trypanosoma brucei*, is a GPI-specific phospholipase C (GPI-PLC). Another, present in mammalian serum (rat, rabbit, or human), is a GPI-specific phospholipase D (GPI-PLD). These enzymes are convenient tools for identifying the presence of a GPI anchor.

Release of a protein from its GPI anchor is followed by using appropriate protein detection methods—e.g., enzyme activity assays, electrophoretic separation (UNIT 10.2) followed by protein staining (UNIT 10.6), and, if specific antibodies are available, immunoprecipitation (UNIT 10.16) or immunoblotting (UNIT 10.8). Alternatively, treated cells may be studied for loss of a specific protein using immunofluorescence detection methods (UNIT 14.6), including fluorescence-activated cell sorting. Also, because release by PLC reveals a specific epitope (termed the cross-reacting determinant, or CRD), antibodies directed against this epitope may be employed to identify cleavage products resulting from PLC treatment (second support protocol).

Lack of release may indicate absence of a GPI anchor, although some caution is required in interpreting negative results. Certain GPI molecules, bearing an additional fatty acid on inositol, are not susceptible to cleavage by either bacterial PI-PLC or trypanosomal GPI-PLC. Some proteins are partly sensitive, suggesting that only a fraction of these polypeptides bear anchors with acyl-inositol. Serum phospholipase D (GPI-PLD) cleaves GPI structures that contain acylated inositols, and is useful in their identification. However, it is not effective on membrane-bound proteins in the absence of detergent.

When intact cells are treated with phospholipase, partial or total resistance to cleavage can also occur due to inaccessibility of the protein to the enzyme, expression of a protein on the cell surface in both GPI-anchored and trans-

membrane-anchored forms, or tight association of a protein with a nonsusceptible protein on the cell surface (reviewed by Rosenberry, 1991).

Critical Parameters

Some details of these procedures will be affected by the method used to detect each protein under study. For example, specific quantities of starting materials are not provided because detection methods vary widely in terms of sensitivity. Also, for activity assays, the conditions of each procedure and whether the activity would survive such treatment must be considered. In general, plan to use two to ten times the amount of protein that would be reasonable for the mode of detection employed, depending upon the availability of material. This should allow for potential losses sustained during the procedure, as well as for the fact that proteins may be recovered in several fractions.

Triton X-114 partitioning provides a first hint of GPI anchorage, although transmembrane domains are also concentrated in the detergent phase of this partition. For example, if a protein is known from sequence data to have no membrane-spanning domain, its detection in the detergent phase of a Triton X-114 partition would be suggestive of lipid modification. In general, however, this method is most useful as a means of assessing release of a protein from its anchor, as shown by an alteration of partitioning behavior. Many of the other methods described specifically release proteins from their anchors to demonstrate GPI-linkage (e.g., nitrous acid deamination or phospholipase digestion); Triton X-114 is a convenient tool for assessing such release. Triton X-114 often contains hydrophilic contaminants, and should be precondensed by several rounds of phase separation before use (Bordier, 1981).

Phospholipase digestion is useful for determining GPI linkage, and bacterial PI-PLC is perhaps the best enzyme to try initially for reasons of cost and efficacy. Although GPI-PLC is more specific, it is generally more expensive.

Some GPI anchors are not susceptible to cleavage by phospholipase C. These structures have an additional fatty acid covalently attached to the inositol of the anchor (Rosenberry, 1991). For this reason, failure of cleavage by PLC does not necessarily imply that a protein is not GPI-anchored. In such cases GPI-PLD may be useful, although this enzyme does not expose the epitope for anti-CRD detection. Ex-

traction and analysis of radiolabeled lipid products from phospholipase digestions provides rapid assessment of cleavage. As mentioned earlier, radiolabeling the protein of interest is often helpful and permits less material and reagents to be used. In particular, if a protein may be radiolabeled with fatty acids, base hydrolysis is a helpful analytical tool, especially if lipid modification is suspected but other methods have yielded negative results.

Anticipated Results

Proteins anchored by GPI structures without acylated inositols should require detergent for solubilization. They may be extracted by Triton X-114 or remain in the cell pellet after such extraction (depending on solubility properties of the protein). In a warmed Triton X-114 solution, anchored protein(s) partition into the detergent-enriched phase. These proteins can be chemically cleaved by nitrous acid deamination, and enzymatically hydrolyzed by treatment with GPI-PLC, PI-PLC, or GPI-PLD. The protein cleaved with PLC will react with α -CRD antibody, and appropriate lipid products will be generated from all cleavage reactions (Fig. 17.8.1). Radiolabel incorporated into the anchor as fatty acid is released by treatment with KOH in methanol, but not by hydroxylamine treatment, if the fatty acid is hydroxy-esterified to glycerol (as in diacyl or alkyl-acyl anchors). Some PI-PLC and nitrous acid-sensitive anchors have been found to contain ceramide instead of diacyl or alkyl-acyl glycerol (e.g., in yeast). These anchors are resistant to mild base treatment, but are sensitive to conditions that hydrolyze amides (Conzelmann et al., 1992).

If the GPI anchor includes an acylated inositol, the above characteristics will hold true except that PLC treatment will not cleave the anchor. In these cases, nitrous acid deamination, GPI-PLD digestion, and radiolabel studies are used to characterize the linkage.

Time Considerations

In general, the methods described above are fairly rapid, with enzyme incubations or chemical reactions and subsequent partitioning requiring 1 to 2 hr. The time required for completion of these analyses depends primarily on the method used to detect the protein(s) of interest. For example, if a protein is radiolabeled in the fatty acid portion of the anchor, cleavage may

be assessed by lipid extraction and scintillation counting in ≤ 1 hr. If immunoprecipitation or immunoblotting is used for product detection, analysis will be more lengthy.

Direct Chemical Analysis of Glycoconjugates for Carbohydrates

The following unit presents protocols for detection of different sugars bound to glycoconjugates. The solution containing the carbohydrate material is treated with a specific reagent, generating a colored reaction product that can be detected spectrophotometrically. For each assay, the absorbance of the colored solution is proportional to the amount of sugar present in the glycoconjugate.

BASIC PROTOCOL 1

PHENOL–SULFURIC ACID ASSAY FOR HEXOSES AND PENTOSES

This protocol describes the use of the phenol–sulfuric acid colorimetry to quantitatively determine the total level of hexoses or pentoses and their derivatives in an experimental sample. Monosaccharide samples of known concentration are used to construct a standard curve for comparison. The assay is optimized for use with small samples.

NOTE: Distilled or deionized water and high-quality sulfuric acid must be used for this procedure, as contamination of these reagents may lead to a false-positive result. It is advisable to check each new bottle of sulfuric acid and the water being used as described in steps 2 to 8 before using them for the assay. Both reagents should show an absorbance <0.05 (measured against water that has not been submitted to the assay).

Materials

- Sample to be assayed
- Monosaccharide standard: e.g., D-(+)-galactose (Sigma, purified-grade anhydrous crystals; Critical Parameters)
- 5% (w/v) phenol (see recipe)
- Concentrated sulfuric acid (ACS reagent-grade)
- Thick-walled, 16 × 125–mm Pyrex test tubes, either brand new and washed with distilled water, or acid washed
- Automatic glass dispenser *or* glass pipet with a portion of the tip removed for rapid flow, suitable for use with concentrated sulfuric acid
- 1.0-ml glass cuvettes (1-cm path length)
- Visible-light spectrophotometer

1. Dissolve sample in water or buffer at an appropriate concentration to 300 or 450 μ l final volume (for duplicate or triplicate samples, respectively).

The sample is dissolved in a new or acid-washed tube.

The quantity of sample dissolved must be such that the sugar concentration is ≥ 10 ng/ml. If insufficient data are available about the sample to estimate its sugar concentration, it is advisable to assay two solutions having at least a ten-fold difference in concentration. Depending on the results, it may be necessary to increase or reduce the concentration to obtain absorbance in the linear range of the assay (0.1 to 0.8). Volumes can be varied according to the quantity of material available as long as the proportions of reagents described are maintained.

2. Transfer two 150- μ l aliquots of the dissolved sample (or three if possible) into new or acid-washed 16 × 125–mm Pyrex test tubes.

If the sample volume is scaled up or down, the test tube used must have a volume considerably higher than the final volume of reaction mixture to reduce the chance of spilling concentrated sulfuric acid. The use of wide-mouth tubes slows dissipation of the heat (produced by the exothermic reaction between sulfuric acid and water) that is required for color development.

3. Set up three blank tubes using 150 μ l sample solvent (water or buffer; see step 1) in each.
4. In triplicate, prepare a series of tubes containing 10, 20, 30, 40, 50, 60, 70, and 80 ng/ μ l of the monosaccharide standard in sample solvent. Adjust all volumes to 150 μ l with water.

To minimize errors, prepare a stock solution of the standard and make sequential dilutions. Keep stock solutions at -20°C .
5. Add 150 μ l of 5% (w/v) phenol solution to each tube and vortex briefly to mix.

CAUTION: *Rubber gloves and eye protection must be worn while performing steps 6 to 8, which involve handling of concentrated sulfuric acid and generation of heat.*
6. Rapidly add 750 μ l concentrated sulfuric acid to each tube, using an automatic glass dispenser or a glass pipet with a portion of the tip removed. Ensure that the acid stream hits the liquid surface directly to produce rapid mixing and even heat distribution. Let tubes stand 10 min at room temperature.
7. Vortex tubes again briefly to mix. Let stand 30 min at room temperature while the color develops.

The color is stable for an additional several hours.
8. Transfer the solution from each tube to a 1.0-ml (1-cm path length) glass cuvette. Using the spectrophotometer, read the absorbance of each tube at 480 nm (to detect pentoses, uronic acids, and their methylated derivatives) and/or 490 nm (to detect hexoses and their methylated derivatives).

Care must be taken when transferring the solutions to the cuvettes. Any spill inside the spectrophotometer should be cleaned up immediately, as the corrosive sulfuric acid will damage the instrument.
9. Average the absorbances of the triplicate tubes for each standard. Subtract the absorbance of the blank from each average. Prepare a standard curve of absorbance versus concentration in ng/ μ l for each absorbance (A_{480} or A_{490}) that was monitored.
10. Average the absorbance of the duplicate or triplicate sample tubes and subtract the absorbance of the blank. Determine the amount of sugar in the sample by reference to the standard curve.

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

Phenol, 5% (w/v)

Dissolve 5 g of 99% phenol crystals in water and bring the volume to 100 ml with water. Store solution in a dark bottle at room temperature (stable indefinitely).

CAUTION: *Use gloves and eye protection when weighing phenol, as it is very corrosive. Store the crystals in a dark bottle at 4°C to prevent oxidation.*

Commentary

Background Information

The phenol–sulfuric acid assay for detecting sugars has been widely used since it was first developed by Dubois et al. (1956). The method is simple, rapid, sensitive, accurate, specific for carbohydrates, and widely applicable. Most

sugars (except hexosamines; see **UNIT 17.11**), sugar derivatives, oligosaccharides, and polysaccharides react with these reagents. The assay is based on the fact that when carbohydrates are heated in the presence of strong acids, they are converted into furfural and its homologs by

oxidation, reduction, and condensation processes. These products can react with organic substances such as phenol to form colored compounds. The type and ratio of the reaction products varies from carbohydrate to carbohydrate and also depends on reagent concentrations, temperature, and time of heating. Although the exact composition of the colored products is indeterminate, the assay has been standardized and the results obtained for each type of carbohydrate are highly reproducible. The reagents are inexpensive, readily available, and stable.

Critical Parameters and Troubleshooting

The monosaccharide used as a standard for constructing the standard curve should be chosen to match the expected composition of the sample, as different individual monosaccharides will give different results. For glycoproteins of animal origin, galactose can be used as the standard. The assay will certainly indicate whether carbohydrates are present in a sample, and will give an idea of its percentage (quantitation). However, when assaying unknown complex carbohydrates, it is not possible to select the exact matching standard, and the values obtained will only be approximate.

Triplicate measurement minimizes errors. For accurate and reproducible results, it is important to use brand-new test tubes that have been rinsed with distilled water to eliminate any lint or paper fiber, or tubes that have been acid-cleaned and rinsed. Accidental contamination with lint may still occur, producing high readings, but the use of triplicate tubes makes it possible to identify and discard such false-positive tubes.

If the assay is used to check the elution profile of a carbohydrate-containing sample

eluted from a column, the buffers and column eluant must first be tested for positive reactions. With columns packed with carbohydrate-based polymers (e.g., Sephadex, Pharmacia), any breakdown of the packing material will cause an extremely intense color in the assay. Buffers used for elution may also contain sugar-bearing contaminants such as bacteria, in which case fresh lots should be prepared before attempting this kind of monitoring. The blank should contain buffer eluted from the column prior to the sample. If organic solvents are present, they must be removed by evaporation prior to performing the assay.

Anticipated Results

The phenol-sulfuric acid assay provides a quantitative measure of the total content of pentoses or hexoses and their derivatives in the sample analyzed, expressed as equivalents of the monosaccharide used as a standard (e.g., galactose). When carried out in triplicate as described, the assay yields results accurate to $\pm 2\%$.

Time Considerations

In general, the complete assay can be performed in <1 hr. However, if a considerable number of experimental samples are to be assayed (e.g., when monitoring effluent from a column), the time required may be longer.

BASIC PROTOCOL 2

FERRIC ORCINOL ASSAY FOR SIALIC ACIDS

When sialic acids are oxidized in concentrated acid in the presence of orcinol, a blue-purple chromophore is formed. The reaction provides an estimation of the sialic acid content.

Materials

- Sample to be assayed
- Sialic acid standard: 1 mM *N*-acetylneuraminic acid (Neu5Ac; Boehringer Mannheim; store frozen at -20°C)
- Bial reagent (see recipe)
- Isoamyl alcohol
- Thick-walled 16 \times 125-mm Pyrex test tubes
- Heating block or boiling water bath

Glass marbles
1.0-ml glass cuvettes (1-cm path length)
Visible-light spectrophotometer

1. Dissolve sample in water to an appropriate concentration.

When no information regarding the sialic acid content of a sample is available, it is a good practice to assay two aliquots differing in concentration ~5- to 10-fold.

2. Transfer three 150- μ l aliquots to 16 \times 125-mm Pyrex test tubes. Adjust volume to 200 μ l with water.
3. In triplicate, prepare a series of tubes containing 5, 10, 20, 30, and 40 nmol Neu5Ac standard (5 to 40 μ l of 1 mM Neu5Ac). Adjust to 200 μ l water. Prepare a blank using 200 μ l of water.
4. Add 200 μ l Bial reagent, vortex, and cover tubes with glass marbles. Heat tubes 15 min at 100°C.
5. Cool tubes by immersing in room temperature tap water.
6. Add 1 ml isoamyl alcohol to each tube. Vortex tubes and let sit 5 min in an ice bath.
7. Centrifuge tubes 3 min in a tabletop centrifuge to separate the phases.
8. Transfer upper phase to 1.0-ml cuvettes with a Pasteur pipet. Measure the absorbance at 570 nm and subtract the absorbance of the blank.
9. Prepare standard curve of absorbance versus nmol Neu5Ac using the average of the triplicate standard solutions.
10. Determine the amount of sialic acid in each unknown sample by comparing to the standard curve. Quantity is expressed as nmol Neu5Ac.

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Bial reagent

0.2 g orcinol (5-methylresorcinol)
81.4 ml concentrated HCl
2 ml 1% (w/v) ferric chloride (analytical grade)
H₂O to 100 ml
Store \leq 1 week at 4°C

Commentary

Background Information

Glycosidically bound and free sialic acids form a blue-purple chromophore when heated in the presence of orcinol/Fe³⁺ (Bial reagent) in concentrated HCl. The chromophore is soluble in organic solvents. The assay is accurate and reproducible, and the minimum detection limit is ~5 nmol (1.5 μ g). Determination of free sialic acids is best achieved by the more sensitive 2'-thiobarbituric acid (TBA) assay (see UNIT 17.18). A more accurate determination can be carried out later, after release of the sugar with sialidase or mild acid and purification as de-

scribed in UNIT 17.18. *N*-acetylneuraminic acid (Neu5Ac) is used as a standard. However, it should be noted that the extinction coefficient is different for different sialic acid derivatives, such as *N*-glycolylneuraminic acid. Any *O*-acylated sialic acids will have the same extinction coefficients as their parent molecules because, under the strong acidic conditions, all ester groups are rapidly hydrolyzed. Even crude biological materials can be tested, and therefore the assay is adequate for monitoring purification and fractionation protocols.

The ferric orcinol assay was introduced by

Klenk and Langerbeins (1941) and has been used since then with some adaptations to reduce the amount of sample required (Schauer, 1978). Interference caused by other saccharides has been observed (Svennerholm, 1963; Spiro, 1966; Veh et al., 1977).

Critical Parameters

Free or glycosidically bound pentoses, hexoses, and uronic acids can interfere with the assay, limiting its quantitative value. Therefore, some error can be expected when analyzing biological materials that, purified or not, have a high content of these sugars. Nevertheless, this assay provides a simple way to detect sialic acids.

Anticipated Results

When working with a crude biological mixture, a clearly positive ferric orcinol assay will indicate the presence of sialic acids in the preparation; however, an accurate estimation of the total content of sialic acids cannot be obtained by this method. A negative assay, on the contrary, will not rule out the presence of sialic acid, because small amounts of these may be masked by other substances (Critical Parameters).

Time Considerations

The content of sialic acids in a set of up to ten samples can be obtained in 1 hr, provided standards and reagents are already prepared.

BASIC PROTOCOL 3

MBTH ASSAY FOR HEXOSAMINES AND ACETYLHEXOSAMINES

Most methods reported for determining the concentration of hexosamines or *N*-acetylhexosamines are based on the procedures proposed by Elson and Morgan (see *UNIT 17.18*). However, the Elson-Morgan reaction is not specific for hexosamines and requires strict attention to reaction conditions. Although several modifications have been developed, in each case the formation of chromophore requires free amino sugars (not bound within an oligosaccharide), *N*-acetylated or not. Quantitative liberation of amino sugars from oligosaccharides is difficult because of their resistance to acid hydrolysis (see *UNIT 17.16*). In this protocol, the concentration of free hexosamines as well as those bound within an oligosaccharide (including *N*-acetylated species) can be determined after deamination of the sample with 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) under mild acidic conditions.

Materials

- Sample to be analyzed
- 1 M HCl (ACS reagent-grade)
- Hexosamine standard: 1 mM *N*-acetyl-D-glucosamine or *N*-acetyl-D-galactosamine (Sigma)
- 2.5% (w/v) sodium nitrite (Sigma; store in dark bottle at room temperature; prepare fresh weekly)
- 12.5% (w/v) ammonium sulfamate (ACS reagent-grade; store ≥ 2 months at room temperature)
- 0.25% (w/v) 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH; Kodak; store in dark bottle at 4°C and replace if yellowish)

0.5% (w/v) ferric chloride (certified ACS reagent-grade; store indefinitely at room temperature)

13 × 100-mm Pyrex test tubes with Teflon-lined screw caps

Heating block, 110°C

Water baths, room temperature and 37°C

1.0-ml glass cuvettes (1-cm path length)

Visible-wavelength spectrophotometer

1. In triplicate, add 100 µl of sample to be analyzed to 13 × 100-mm Pyrex test tubes. Add 100 µl of 1 M HCl. Mix well by vortexing.
2. Set up a blank tube containing 100 µl water and 100 µl of 1 M HCl.
3. Prepare a series of tubes containing 5, 10, 15, 20, 25, and 30 nmol *N*-acetyl-D-glucosamine or *N*-acetyl-D-galactosamine standard in 100 µl water. Add 100 µl of 1 M HCl. Prepare each determination in triplicate.
4. Cap tubes and place in heating block 2 hr at 110°C.
5. Transfer tubes to a rack and place in a water bath. Allow samples to cool to room temperature.
6. In a fume hood, add 400 µl of 2.5% sodium nitrite and vortex. Let stand 15 min at room temperature.
CAUTION: Steps 6 to 8 should be done in a fume hood.
7. Add 200 µl of 12.5% ammonium sulfamate and vortex. Let stand 5 min at room temperature.
Allow the nitrogen oxides (brownish fumes) to dissipate.
8. Remove tubes from fume hood. Add 200 µl of 0.25% MBTH and vortex. Cap tubes and incubate 30 min at 37°C.
9. Add 200 µl of 0.5% ferric chloride, cap tubes, and incubate 5 min at 37°C.
10. Allow tubes to cool to room temperature and carefully transfer solutions to 1.0-ml cuvette with a Pasteur pipet.
11. Measure absorbance of samples at 650 nm, using reagent blank to zero spectrophotometer.
Absorbances between 0.1 and 1.0 U should be expected for the standards.
12. Prepare standard curve of absorbance versus nmol hexosamine using the average value for each hexosamine concentration.
13. Determine the amount of hexosamine in the sample by comparing to standard curve.

Commentary

Background Information

The MBTH assay is highly specific for amino sugars. This method is based on the formation of an intense blue-colored complex between the 2,5-anhydrohexoses produced upon deamination of hexosamines and 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) under mild acidic conditions. Strong acidic conditions are not required because complete cleavage of the glycosidic linkage is not necessary for the MBTH color reac-

tion to occur. Heating in mild acid is sufficient for the complete de-*N*-acetylation of *N*-acetylhexosamines (i.e., *N*-acetylglucosamine and *N*-acetylgalactosamine) that is required for the reaction to proceed. Sodium nitrite is added to the acidic solution and the liberated nitrous acid produces the deamination. Sodium sulfamate is used to destroy the excess of nitrous acid. Final color is developed upon addition of ferric chloride to the samples. The proposed reaction mechanism is shown in Figure 17.9.1. The

method is useful for determination of free or glycosidically bound hexosamines, including *N*-acetylated species.

The MBTH method was introduced by Tsuji et al. (1969a), who proposed a mechanism for the formation of the blue chromophore. They also found that methyl glucosaminide gives an extinction coefficient almost identical to that of free hexosamine, showing that complete hydrolysis is not required (Tsuji et al., 1969b). Several modifications were introduced (Smith and Gilkerson, 1979) to reduce the difficulty of the original protocol developed by Tsuji et al. (1969a).

Critical Parameters

The color reaction is highly specific for amino sugars because *N*-acetylated hexosamines, neutral monosaccharides, glucuronic

acid, ascorbic acid, and most amino acids yield no color. Some amino acids (e.g., tryptophan, threonine, and methionine) exhibit color, but the intensities are far lower than those obtained with hexosamines. The complete de-*N*-acetylation of *N*-acetylhexosamines necessary for the reaction is achieved by heating the sugar-containing samples in 0.5 M HCl for 2 hr at 110°C. Glucosamine and galactosamine give practically identical color yields ($\epsilon_{\max} = 3.86$ and 3.62×10^{-4} , respectively). Both monosaccharides show linear absorbances in the range of 1 to 30 $\mu\text{g/ml}$. The response of mannosamine is very low ($\epsilon_{\max} = 0.80 \times 10^{-4}$), although it is also linear. This color reaction also allows the estimation of free hexosamines in the presence of *N*-acetylhexosamines, if the de-*N*-acetylation step is omitted.

Figure 17.9.1 Probable mechanism of MBTH color reaction.

Anticipated Results

The application of this protocol will indicate the total content of glucosamine or galactosamine (*N*-acetylated or free) in the sample under analysis.

Time Considerations

The complete assay requires 4 hr, provided all reagents and solutions are prepared in advance.

Describes the simplified protocol and its application to glycosaminoglycans.

ASSAYS FOR URONIC ACIDS

Hexuronic acids occur in polysaccharides of plants, fungal cell walls, bacterial capsules, animal tissues, and cultured cells. In animal tissues and cells, most uronic acid is found in glycosaminoglycans and proteoglycans. Considerable effort has been expended to develop specific, rapid methods for detecting and quantifying free and polymeric uronic acids. The simplest procedures involve hydrolysis of polysaccharides with mineral acid, dehydration of the uronic acid, and conjugation to a chromogen such as carbazole (Basic Protocol 4) or *meta*-hydroxybiphenyl (Alternate Protocol) to form a chromophore that can be quantitated by spectrophotometry. The reactions are generally specific for hexuronic acids, sufficiently sensitive for most laboratory situations (≥ 10 nmol), and require only routine laboratory equipment.

Carbazole Assay for Uronic Acids

Uronic acid is detected by monitoring the formation of a chromophore following reaction with the chromogen carbazole. The reaction is carried out in two steps: samples are first treated with strong acid to hydrolyze polysaccharides and dehydrate the sugars, and the products are then treated with carbazole or *meta*-hydroxybiphenyl to generate the chromophore.

Materials

Sample to be assayed

Uronic acid standard: 1 mM glucuronolactone (see recipe)

4 M ammonium sulfamate (Sigma)

25 mM sodium tetraborate in sulfuric acid (see recipe)

0.1% (w/v) carbazole (Kodak) in 95% ethanol (store at 4°C)

16 × 125-mm Pyrex tubes (open, glass-stoppered, or screw-cap culture tubes fitted with Teflon-lined caps)

Water bath, 100°C, or heating block

Disposable glass or plastic 1.0-ml cuvettes

UV/VIS spectrophotometer

1. Prepare duplicates of unknown sample in 16 × 125-mm Pyrex tubes. Adjust volume to 200 μ l with water. Set up a blank reaction tube containing 200 μ l water.
2. Prepare a series of tubes containing 10, 20, 30, 40, 50, 75, and 100 nmol glucuronolactone standard in 200 μ l water. Include a blank containing only 0.2 ml water.
3. Add 20 μ l of 4 M ammonium sulfamate and vortex.

BASIC PROTOCOL 4

Preparation and Analysis of Glycoconjugates

17.9.8

4. Add 1 ml of 25 mM sodium tetraborate in H_2SO_4 and mix carefully. Cover tubes with caps or marbles and heat 5 min at 100°C. Cool samples to room temperature.

CAUTION: Mixing sulfuric acid with the sample liberates considerable heat. Some investigators chill the samples on ice and use cold ammonium sulfamate. Make sure the tubes are vented during the heating procedure and wear eye protection.

5. Add 40 μ l of 0.1% carbazole and heat 15 min at 100°C. Cool samples to room temperature.

Color develops during this step.

6. Transfer samples to 1.0-ml disposable cuvettes using a Pasteur pipet and read absorbance at 520 nm.

Absorbance of blank sample should be ≤ 0.025 when read against water.

NOTE: Plastic disposable cuvettes can be used. Do not spill the sulfuric acid-containing samples on the outside of the cuvette or into the spectrophotometer.

7. Prepare a standard curve of A_{520} versus nmol glucuronic acid. Determine the amount of uronic acid in unknown sample by reference to the standard curve.

Amount of uronic acid will be expressed as glucuronic acid equivalents.

ALTERNATE PROTOCOL

Meta-Hydroxybiphenyl Assay for Uronic Acids

Substitution of *meta*-hydroxybiphenyl for the carbazole used in Basic Protocol 4 allows color development at room temperature.

Additional Materials (also see Basic Protocol 4)

0.15% (w/v) *meta*-hydroxybiphenyl (Kodak) in 0.5% (w/v) NaOH

1. Prepare samples and treat with ammonium sulfamate and sodium tetraborate in sulfuric acid (see Basic Protocol 4, steps 1 to 4).
2. Add 40 μ l of 15% *meta*-hydroxybiphenyl and incubate 15 min at room temperature.
3. Transfer samples to disposable cuvettes, read absorbance, and determine the amount of uronic acid by reference to the standard curve (see Basic Protocol 4, steps 6 and 7).

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Glucuronolactone, 1 mM

Dissolve 88 mg of glucuronolactone in 1 ml water and freeze in 0.2-ml aliquots. Before assay, dilute one 0.2-ml aliquot to 100 ml with water to obtain 1 mM solution. Store 3 to 6 months at 4°C.

Sodium tetraborate, 25 mM in H_2SO_4

Working in a fume hood, dissolve 0.95 g sodium tetraborate ($Na_2B_4O_7 \cdot 10H_2O$; Sigma) in 100 ml concentrated sulfuric acid. Stir at room temperature with magnetic stir bar.

A large volume of solution can be prepared in advance because the reagent is quite stable. Store at room temperature.

CAUTION: Sulfuric acid will cause severe burns.

Commentary

Background Information

Carbazole reacts with hexuronic acids treated with strong acid. The reaction was first described by Dische (1947) and subsequent modifications have improved sensitivity, specificity, and rapidity. The original reaction conditions gave varying color yields with different uronic acids, but the inclusion of borate (Bitter and Muir, 1962) lessened this problem. Nevertheless, it should be noted that different uronic acids give somewhat different responses in the assay. When uronic acids constitute a small proportion of the total sugar, the accuracy of the assay is reduced due to the Browning reaction of other sugars in hot sulfuric acid. Inclusion of sulfamate (Galambos, 1967) reduces the color yield from neutral sugars to $\leq 5\%$ that of uronic acids. Substitution of *meta*-hydroxybiphenyl for carbazole further reduces interference from neutral sugars (Blumenkrantz and Asboe-Hansen, 1973; Filisetti-Cozzi and Carpita, 1991), because color development can be carried out at room temperature. Thus, the Alternat Protocol should be used if uronic acid represents $<20\%$ of the total hexose in the sample.

Critical Parameters

The three most substantial problems encountered in quantitating uronic acids are the varying color yields of different uronic acids, presence of colored reaction products from other components in mixtures, and interference by certain salts. The inclusion of borate substantially improves the reactivity of recalcitrant uronic acids such as mannuronic acid. Uronic acids in glycosaminoglycan chains can react differently than free sugars, e.g., heparin gives an anomalous high color yield (Kosakai and Yosizawa, 1978). The differential color yields of uronic acids require use of appropriate standards for accuracy. When the identity of the glycosaminoglycan (GAG) chains is known, preparation of a standard curve using the same GAG rather than glucuronolactone will give more accurate results.

The substitution of *meta*-hydroxybiphenyl for carbazole lowers the production of nonspecific color due to hexoses beyond that obtained by inclusion of 0.1 M sulfamate. Hexosamines and pentoses do not produce color in either reaction. The amount of sulfamate included assures maximum reduction of interference. Larger amounts will result in decreased produc-

tion of the uronic acid chromophore. Carbazole produces somewhat more chromophore than *meta*-hydroxybiphenyl, but the difference is small. Addition of sulfamate reduces the color yield by only $\sim 30\%$.

Interference by salts and other cellular components has been surveyed in greater detail in the carbazole reaction than in the *meta*-hydroxybiphenyl reaction. Samples containing sodium chloride (<2 M), urea (<6 M), guanidine-HCl (<2 M), and protein (<0.2 mg/ml) yield the expected color. Sodium nitrite (>5 μ M) and hydrogen peroxide (>10 nM) give a green color that overwhelms the signal from uronic acids. Sulfhydryl reagents accelerate color formation. Because the *meta*-hydroxybiphenyl assay works under milder conditions, it is preferable to the carbazole assay. However, interference by contaminants should be checked by adding them to a standard solution.

Anticipated Results

The assay will provide an estimate of total glycosyluronic acids in a sample. The extinction coefficient at 520 nm for a 1% solution is ~ 1000 . Thus, the assay is sufficiently sensitive to detect ~ 10 to 25 nmol uronic acid.

Time Considerations

The assay can be completed in ~ 20 to 30 min if the reagents and solution are prepared in advance.

Inhibition of N-Linked Glycosylation

UNIT 17.10A

**BASIC
PROTOCOL**

Treatment of cells with inhibitors of the enzymes that synthesize N-linked oligosaccharide chains results in production of glycoproteins (this unit) or glycolipids (UNIT 17.10B) containing missing or altered chains. This approach is useful for examining potential functional roles of oligosaccharides on specific proteins or intact cells. Table 17.10.1 lists the enzymes blocked by each inhibitor and the consequences; Figure 17.10.1 diagrams the early processing steps in the assembly of N-linked oligosaccharides, showing the enzymes blocked by each inhibitor except tunicamycin (which affects an earlier stage). These inhibitors can be used to prevent N-linked glycosylation in cultured cells. First, the optimal concentration of inhibitor (i.e., highest nontoxic concentration) is determined by monitoring [³⁵S]methionine incorporation as a measure of protein biosynthesis (UNIT 10.18). The inhibitor's ability to inhibit oligosaccharide processing is then determined by analyzing cells labeled with [³H]mannose using TCA precipitation (UNIT

Table 17.10.1 Inhibitors of Enzymes that Synthesize N-linked Oligosaccharides

Type of inhibitor	Target enzyme	Effect on oligosaccharide structure	Effective concentration range
Glycosylation inhibitor			
Tunicamycin	GlcNAc transferase	Prevents assembly of GlcNAc-PP-dolichol and thus assembly of G ₃ M ₉ GlcNAc ₂ -PP-dolichol ^a ; glycosylation of Asn residues does not occur; proteins migrate faster on SDS-PAGE and generally show less size heterogeneity; proteins will not shift to a faster mobility on SDS-PAGE after PNGase F treatment	0.5-10 µg/ml
Processing inhibitors			
Deoxynojirimycin Castanospermine	Glucosidase I and/or II	Prevents removal of first glucose residue, thereby inhibiting any further processing of the oligosaccharide chain; proteins may migrate with a larger or smaller size on SDS-PAGE, depending on extent of processing that normally occurs; sensitive to endo H ^b	0.5-200 mM 1-50 µg/ml
Deoxymanno- jirimycin	α-mannosidase I	Prevents removal of mannose residues on the α1-3 arm of the high mannose structure, thereby blocking the activity of GlcNAc T I and thus α-mannosidase II; proteins generally run as a smaller size on SDS-PAGE, depending on size of the normal oligosaccharide; structures remain sensitive to endo H ^c	1-5 mM
Swainsonine	α-mannosidase II	Prevents removal of mannose residues on the α1-6 arm of the high mannose structure, preventing the activities of GlcNAc T II and V (which add GlcNAc to the α1-6 mannose residue); addition of GlcNAc, galactose, and sialic acid to the α1-3 mannose can occur normally, although the structures remain sensitive to endo H digestion	1-10 µg/ml

^aAbbreviations: G₃M₉GlcNAc₂-PP-dolichol, Glc₃Man₉GlcNAc-PP-dolichol; GlcNAc T I, II, V, *N*-acetylglucosaminyltransferase I, II, V; PNGase F, peptide N:glycosidase F.

^bMature processed oligosaccharide structures cannot be cleaved from the protein by endoglycosidase H; structures retaining mannose residues on the α1-6 arm can be removed, generally resulting in a difference in size easily detected by SDS-PAGE.

^cEndomannosidases can bypass this block.

17.10.1

Supplement 32

Figure 17.10.1 Structures of early processing intermediates in the assembly of N-linked oligosaccharides. Structure A is initially assembled on the lipid carrier dolichol phosphate, a process blocked by tunicamycin, and then transferred to the Asn residue. The initial trimming glucosidases I and II convert A into B; these glucosidases are inhibited by castanospermine and deoxynojirimycin. Deglucosidation is followed by removal of the outer four mannose residues by mannosidase I (inhibited by deoxymannojirimycin), to form C. Removal of these mannose residues is the signal for the first *N*-acetylglucosaminyltransferase (GlcNAc Transferase I) to form D. Structure D, but not C, is a substrate for mannosidase II, resulting in the formation of E, which can be further extended into bi-, tri- and tetraantennary structures (sialylated and neutral) by a series of *N*-acetylglucosaminyltransferases, galactosyltransferases, and sialyltransferases plus the appropriate sugar-nucleotide donors.

17.10.2

10.18) or endo H digestion (UNIT 17.13). Further suggestions are given on how to use methods for identifying a specific glycoprotein (if available) to measure the effect of the inhibitor on its N-linked oligosaccharide chains. A support protocol details a method for concentrating proteins by acetone precipitation.

NOTE: All media and solutions should be made with distilled, deionized water. All media and equipment coming into contact with cells should be sterile. Incubations of cells should be performed in a humidified 5% CO₂, 37°C incubator.

Materials

Cultured cell line, either adherent or suspension
Complete culture medium
Inhibitor of N-linked glycosylation (one or more of the following: tunicamycin, deoxynojirimycin, castanospermine, deoxymannojirimycin, or swainsonine; see reagents and solutions and Table 17.10.2)
Solvent used for making inhibitor solution (see reagents and solutions)
Multiply deficient medium (MDM; UNIT 17.4) without glucose
 [³H]mannose (5 to 20 Ci/mmol)
Phosphate-buffered saline (PBS; APPENDIX 2), ice-cold
Lysis buffer (UNIT 10.16) without 1% bovine hemoglobin
0.5 U/ml endoglycosidase H (endo H) and endo H digestion buffer (reagents and solutions)
20% (w/v) SDS
Sephacryl S-200 column (Table 10.9.2)
25 mM ammonium formate/0.1% (w/v) SDS
24-well tissue culture plate
100-mm tissue culture plates
Disposable plastic scraper or rubber policeman
1.5-ml, 15-ml, or 50-ml conical polypropylene centrifuge tube
Additional reagents and equipment for tissue culture (Chapter 9 introduction), counting viable cells (UNIT 11.5), short-term labeling of suspension or adherent cells with [³⁵S]methionine (UNIT 10.18), metabolic radiolabeling of glycoconjugates (UNIT 17.4), lysis of cells (as for immunoprecipitation; UNIT 10.16), TCA precipitation (UNIT 10.18), endo H digestion (UNIT 17.13), gel-filtration chromatography (UNIT 10.9), and one-dimensional gel electrophoresis of proteins (UNIT 10.2)

Determine optimal inhibitor concentration

1. For each inhibitor tested, set up 15 wells of cells in a 24-well tissue culture plate by splitting the cells (by trypsinization for adherent cells or dilution for suspension cells) into 1.8 ml final per well of complete medium. Incubate 24 hr.

A ratio of splitting should be used to yield confluent (but not overgrown) cultures by the third day (i.e., 48 hr after splitting).

2. While cells are incubating, make a series of 1:1 (v:v) dilutions of inhibitor(s) as follows. Place the volume of inhibitor stock solution indicated in Table 17.10.2 in a sterile microcentrifuge tube and dilute to 800 µl final volume with complete culture medium. Transfer 400 µl to a second tube and dilute with 400 µl complete culture medium. Repeat for a total of 7 tubes. As a control, prepare an identical series of dilutions of the solvent used for making the inhibitor solution.

Table 17.10.2 Range of Inhibitor Concentrations for Dilution Series

Inhibitor	Stock solution	Stock added to first dilution (μ l)	Concentration range
Tunicamycin	1 mg/ml	80	0.15-10 μ g/ml
Swainsonine	1 mg/ml	80	0.15-10 μ g/ml
Deoxynojirimycin	400 mM	200	0.15-10 mM
Deoxymannojirimycin	400 mM	200	0.15-10 mM
Castanospermine	400 mM	200	0.15-10 mM

3. Add 200 μ l from each tube (from step 1) to a well of the tissue culture plate containing cells (2 ml final). Add 200 μ l complete culture medium alone to the remaining well (as a zero-inhibitor control point). Incubate plate 24 hr. Store unused inhibitor-containing media at 4°C.

If the inhibitor is tunicamycin, dilutions should be prepared fresh each day, as it may precipitate out of solution during storage.

4. Perform short-term labeling of cells with [³⁵S]methionine (UNIT 10.18) using 0.2 mCi/ml label and 1.8 ml final volume per well.
5. Add to wells the remaining 200 μ l of each dilution of inhibitor (from step 2) and incubate a further 4 hr.
6. Harvest cells and determine the incorporation of [³⁵S]methionine into macromolecules by TCA precipitation (UNIT 10.18). Plot label incorporation versus inhibitor concentration.

CAUTION: Safety precautions for disposing of radioactive waste should be followed.

Comparing incorporation by cells incubated with and without inhibitor will indicate the maximum concentration of inhibitor that does not inhibit protein synthesis. This is the optimal concentration for the following steps.

Label cells in the presence of N-linked glycosylation inhibitor

7. Split a new cell sample into complete medium in a 100-mm tissue culture plate and incubate 24 hr.
8. Add inhibitor to the optimal concentration determined above. Set up a control plate containing the same quantity of stock solution solvent but no inhibitor. Incubate for 24 hr.
9. Wash the cells using the same procedure as employed during labeling (step 4) and, to each plate, add sufficient glucose-free MDM to cover the cells (5 ml for a 100-mm plate). Add inhibitor or solvent as in step 8. Add [³H]mannose to 0.02 to 0.1 mCi/ml. Incubate 4 to 12 hr.

The duration of incubation will depend on how well the cells label with [³H]mannose. The amount of [³H]mannose used will depend on the cell line examined. However, for most cells, a single 100-mm plate with 5 ml media incubated with 0.02 mCi/ml [³H]mannose for 6 hr should yield sufficient radioactive material for the analyses described below. Extended incubations in glucose-free labeling medium should be avoided.

10. Harvest the cells by scraping with a disposable scraper or rubber policeman (for adherent cells) or centrifugation (for suspension cells) into ice-cold PBS.

CAUTION: Safety precautions for disposing of radioactive waste should be followed.

Measure incorporated macromolecular radioactivity

11. If tunicamycin was used as the inhibitor, determine the amount of incorporated macromolecular radioactivity by TCA precipitation and proceed to step 18. If another inhibitor was used, carry out steps 12 to 17.

The amount of radioactivity incorporated into macromolecules reflects the effect of the inhibitor(s) on oligosaccharide biosynthesis: the presence of inhibitor should block incorporation of [³H]mannose into macromolecules.

12. Wash the cells twice by resuspending the pellet in ice-cold PBS, centrifuging, and removing the supernatant. Resuspend the pellet in lysis buffer without bovine hemoglobin and lyse as described in UNIT 10.16 (steps 1 to 4, basic protocol).
13. Divide each sample into two equal aliquots in conical polypropylene centrifuge tubes and precipitate protein with acetone (support protocol).

Use 1.5-ml, 15-ml, or 50-ml centrifuge tubes depending on the quantity of sample (8 vol acetone must be added).

14. Resuspend pellets in 20 to 40 μ l endo H digestion buffer per 10^7 cells and boil 10 min to inactivate endogenous hydrolases.
15. Add 5 μ l endo H per 100 μ l sample to one tube of each sample pair and incubate both overnight at 37°C.
16. Add $\frac{1}{10}$ vol of 20% (w/v) SDS to each sample and boil 3 to 5 min to terminate the digestion.
17. Apply one sample at a time to a calibrated Sephacryl S-200 column equilibrated in 25 mM ammonium formate/0.1% SDS, in a sample volume that is <5% of the bed volume. Collect the eluate and use a scintillation counter to measure the radioactivity associated with glycoproteins (eluting in the void volume of the column, V_o) and with free oligosaccharides (eluting after V_o) for each of the four samples. Wash column with 2 to 4 vol 25 mM ammonium formate/0.1% SDS between sample applications.

In the absence of endo H digestion, all of the radioactivity from both the inhibitor-treated and untreated samples should elute in V_o . Elution of any radioactive material after V_o may indicate that the wash steps following acetone precipitation did not completely remove low-molecular-weight contaminants present in the cell lysate.

For samples digested with endo H, elution profiles should demonstrate a marked increase in the amount of endo H-releasable radioactivity in samples from inhibitor-treated cells relative to treated cells. For samples not treated with inhibitor, the oligosaccharides cleaved from the peptide backbone by endo H represent immature oligosaccharides still being processed in the Golgi apparatus and a small population of endo H-sensitive structures found on some mature glycoproteins. For samples treated with inhibitor, a much higher percentage of the total radioactivity should be released, as the inhibitors prevent the processing of the oligosaccharides into mature oligosaccharide structures (Fig. 17.10.1) and the underprocessed oligosaccharides contain more mannose residues than the processed ones. Theoretically, 100% of the radioactivity should be releasable by endo H digestion of the inhibitor-treated samples (see critical parameters), although in reality no inhibition is ever complete.

To save time, analyze only the first and last tubes of the control cells in this fashion, i.e., those not treated at all and those treated with the highest concentration of the inhibitor solvent (from step 2 above). If there is no difference in the results from these two groups of cells, it is reasonable to assume that those cells treated with lower concentrations of the inhibitor solvent will yield the same results. However, if the solvent is found to be toxic, then the cells exposed to lower concentrations will need to be examined to find the maximally tolerated concentration of inhibitor solvent.

18. If desired, and if methods are available for purifying and identifying a specific glycoprotein from cells radiolabeled with [³⁵S]methionine, examine the effect of a given inhibitor by SDS-PAGE and autoradiography.

Each N-linked carbohydrate chain contributes ~2000 to 4000 Da to a protein's mass, so synthesis of a protein in the presence of tunicamycin will result in faster mobility on SDS-PAGE. The effect of other inhibitors can be demonstrated by an increased sensitivity to digestion by endo H, which is also detectable as an increase in migration rate in SDS-PAGE.

SUPPORT PROTOCOL

ACETONE PRECIPITATION

Acetone precipitation is a useful step for concentrating proteins and for exchanging them from one buffer to another. As little as 10 ng of protein can be precipitated successfully.

Additional Materials

100% acetone (HPLC or ACS grade), -20°C

1.5-ml, 15-ml, or 50-ml conical polypropylene or other centrifuge tubes

1. Place the protein solution on ice, add 8 vol acetone (-20°C), mix gently, and precipitate at -20°C overnight.

If the sample volume is too large to be conveniently diluted with 8 vol, concentrate it by lyophilizing and resuspending in a smaller volume. If the sample contains NP-40 or Triton X-100 detergent, however, there is a limit to how much it can be concentrated, as high concentrations of detergent (e.g., >1%) will partition out of acetone solutions, appearing as an oily pellet after centrifugation (step 2).

If a large amount of protein is present (i.e., a precipitate is readily visible after the acetone is added), it can be precipitated after standing at -20°C for only a few hours instead of overnight. Leaving the material in acetone for longer than 1 day should be avoided, as it may become increasingly difficult to redissolve the protein.

2. Collect the precipitate by centrifuging 15 min at 3000 × g, 4°C (a small pellet should be visible). Carefully invert the tube and pour out the acetone into a clean tube.

If the pellet is oily due to the presence of detergent, it should be extracted by adding 85% (v/v) acetone (-20°C), mixing, incubating at -20°C for >1 hr, and recentrifuging.

3. Centrifuge the tube containing the pellet briefly to concentrate the remaining acetone and remove it with a micropipettor. Allow pellet to dry until moist but not powder-dry, and resuspend in an appropriate quantity of the desired solvent.

Care must be taken in drying the pellet, as great difficulty may be encountered in resuspending some proteins if the pellet dries completely. This insolubility depends on both the individual protein and the total amount present.

REAGENTS AND SOLUTIONS

NOTE: Deionized, distilled water should be used for buffer and inhibitor solutions.

Endo H digestion buffer

15 µl 0.5 M sodium citrate, pH 5.5

75 µl water

5 µl 10% PMSF in isopropanol

This is sufficient for 5 µl of 0.5 U/ml endo H (100 µl digestion volume). The PMSF prevents proteolysis. The presence of nonionic detergent is not required. Prepare just before use; PMSF is unstable in water.

Inhibitor stock solutions

Dissolve castanospermine (mol. wt. 189.2), 1-deoxymannojirimycin (mol. wt. 199.6), or 1-deoxynojirimycin (mol. wt. 163.2) in water to 400 mM; dissolve swainsonine (mol. wt. 173.2) in water to 1 mg/ml. Sterilize by filtration through a 0.2- μ m filter. Store frozen at -20°C (stable indefinitely).

Dissolve tunicamycin (mol. wt. 840) in dimethylsulfoxide (DMSO), dimethylformamide (DMF), 95% ethanol, or 25 mM NaOH to 1 mg/ml. Store frozen at -20°C (stable \sim 1 yr).

If NaOH is used, store stock solution in a small tube that is tightly capped to prevent adsorption of carbon dioxide, which will lower the pH. Tunicamycin's solubility in neutral aqueous solution is <1 mg/ml (attempting to make such a solution will produce a visible precipitate).

COMMENTARY

Background Information

Assembly of N-linked oligosaccharide chains involves the sequential action of several glycosidases and glycosyltransferases (reviewed by Hubbard and Ivatt, 1981, and Kobata and Takasaki, 1992). Growth of cells in the presence of inhibitors of these enzymes produces glycoproteins with underprocessed or missing oligosaccharide chains. Depending on the protein, these changes may alter biological functions and/or rates of transport, secretion, or turnover (Elbein, 1987; McDowell and Schwarz, 1988).

N-linked glycosylation begins with the assembly of the lipid-linked precursor glucose₃mannose₉N-acetylglucosamine₂-pyrophosphate-dolichol (Glc₃Man₉GlcNAc₂-PP-dolichol; similar to Structure A, Fig. 17.10.1). Assembly of this precursor requires N-acetylglucosamine-pyrophosphate-dolichol (GlcNAc-PP-dolichol), whose formation is blocked by tunicamycin (Tkacz and Lampen, 1975). Thus, the presence of tunicamycin results in proteins missing some or all of their N-linked side chains; however, those that are added due to incomplete inhibition are processed normally. Tunicamycin may also inhibit protein synthesis; not all proteins will be affected to the same degree. Tunicamycin also blocks the assembly of type II keratan sulfate chains, because these glycans also utilize GlcNAc-PP-dolichol (Hart and Lennarz, 1978). Glycolipid biosynthesis may also be inhibited, although the mechanism underlying this has not been established (Yusuf et al., 1983; Guarnaccia et al., 1987).

The glycosidase inhibitors castanospermine, deoxynojirimycin, deoxymannojirimycin, and swainsonine are considerably less toxic than tunicamycin. Castanospermine inhibits glucosidase I, and deoxynojirimycin in-

hibits both glucosidases I and II (Fig. 17.10.1; Pan et al., 1983; Saunier et al., 1982). In some studies, the metabolic block produced by these two drugs is not complete, yielding a mixture of normally processed and underprocessed structures. More recently, an endo- α -D-mannosidase has been described that cleaves the tetrasaccharide Glc₃-Man₁ from Glc₃Man₉-GlcNAc₂, effectively bypassing the block produced by the glucosidase inhibitors (Lubas and Spiro, 1987). Although the question has not been examined fully, the level of this endo- α -D-mannosidase may vary between different cell lines.

Deoxymannojirimycin and swainsonine are inhibitors of mannosidases I and II, respectively (Fig. 17.10.1; Fuhrmann et al., 1984; Tulsiani et al., 1982). By inhibiting mannosidase I, deoxymannojirimycin prevents addition of the α 1-2 N-acetylglucosamine (GlcNAc) residue required to produce Structure D, Figure 17.10.1, which is a necessary step for the action of mannosidase II. Thus, deoxymannojirimycin prevents addition of any GlcNAc residues, blocking galactosylation and sialylation as well. Swainsonine blocks mannosidase II. However, it does not prevent the single GlcNAc residue (Structure D, Fig. 17.10.1) from being galactosylated and sialylated, resulting in hybrid structures (Tulsiani and Touster, 1983).

Some of the glycosidase inhibitors are also active against lysosomal enzymes, although the significance of this effect in tissue culture cells has been little explored. Deoxynojirimycin can inhibit synthesis of the lipid-linked precursor in cell-free extracts (Romero et al., 1985); this also has not been thoroughly investigated with intact cells. No information is available on the metabolism or half-lives of these inhibitors in cultured cells.

Critical Parameters and Troubleshooting

The two most critical variables are duration of exposure and inhibitor concentration. The treatment times suggested in this unit (24 hr) will permit a cell to replace most of its endogenous glycoproteins with glycoproteins synthesized in the presence of inhibitor. For proteins that turn over slower or faster than average, longer or shorter incubation times may be appropriate. If pulse-chase studies with radiolabeled sugar or amino acid precursors (*UNITS 17.4 & 10.18*) are being carried out, it is necessary to incubate cells in inhibitor for only 1 to 2 hr before adding label.

N-linked glycosylation inhibitors may be toxic to the cells, as indicated by decreased cell viability and/or reduced protein synthesis. The concentration of tunicamycin that can be used is generally limited by its toxicity, which may be considerable in some cell lines (more so with tumor cells than nontransformed cells). Other glycosidase inhibitors are usually not toxic in the concentration ranges suggested in Table 17.10.1 (the highest concentrations listed represent those used in most published studies).

It is important to realize that in a given cell line, not all glycoproteins will be affected to the same extent by a given inhibitor. Moreover, it is possible that not all sites on the same glycoprotein will be affected equally. These caveats should be kept in mind when interpreting the results from studies employing these inhibitors.

Failure to observe an effect from an inhibitor may indicate that concentration of inhibitor was too low and/or length of exposure was too short. Cell lines differ in their susceptibility to these compounds.

Safety precautions and experimental parameters for labeling—including labeling time, label concentration and specific activity, cell density, and culture conditions—are discussed in the critical parameters of *UNIT 10.18*.

Anticipated Results

These experiments will demonstrate the chosen inhibitor's toxicity, as assessed by protein synthesis, and its ability to alter oligosaccharide biosynthesis, as assessed by total [³H]mannose incorporation (for tunicamycin) or endo H release of the oligosaccharides (for the other inhibitors listed in Table 17.10.1).

Time Considerations

Setting up the initial round of cell cultures for determining the optimal inhibitor concentration takes 2 hr, after which they are incubated 24 hr. On the second day, the dilution series of medium containing inhibitor is set up, the cells are transferred to these media (<1 hr), and the plates incubated 24 hr. On the third day, the incubation of the cells with the radiolabeled precursor is set up (~4 hr); the actual incubation takes 4 to 16 hours. Following incubation, the cells are assayed for radiolabel incorporation by TCA precipitation (2 to 4 hr).

The main part of the experiment follows a similar time course if the inhibitor used is tunicamycin. If a different inhibitor is used, analysis of endo H susceptibility by Sephacryl S-200 chromatography will take ~1 day, including the overnight incubation.

Inhibition of Glycolipid Biosynthesis

BASIC PROTOCOL

Adequate inhibition of glycolipid biosynthesis allows the study of their biological functions. The method presented in this unit employs a synthetic analog of ceramide, PDMP (1-phenyl-2-decanoylamino-3-morpholino-1-propanol), that inhibits glycolipid biosynthesis in cultured cells. Optimum conditions for inhibition of glycolipid biosynthesis are determined, glycolipids extracted from cultures grown with and without inhibitor, and the patterns of glycolipids analyzed by HPTLC (UNIT 9.7A). Detection is achieved using colorimetric reactions, or by monitoring radioactivity when cells have been metabolically radiolabeled. The effects of these changes in biological functions can then be studied later.

Materials

Adherent cell culture
 10 mM PDMP in ethanol (see recipe)
 Culture medium appropriate for cell line, with or without serum
 Ethanol
 Radiolabeled precursors (UNIT 17.4; for metabolic labeling)
 PBS (APPENDIX 2)
 2:1, 1:1, and 1:2 (v/v) chloroform/methanol
 10:10:1 (v/v/v) chloroform/methanol/water
 HPTLC standards: mixture of gangliosides or neutral lipids from bovine brain (Sigma or Accurate Chemical) or mixture of neutral glycolipids (Accurate Chemical)
 Orcinol/sulfuric acid reagent (see recipe)
 Resorcinol/hydrochloric acid reagent (see recipe)
 Screw-cap glass tube, sterile
 Conical glass tubes (10- or 50-ml, depending on volume of pellet to be extracted)
 Sonicator bath
 Nitrogen stream
 Rotary or shaker evaporator
 Silica-gel HPTLC plates
 Enhance spray (DuPont NEN; for metabolic labeling)
 Glass spray unit
 Oven adjustable up to 140°C
 Additional reagents and equipment for HPTLC (UNIT 9.7A) and for metabolic radiolabeling (UNIT 17.4) and autoradiography (APPENDIX 3A; both optional)

NOTE: All incubations should be carried out under the conditions normally used for the cell line to be analyzed.

Incubate cells with inhibitor

1. Prepare cell cultures and maintain as usual until subconfluent. Set up sufficient flasks or plates for the set of experiments using different POMP concentrations and incubation times (see steps 4 and 5).

This procedure can be performed in either the presence or absence of fetal bovine serum, and with adherent cells or (with appropriate modifications) suspension cultures.

2. Allow 10 mM PDMP in ethanol to warm up to room temperature. Transfer to a sterile screw-cap glass tube a sufficient amount of this solution to set up a series of incubations with 5 to 25 μ M final concentration of PDMP and different time points (see steps 4 and 5). Evaporate to dryness with a nitrogen stream.

3. Add culture medium and sonicate 10 min in a sonicator bath to suspend the drug.
4. Add PDMP solution to aliquots of the cell culture to obtain final concentrations of 5, 10, 15, 20, and 25 μM . Add ethanol as needed to achieve the same ethanol concentration in all samples, and add the same total volume of ethanol without PDMP to a control culture.
5. Incubate the cells for selected durations.

Periods ranging from 10 hr to 4 days have been employed. Optimum inhibition times may differ from one particular cell line to another. It is necessary to check the cells for viability as well as for morphological changes, particularly after prolonged incubations with the inhibitor.

6. Remove medium and add fresh medium containing PDMP as before. If the cells are being metabolically labeled, add the radiolabeled precursor at this point (see *UNIT 17.4*).

Prepare total lipid extract

7. Harvest cells into a 10- or 50-ml conical glass tube, pellet the cells, and wash three times with PBS.
8. Add 10 vol of 2:1 (v/v) chloroform/methanol to the cell pellet. Extract the lipids by homogenizing or sonicating 5 min. Centrifuge 10 min at $\sim 350 \times g$, 4°C . Transfer the supernatant (extract) to a clean glass tube using a Pasteur pipet.
9. Repeat the extraction as in step 8 with, successively, 1:1 (v/v) chloroform/methanol, 1:2 (v/v) chloroform/methanol, and 10:10:1 (v/v/v) chloroform/methanol/water.
10. Pool all extracts and dry them under reduced pressure, using a rotary or shaker evaporator or a nitrogen stream depending on the volume of extract to be dried.

Analyze extract by HPTLC and (optionally) autoradiography

11. Dissolve the pooled dry extract (total lipid extract) in a small volume of 2:1 (v/v) chloroform/methanol and spot one aliquot on silica-gel HPTLC plates (*UNIT 9.7A*). Spot a mixture of ganglioside and/or neutral glycolipid standards on one side of the plate. Perform HPTLC analysis. Allow the plates to dry completely after developing.

The amount of total lipid required for positive resulting in observable bands (~ 1 nmol/band) will vary between cell lines because of different compositions and ratios of components. It may be necessary to do several trials until adequate results are obtained. When analyzing radiolabeled extracts, it is advisable to spot the same number of total counts in each lane.

When analyzing nonradiolabeled glycolipids, and if sufficient material is available, two different HPTLC plates can be spotted in parallel with the same total lipid extracts. Staining one with orcinol/sulfuric acid and the other with resorcinol/hydrochloric acid will allow determination of which bands correspond to neutral glycolipids and which to gangliosides.

12. When analyzing nonradiolabeled glycolipids, proceed directly to step 13. When analyzing metabolically radiolabeled glycolipids, visualize them by autoradiography (*APPENDIX 3A*) using Enhance scintillant spray, then proceed to step 13 to visualize the nonradiolabeled standards.
- 13a. Using a glass spray unit, spray plates with orcinol/sulfuric acid reagent. Heat in a 100°C oven until bands are observed (~ 10 min, but check the plate often to avoid overstaining).

This step detects all glycolipids, which give brown bands.

In steps 13a and 13b, it is possible to stain only the side of the plate containing the standards by covering the rest of the plate with a piece of glass held in position with binder clips.

- 13b. Alternatively, spray the plate with resorcinol/hydrochloric acid reagent and heat 15 min in a 140°C oven.

This step detects only gangliosides, which give blue bands.

14. Compare the pattern of glycolipids obtained for the control cells with those obtained with different concentrations of inhibitor after different incubation periods.
15. If cells were metabolically radiolabeled, quantitate the individual components by scraping off the corresponding areas of silica gel and measuring radioactivity by liquid scintillation counting. If a scanning densitometer is available, quantitation can be achieved by scanning the autoradiograph or the stained glass plate.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

PDMP stock solution, 10 mM in ethanol

Dissolve 3.86 mg *d,l-threo*-1-phenyl-2-decanoylamino-3-morpholino-1-propanol-HCl (PDMP; FW 390.6; available from Matreya) in 1.0 ml ethanol. Store at -20°C until used.

PDMP is quite stable in aqueous solvents. No breakdown was observed after incubating a 1 mM solution in PBS (pH 7.4) for 10 days at 41°C. Stability in ethanol is even higher.

Orcinol/sulfuric acid reagent

Dissolve 200 mg orcinol in 33 ml water. Dilute to 100 ml with concentrated sulfuric acid. Store in dark bottle at 4°C. Discard when the solution turns brownish (8 to 10 days).

Orcinol from Sigma (FW 142.2) is suitable for making this reagent.

Resorcinol/hydrochloric acid reagent

80 ml concentrated HCl

10 ml 2% resorcinol (1,3-benzenediol) in H₂O

250 μl 0.1 M copper sulfate in H₂O (2.5 mM final concentration)

Store in a dark bottle at 4°C

Discard if the solution turns brown

Resorcinol from Sigma (crystalline; ~98% pure; FW 110.1) is suitable for making this reagent.

COMMENTARY

Background Information

Many studies have shown that glycosphingolipids and gangliosides are involved in a great variety of biological phenomena. As constituents of mammalian cell membranes, gangliosides significantly affect cell-surface and transmembrane signalling events such as cellular immune responses, cell growth, and differentiation. Other observed effects of gangliosides include those of “shed” gangliosides in malignancy; the effects of gangliosides and their products on protein kinase C; calcium

binding; and their interaction with various bioeffectors, including bacterial toxins, bacterial binding proteins, interferons, serotonin, fibronectin, plasma low-density lipoproteins, lectins, and glycoprotein hormones.

Many studies of the role of these molecules have been carried out by adding specific exogenous glycosphingolipids or gangliosides, or mixtures thereof, to cultured cells. Interpretation of these studies is difficult for various reasons. True incorporation of the added molecules into the cell membrane is hard to prove,

and the possibility of abnormal effects caused by micelles associated with the cell is hard to rule out. Also, exogenous material may displace the controlling factor from its normal location in the cell membrane or influence its metabolism.

Another approach to clarifying the biological roles of glycosphingolipids and gangliosides is the use of enzyme inhibitors to study the effects of their depletion in cultured cells and animals. This inhibition can be achieved using a synthetic analog of ceramide, PDMP. This method was developed by Radin and Inokuchi, whose idea that cancer results from microsphingolipidosis led them to explore ways to change the biological processes in which glycolipids are involved. One such process is the synthesis of glycolipids from nonglycolipid precursors and lower glycolipids. Most neutral glycolipids and gangliosides have a common precursor, GlcCer, which is formed enzymatically from ceramide and UDP-Glc. The synthetase responsible for this transfer is UDP-glucose:*N*-acylsphingosine glycosyltransferase (EC 2.4.1.80). Because rapid liver growth was observed in mice when glucosylceramide accumulated (Datta and Radin, 1986), the authors explored the possibility that inhibiting the synthesis of the common precursor GlcCer would decrease the amount of glycolipids due to normal turnover (Hospattankar and Radin, 1982). After a few attempts, they obtained an active inhibitor, PDMP (*D*-*threo*-1-phenyl-2-decanoylamino-3-morpholino-1-propanol; Inokuchi and Radin, 1987). This compound was shown to inhibit ganglioside biosynthesis effectively in intact cells, without any major toxic effects (Inokuchi and Radin, 1987; Inokuchi et al., 1987). The effects of the enzyme inhibitor were counteracted by including GlcCer in the culture medium (Inokuchi et al., 1989). For a review of the available data, see Radin and Inokuchi (1991).

Critical Parameters

It is critical to understand that very little is known about the regulation of glycosphingolipid biosynthesis, turnover, or even which steps are regulation points. On the other hand, the composition of glycosphingolipids varies tremendously between different types of cells. The time required to obtain optimum inhibition of any glycolipid or collection of glycolipids depends on how completely the enzyme is inhibited, the activity of the specific hydrolases involved, the susceptibility of each glycolipid to attack by its hydrolase, and the rates of the

synthases that recycle smaller glycolipids into larger ones. Although the effects on simple gangliosides such as GM₃ are readily observed, complex molecules such as GD1b require more time to become affected. Complete inhibition, as well as complete recovery from the inhibitor, should be expected to take at least 24 hr.

In consequence, the conditions required for inhibition and recovery of each particular system need to be carefully established. Various concentrations of inhibitor should be tried to establish the minimum amount required for inhibition. It is also important to understand that an inhibitor may have pleiotropic effects, including the accumulation of precursors (e.g., ceramide), expansion of alternate pathways (e.g., sphingomyelin synthesis), and other non-specific effects (e.g., on protein synthesis). Depending on the experiment, such alternate explanations for the observed effects may need to be explored.

Anticipated Results

The protocol allows optimization of the conditions for maximum inhibition of glycolipid biosynthesis with minimum effects on the morphology and viability of cells. Once these conditions are established, different studies of the biological roles of glycosphingolipids and gangliosides can be performed.

Time Considerations

Complete inhibition of glycolipid biosynthesis may require up to 4 days of cell culture. Further extraction of glycolipids and analysis of the resulting data are expected to take a maximum of 2 days, including quantitation. When metabolic labeling and autoradiography are included, extra time is required for detection, and will depend on the total counts available and their distribution among components.

Synthetic Glycosides as Primers of Oligosaccharide Biosynthesis and Inhibitors of Glycoprotein and Proteoglycan Assembly

UNIT 17.11

With the exception of hyaluronic acid, all mammalian saccharides assemble while attached to a lipid or protein primer. Several cases are now known in which oligosaccharide synthesis will occur on synthetic glycoside primers added to cells. β -D-xylosides initiate glycosaminoglycan (GAG) synthesis (Okayama et al., 1973) by substituting for endogenous xylosylated core proteins (Basic Protocol 1). At high concentration xylosides will also prime oligosaccharides that resemble glycolipids (Freeze et al., 1993). *N*-acetyl- α -D-galactosaminides initiate the synthesis of O-linked oligosaccharides found on mucins and other glycoproteins (Basic Protocol 2) in an analogous manner. Even disaccharides, such as peracetylated *N*-acetylglucosaminide, can act as primers (Sarkar et al., 1995). Because these primers compete with endogenous substrates, they also act as inhibitors of proteoglycan (PG) and glycoprotein synthesis. Thus, primers have utility for studying the biological activity of glycoconjugates in cells, tissues, and animals. This unit describes procedures for using glycoside primers in cell culture.

XYLOSIDE INITIATION OF GAG SYNTHESIS AND INHIBITION OF PG ASSEMBLY

BASIC
PROTOCOL 1

Materials

- 0.2 M *p*-nitrophenyl- β -D-xyloside in DMSO (see recipe)
- Tissue culture growth medium appropriate for cell line
- Cultured cells, in suspension or adherent
- Dimethylsulfoxide (DMSO, C₂H₆SO; mol. wt. 78.13)
- Radioactive precursors: H₂³⁵SO₄, [6-³H]GlcNH₂, or [1-³H]Gal

Additional reagents and equipment for metabolic radiolabeling (UNIT 17.4), isolating proteoglycans and glycosaminoglycans (UNIT 17.3), and gel filtration (UNIT 17.20) and reversed-phase chromatography (UNIT 17.21)

NOTE: All incubations should be carried out in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

1. Add 0.2 M *p*-nitrophenyl- β -D-xyloside in DMSO to aliquots of growth medium to achieve final concentrations of 0, 0.01, 0.03, 0.1, 0.3, and 1 mM. Add DMSO as needed to achieve the same concentration of the solvent in all samples.

Alternatively, dissolve enough inhibitor directly in growth medium to achieve a final concentration of 10 mM, then prepare the indicated serial dilution series with fresh growth medium.

DMSO can cause some cells to differentiate, which can change the pattern of glycosylation.

2. Add each supplemented growth medium to a previously established cell culture by replacing the spent growth medium with the supplemented medium. Incubate 1 hr.

Do not add concentrated stocks of glycosides directly to cell cultures, as high local concentrations of solvent and glycoside can kill cells.

3. Add radioactive precursors to each culture (generally 10 μ Ci/ml ³⁵SO₄²⁻, 20 μ Ci/ml [6-³H]GlcNH₂, or 50 μ Ci/ml [1-³H]Gal should be sufficient; see UNIT 17.4). Continue to incubate cells \geq 1 hr.

Preparation and
Analysis of
Glycoconjugates

17.11.1

4. Isolate the PGs and GAGs made by the cells and the oligosaccharides primed on the glycoside from the growth medium (UNIT 17.3).
5. Analyze the material by gel filtration and reversed-phase chromatography (see UNITS 17.20 & 17.21).

Oligosaccharides generated on primers are generally smaller than glycoproteins and proteoglycans.

N-ACETYL- α -D-GALACTOSAMINIDE INITIATION OF OLIGOSACCHARIDE SYNTHESIS AND INHIBITION OF O-LINKED GLYCOPROTEIN ASSEMBLY

Additional Materials (also see Basic Protocol 1)

0.2 M *p*-nitrophenyl-*N*-acetyl- α -D-galactosaminide in DMSO (see recipe)

NOTE: All incubations should be carried out in a humidified 37°C, 5% CO₂ incubator unless otherwise specified.

1. Add 0.2 M *p*-nitrophenyl-*N*-acetyl- α -D-galactosaminide in DMSO to aliquots of growth medium to achieve final concentrations of 0, 1, 2, 5, and 10 mM. Add DMSO as needed to achieve the same concentration of the solvent in all samples.

Alternatively, dissolve enough inhibitor directly in growth medium to achieve a final concentration of 10 mM, then prepare the indicated serial dilution series with fresh growth medium.

2. Add each supplemented growth medium to a previously established cell culture. Incubate 1 hr.

Do not add concentrated stocks of glycosides directly to cell cultures, as high local concentrations of solvent and glycoside can kill the cells.

3. Add radioactive precursors to cultures (generally 20 μ Ci/ml [6-³H]GlcNH₂ or 50 μ Ci/ml [1-³H]Gal should be sufficient; see UNIT 17.4). Incubate cells a further 3 hr.
4. Harvest the glycoproteins from the cells and growth medium (UNIT 17.3).
5. Analyze the material by gel filtration and reversed-phase chromatography (UNITS 17.20 & 17.21). Small oligosaccharides linked to hydrophobic aglycones will bind to C18 reversed-phase resins, aiding the separation of primed material from endogenous glycoproteins.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

***p*-nitrophenyl-*N*-acetyl- α -D-galactosaminide, 0.2 M in DMSO**

Dissolve 68.5 mg *p*-nitrophenyl-*N*-acetyl- α -D-galactosaminide (C₁₄H₁₈N₂O₈; mol. wt. 342.3) in 1 ml dimethylsulfoxide. Warm if necessary to dissolve.

***p*-nitrophenyl- β -D-xyloside, 0.2 M in DMSO**

Dissolve 54.2 mg *p*-nitrophenyl- β -D-xyloside (C₁₁H₁₃NO₇; mol. wt. 271.2) in 1 ml dimethylsulfoxide. Warm if necessary to dissolve.

Other β -D-xylosides are also commercially available, including the fluorescent compounds naphthol- β -D-xyloside and 4-methylumbelliferyl- β -D-xyloside. Using these latter compounds, the fluorescence of the aglycone can be used to monitor the recovery of oligosaccharides primed on the glycoside.

COMMENTARY

Background Information

Proteoglycan (PG) biosynthesis is initiated by the transfer of D-xylose from UDP-xylose to specific serine residues in core proteins. This intermediate acts as a natural primer for the assembly of heparan sulfate, heparin, chondroitin sulfate, and dermatan sulfate chains, depending on the tissue. In 1973, Okayama et al. (1973) reported that synthetic β -D-xylosides would prime glycosaminoglycan (GAG) synthesis, apparently by substituting for xylosylated core proteins. Since then, a variety of β -D-xylosides have been studied as primers with the following results. (1) Priming requires the β -anomer of D-xylose (Galligani et al., 1975). Other pentosides (β -D-lyxoside, β -D-ribose, and α -L-arabinoside) and hexosides of the linkage region generally lack activity (Robinson and Robinson, 1985; F.N. Lugemwa, A.K. Sarkar, and J.D. Esko, unpub. observ.). (2) Priming activity correlates with hydrophobicity of the aglycone (Robinson et al., 1975; Robinson and Robinson, 1981; Sobue et al., 1987; Kolset et al., 1990; Lugemwa and Esko, 1991). Thus, methyl- β -D-xyloside is a weak primer compared to *p*-nitrophenyl- β -D-xyloside or 4-methylumbelliferyl- β -D-xyloside. (3) The most active primers contain O or S in the glycosidic linkage, but *N*-xylosides and homo-*C*-xylosides also have activity (Sobue et al., 1987). (4) Priming is dose dependent (Esko et al., 1987; Lugemwa and Esko, 1991). (5) β -D-xylosides prime GAGs in most cells and can cause more GAG to be made than normally occurs on natural core proteins. (6) Cells secrete the majority of material generated on β -D-xylosides into the growth medium. (7) β -D-xylosides prime chondroitin sulfate or dermatan sulfate in virtually all cells, but priming of heparan sulfate occurs poorly, except with appropriate aglycones (Lugemwa and Esko, 1991; Fritz et al., 1994). (8) The fine structure of the chains depends on the concentration of the primer and may not precisely duplicate the structure of chains on natural core protein substrates (Fransson et al., 1992; Fritz et al., 1994). (9) β -D-xylosides compete with endogenous xylosylated core proteins for precursors and the various biosynthetic enzymes. Thus, β -D-xylosides act as inhibitors of PG synthesis. The inhibitory activity of xylosides has been exploited to examine the biological activity of PGs in cells.

The enormous success of β -D-xylosides in altering PG synthesis suggested that other gly-

cosides might act as artificial primers. Kuan et al. (1989) showed that aryl-*N*-acetyl- α -D-galactosaminides inhibited mucin assembly in colon carcinoma cells. Benzyl- α -D-galactosaminide inhibits O-linked oligosaccharide synthesis on cell-surface glycoproteins as well, which can have profound effects on cell adhesion (Kojima et al., 1992). Zhuang et al. (1991) showed that α -D-galactosaminides prime the synthesis of O-linked oligosaccharides. Thus, the inhibition of glycoprotein assembly is most likely due to competition between endogenous core protein substrates and the added glycoside. Recently, Neville et al. (1995) showed that *N*-acetylglucosaminides will prime poly-lactosamines. Sarkar et al. (1995) extended these studies by showing that more complex glycosides consisting of two sugar residues will prime oligosaccharides and inhibit the formation of glycoproteins involved in cell adhesion. These latter compounds are not commercially available, but they can be made relatively easily and inexpensively. The activity of disaccharide-based primers creates the opportunity to customize compounds that act at later points in glycoprotein synthesis.

Critical Parameters

Glycosides containing hydrophobic aglycones are moderately soluble in aqueous solutions. Stock solutions can be prepared in DMSO or ethanol and appropriate dilutions made into growth medium. β -D-xylosides are stable in both organic and aqueous solvents. It is important to add glycosides to growth medium before adding them to cells, because the concentrated solvent can cause cells to lyse. To avoid this problem, the glycosides can be dissolved directly into growth medium at a final concentration of ≤ 10 mM. A serial dilution series prepared in fresh growth medium can then be added to previously established cell cultures. This method minimizes the use of solvent and provides more accurate control over the concentration of glycoside.

Priming of oligosaccharides occurs in a concentration-dependent manner. Priming efficiency is easily assessed by adding a radioactive precursor, such as [6 - 3 H]GlcNH $_2$ or [1 - 3 H]Gal. 35 SO $_4^{2-}$ can be used to measure GAG synthesis. After brief incubation, the mixtures of radioactive oligosaccharides can be isolated from the growth medium, because cells secrete the majority of material generated on primers (UNITS 17.1 & 17.3). Usually this will require separation

of endogenous glycoproteins and PGs from the primed oligosaccharides and GAGs, e.g., by gel filtration or reversed-phase chromatography (UNITS 17.20 & 17.21).

In general, GAG biosynthesis peaks in most cells when the β -D-xyloside concentration reaches 10 to 100 μ M. However, this value varies in different cells. Thus, it is important to vary the concentration from 1 μ M to 1 mM and assess the minimal concentration needed for maximally priming GAGs. The priming of glycolipid-like compounds on β -D-xylosides requires relatively higher concentrations of primer (Freeze et al., 1993). Similarly, the priming of O-linked oligosaccharides by *N*-acetyl- α -D-galactosaminides depends on concentration, but the effective dose is considerably higher (1 to 10 mM) than that observed for β -D-xylosides (Kuan et al., 1989). In contrast, priming by modified disaccharides occurs in the 10 to 100 μ M range (Sarkar et al., 1995). These differences may relate to the relative abundance of endogenous substrates, solubility of the glycoside, its uptake through plasma membranes into the Golgi, its relative affinity for the glycosyltransferases, enzyme concentration and composition, or its susceptibility to hydrolysis.

Excessive concentrations of glycosides can be deleterious (Kanwar et al., 1986; Lugemwa and Esko, 1991). All glycosides exhibit detergent properties, because the molecules have both a hydrophilic end (the glucose unit) and a hydrophobic end (the aglycone). To test for toxic effects, one can employ glycosides with the wrong anomeric stereochemistry (e.g., α -D-xylosides; Farach et al., 1988), other pentosides (e.g., *p*-nitrophenyl- α -L-arabinoside), or the aglycone alone (e.g., *p*-nitrophenol).

Specificity exists with respect to the composition of GAG chains generated on β -D-xylosides (Lugemwa and Esko, 1991). Most xylosides (e.g., those containing linear aliphatic chains, single aromatic rings, and saturated multicyclic ring systems) tend to prime chondroitin sulfate and dermatan sulfate. The priming of chondroitin sulfate does not seem to depend on the aglycone: D-xylose and methyl- β -D-xyloside will initiate chondroitin sulfate (Okayama et al., 1973; Schwartz et al., 1974; Galligani et al., 1975; Lugemwa and Esko, 1991). Recent studies show that priming of heparan sulfate depends on aglycone structure (Lugemwa and Esko, 1991; Fritz et al., 1994). For example, naphthol- β -D-xyloside and estradiol- β -D-xyloside will prime heparan sulfate in Chinese hamster ovary cells. At low concentra-

tions, these primers initiate mostly chondroitin sulfate. As the concentration increases beyond 10 μ M, the proportion of heparan sulfate increases. Similar dose-dependent effects have been observed on the priming of different O-linked oligosaccharides by *N*-acetyl- α -D-galactosaminides (Zhuang et al., 1991; Kuan et al., 1989). The partitioning of intermediates into different biosynthetic pathways may reflect molecular recognition between the aglycone and specific enzymes.

Feeding cells glycosides provides an easy method to determine if a relationship exists between glycosylation and a particular biological activity. Glycoside primers subvert the cellular machinery for making oligosaccharides from the assembly of chains on endogenous core protein primers. Thus, glycosides inhibit the glycosylation of glycoproteins and PGs. Inhibition occurs in a dose-dependent fashion, but the inhibition is rarely complete, probably due to the inability of glycosides to mimic the endogenous core protein substrates. It is important to remember the following points. (1) Glycosides inhibit the formation of entire classes of glycoconjugates. The effects on individual proteins and PGs may vary. (2) Inhibition occurs in the midst of priming. The primed material may also have a different composition than the oligosaccharides produced on core proteins. Thus, any effect on a biological phenomenon may be due to the decline in glycoprotein or PG assembly or the increase in free oligosaccharide chains. (3) One should always consider the possibility that the enhanced rate of synthesis of oligosaccharides on primers may deplete pools of nucleotide sugars and thus alter the assembly of other types of glycoconjugates. (4) Primers may not always be as specific as once thought. For example, Freeze and coworkers have shown that β -D-xylosides will prime compounds resembling ganglioside GM₃ and an unusual pentasaccharide containing a terminal α -linked GalNAc (Freeze et al., 1993; Salimath et al., 1995).

Anticipated Results

The addition of glycosides to cultured cells primes the synthesis of free oligosaccharide chains and inhibits the formation of mature glycoconjugates. Priming and inhibition occur in a dose-dependent manner, and the appropriate concentration required for optimal priming and inhibition must be determined empirically. Figure 17.11.1 shows gel filtration profiles of GAG and PG synthesized by a murine mastocytoma cell line (Montgomery et al.,

Figure 17.11.1 Gel filtration chromatography of glycosaminoglycans (GAGs) and proteoglycans (PGs) generated in the presence of naphthol- β -D-xyloside. Mastocytoma cells (Montgomery et al., 1992) were incubated 4 hr with the indicated concentration of naphthol- β -D-xyloside and 20 μ Ci/ml ^{35}S SO_4^{2-} . The [^{35}S]GAGs and [^{35}S]PGs in the cells and growth medium were solubilized in Triton buffer and fractionated over a small DEAE-Sephacel column as described in UNIT 17.5. An aliquot was analyzed by gel filtration HPLC (TSK G4000 SW, 30 cm \times 7.5 mm i.d., Pharmacia Biotech). Samples were eluted with 0.5 M NaCl/0.1 M KH_2PO_4 (pH 6.0)/0.2% (w/v) Zwittergent 3-12 (Calbiochem) at a flow rate of 0.5 ml/min.

1992). As the concentration of β -D-xyloside rises, the amount of free GAG chains increases, as measured by material eluting in more retarded fractions. The size of these chains decreases as the primer concentration continues to rise. Presumably, this reflects the enhanced initiation of GAG chains and the competition of primers with endogenous xylosylated core proteins for limited precursors. The amount of mature PG decreases further as primers divert more resources away from the formation of GAG chains on core proteins. *N*-acetyl- α -D-galactosaminides and acetylated disaccharides have similar effects on the assembly of O-linked oligosaccharides on glycoproteins (Kojima et al., 1992; Sarkar et al., 1995). The relatively small oligosaccharides generated on these primers can be purified by reversed-phase and gel filtration chromatography (Zhuang et al., 1991).

RELEASE OF SACCHARIDES FROM GLYCOCONJUGATES

In many instances, it is useful to release a part or all of the oligosaccharide chains from a glycoconjugate before analyzing their structure, and the units presented in this section describe a variety of ways in which this can be achieved. Some of the methods described here (particularly the enzymatic ones) can also be applied to the study of free oligosaccharides or to oligosaccharides that are still attached to macromolecules.

Enzymes that degrade sugar chains fall into two general classes. Endoglycosidases cleave at defined sites within a sugar chain, with a specificity often based on certain features of the adjacent monosaccharide units. Thus, they are analogous to the restriction endonucleases that work on nucleic acids (*UNIT 3.1*). On the other hand, exoglycosidases specifically release single monosaccharides only when they are present as terminal units on sugar chains. Unlike the cases with exonucleases, the types of possible terminal units on oligosaccharide chains are numerous. Correspondingly, the number of available exoglycosidases with different specificities is quite large. In this section, one of the most commonly used group of exoglycosidases, the sialidases (also known as neuraminidases), is discussed in *UNIT 17.12*. Some commonly used endoglycosidases and glycoamidases for N-linked oligosaccharides (*UNIT 17.13A*) and polysaccharide lyases (*UNIT 17.13B*) are then considered.

Additional methods will be provided in future supplements (see Chapter 17 table of contents). One of the simplest and most direct ways to free an oligosaccharide chain from a glycoprotein or proteoglycan is to digest away the peptide with a broad-spectrum protease such as pronase or proteinase K (*UNIT 17.14*). In these cases, most of the peptide is removed except for the amino acids immediately surrounding the glycosylation site(s). If needed, more specific proteases (e.g., trypsin, chymotrypsin) can be used to generate glycopeptides with large stretches of amino acids still attached to the glycosylation sites. This approach is particularly useful for the detection of individual glycosylation sites on glycoproteins (*UNIT 17.14*).

There are also many classic and well-established methods for the chemical release of saccharides from glycoconjugates (*UNIT 17.15*). Some are designed to release intact sugars chains and others release the individual monosaccharide units. Although these methods tend to be somewhat less specific and potentially more destructive than the enzymatic approaches, they are cheap, convenient, and generally easy to use. These methods will be presented in future supplements.

Of course, there are many other techniques for the release of saccharides from glycoconjugates that could have been presented in this section. The current and upcoming selections were based on the criterion of broad general utility to the average molecular biologist. As methods in “glycotechnology” improve and simplify, further additions to this section may become appropriate.

Sialidases

Sialic acids are a family of nine-carbon acidic sugars found at the nonreducing terminus of many glycoconjugates. Sialidases (a term preferred to neuraminidases) can remove these sugar units selectively from cell surfaces, membranes, or purified glycoconjugates. This may be done to analyze the sialic acids or to study the consequences of their removal. The more sensitive and specific colorimetric assays for sialic acids work on free but not on glycosidically bound molecules (UNIT 17.16). Although careful acid hydrolysis also can be used to release sialic acids (UNIT 17.15), partial destruction of modifications and/or incomplete release can be problematic. Furthermore, acid hydrolysis may alter the underlying glycoconjugate or may be incompatible with functional studies.

In this unit, sialidase digestion of purified glycoproteins is described in the basic protocol and treatment of intact cells is outlined in the alternate protocol. The physical properties of the four most useful sialidases are listed in Table 17.12.1; their relative activities against sialic acids with different modifications and in different linkages are listed in Table 17.12.2 (see also critical parameters). The choice of enzyme depends upon the nature of the sample and knowledge of the type of sialylated glycoconjugates present.

BASIC PROTOCOL

SIALIDASE TREATMENT OF PURIFIED GLYCOPROTEINS

A purified glycoprotein sample is dissolved in digestion buffer and digested with a sialidase. Controls of sample alone and enzyme alone are also prepared. Digestion of gangliosides (glycolipids with sialic acid) requires detergent (e.g., deoxycholate, cholate, or taurocholate). After digestion, the reaction is terminated and desialylation is monitored.

Materials

Sialic acid-containing sample
Sialidase digestion buffer
Sialidase (Table 17.12.1)

Additional reagents and equipment for quantitating sialic acid (UNIT 17.16)

1. Dissolve the sialic acid-containing sample in sialidase digestion buffer at ~0.1 to 1 mM sialic acid concentration (final).

If the amount of sialic acid is not known, it can be estimated by acid hydrolysis (UNIT 17.15) or by quantitating the amount of sialic acid released with increasing amounts of

Table 17.12.1 General Properties of Commercially Available Sialidases

Feature	<i>Vibrio cholerae</i>	<i>Clostridium perfringens</i>	<i>Arthrobacter ureafaciens</i>	Newcastle disease virus

Sialidases

17.12.2

sialidase. If the amount of sialidase added is suboptimal, free sialic acid measured (by the TBA or DMB assays, UNIT 17.16) will increase with increasing amounts of sialidase.

If the sample contains gangliosides, include $1/50$ vol of 10% sodium deoxycholate (0.2% final) and place tubes in a sonicator bath for 1 to 2 min to ensure complete dispersal. If large amounts of gangliosides are present, the amount of detergent in the sample should be kept equal to or greater than the amount of ganglioside on a weight-to-weight basis. If no direct information is available concerning the amount of ganglioside present, a series of digestions with increasing amounts of detergent (e.g., 0.1%, 0.3%, 1.0%) may need to be done. Excess detergent may actually inhibit digestion. The *Arthrobacter ureafaciens* sialidase (see Table 17.12.1) is most active with gangliosides. Deoxycholate solutions may become cloudy in the presence of salts.

2. Add 1 to 20 mU sialidase to the sample and enzyme control tubes. Mix well.

Select the enzyme to be used based on the properties in Table 17.12.1. The amount of enzyme to use depends on the amount of releasable sialic acid in the sample. Initially, use ~ 1 mU/nmol of sialic acid. Further experiments may indicate that more or less enzyme is required.

3. Prepare blank tubes containing either sample alone or enzyme alone (in sialidase digestion buffer).

Alternative controls could include reactions incubated with inactivated sialidase (prepared by boiling 5 min) or active sialidase plus 1 mM 2,3-dehydro-2-deoxy-N-acetylneuraminic acid (Boehringer Mannheim), a sialidase inhibitor.

Table 17.12.3 Sialic Acid Standards

Glycoconjugate	Molecule	Linkages	Sialic acids ^a	Sialic acid concentration (nmol/mg)	Stock solution preparation ^b
Sialylactose (mixed isomers ^c)	Oligosaccharide	α 2-3 α 2-6	Neu5Ac	1600	31 mg/ml in water (100 \times)
Fetuin ^d	Glycoprotein (N- and O-linked)	α 2-3 α 2-6	Neu5Ac Neu5Gc(?)	280	20 mg/ml in water (10 \times)
Bovine submaxillary mucin	Mucin (O-linked)	α 2-6	mono- and di- <i>O</i> -acetylated Neu5Ac and Neu5Gc	150-400	20 mg/ml in water (10 \times)
Colominic acid	Polysaccharide	α 2-8	Neu5Ac	3400	15 mg/ml in water (100 \times)
Mixed brain gangliosides	Glycolipid	α 2-3 α 2-8	Neu5Ac ^f	950 ^e	5 mg/ml in 2:1:0.1 (v/v/v) chloroform/methanol/water (10 \times)

^aAbbreviations: Neu5Ac, *N*-acetylneuraminic acid; Neu5Gc, *N*-glycolylneuraminic acid.

^bStore all stock solutions at -20°C . Dilution to 1 \times will yield ~ 0.5 mM sialic acid.

^cRatio of α (2-3) to α (2-6) $\sim 4:1$, although lot-to-lot variation probably occurs.

^dRatio of α (2-3) to α (2-6) $\sim 1.6:1.4$ in commercial preparations, including Sigma (#F-3004) or GIBCO/BRL (Townsend et al., 1989).

^eDepending on the manufacturer.

^fCommercial preparations of bovine brain gangliosides have been treated with base during purification, resulting in loss of *O*-acetyl esters.

4. Incubate 3 to 4 hr at 37°C .

Digestion of gangliosides may require 24 to 48 hr.

For selective digestion of α (2-3) and α (2-8) linkages by the Newcastle Disease virus sialidase, use 1 to 5 mU in a 25 to 50 μl reaction and incubate 15 to 30 min at 37°C . These conditions are appropriate when the enzyme is present in excess of substrate, as is often the case when radiochemical amounts of substrate are present. The enzyme has a low level of activity against α (2-6) linkages; this becomes evident with prolonged incubations. If large amounts of sialic acids are present (e.g., >1 nmol), it will be necessary to titrate the enzyme. This can be done by setting up digests of standards containing α (2-3) or α (2-6)-linked sialic acids (Table 17.12.3) at the same concentration as the unknown sample and determining the amount of Newcastle disease virus sialidase that releases $>90\%$ of the α (2-3)-linked and $<5\%$ of the α (2-6)-linked sugar.

5. Terminate the reaction by boiling for 5 min. Check for release of sialic acid by monitoring:

- Sialic acid by direct measurement (UNIT 17.16)
- Shift in pI of a glycoprotein by isoelectric focusing (UNIT 10.4)
- Shift in TLC pattern for glycolipids (UNIT 17.3)
- Shift in apparent molecular weight on SDS-PAGE (UNIT 10.2; generally a loss of several sialic acid residues will be visible by small shifts on SDS-PAGE to either lower or higher apparent molecular weights)
- Alteration in lectin-binding patterns for some lectins (UNIT 17.7)
- Shift in negative charge of isolated oligosaccharides or glycolipids (UNIT 17.17).

Sialidases

17.12.4

SIALIDASE TREATMENT OF INTACT CELLS

Although the pH optima of bacterial and viral sialidases range from 4.5 to 5.5, these enzymes can be used to treat intact, viable cells at pH 7.0. Cells are washed and resuspended in isotonic serum-free buffer, then treated with the sialidase. The reaction is terminated by centrifugation and washing.

Additional Materials

Cells, prepared as a single-cell suspension
HEPES-buffered saline (HeBS)
Culture medium appropriate for cells, with serum

1. Wash cell suspension free from serum-containing medium by centrifuging 10 min at $500 \times g$ and resuspending twice in HeBS. After the last wash, resuspend in HeBS at $0.2\text{--}1 \times 10^7$ cells/ml. Divide the cells between two tubes.

Use HeBS containing 1 mM CaCl₂ if Vibrio cholerae sialidase is to be used.

Cell number can be determined by trypan blue exclusion as described in UNIT 11.5.

2. To one tube, add sialidase. To the second tube, add no enzyme. Incubate 30 min at 37°C.

Select the enzyme to be used based on the properties in Table 17.12.1. Initially use the sialidase in vast excess, e.g., 100 mU/ml for 10^7 cells/ml (presuming 10^7 cells will yield ~1 nmol), then titrate down for the optimum amount.

Alternative controls could include reactions incubated with inactivated sialidase (prepared by boiling 5 min) or active sialidase plus 1 mM 2,3-dehydro-2-deoxy-N-acetylneuraminic acid (Boehringer Mannheim), a sialidase inhibitor.

- 3a. *To characterize the sialic acid molecules released from the cells:* Chill reactions to 4°C and centrifuge 10 min at $2000 \times g$, 4°C. Collect supernatant, boil 5 min to inactivate sialidase, and proceed with characterization of the released sialic acid (UNIT 17.16).

It is important to inactivate the sialidase as otherwise it will continue to work on any glycoproteins shed or secreted into the medium during the 30-min incubation.

- 3b. *To characterize the glycoconjugates on the cell surface:* Wash cells three times in culture medium containing serum (to remove free sialidase) before proceeding with biochemical or functional assays.

REAGENTS AND SOLUTIONS**HEPES-buffered saline (HeBS)**

476 mg HEPES (20 mM final)
812 mg NaCl (140 mM final)
H₂O to 100 ml
Adjust pH to 7.0 with HCl
Stable <1 year at 4°C.

Sialidase digestion buffers

Clostridium perfringens and Arthrobacter ureafaciens sialidases: Dissolve 8.6 g sodium acetate in 100 ml water to obtain a 0.1 M sodium acetate stock solution. Adjust pH to 5.5 with 0.1 M acetic acid. Store <1 year at 4°C.

Vibrio cholerae sialidase: Add 14.7 mg CaCl₂ dihydrate and 580 mg NaCl to 100 ml of 0.1 M sodium acetate, pH 5.5. Store <1 year at 4°C.

Newcastle disease virus sialidase: Add 2 mg of fatty acid-free BSA (Sigma A7511)

per milliliter of 0.1 M sodium acetate, pH 5.5. Any high-purity BSA can be used (contaminating glycosidases may be present in low levels in some BSA preparations). Store indefinitely at -20°C .

Sialidases

Commercial sources for sialidases include Sigma, Calbiochem, Boehringer Mannheim, and Oxford GlycoSystems (see Table 17.12.1 and APPENDIX 4).

***Clostridium perfringens* sialidase:** Supplied as a lyophilized powder. Reconstitute to 10 mU/ μl in digestion buffer (see above) and store for several months at 4°C .

***Arthrobacter ureafaciens* sialidase:** Supplied as a lyophilized powder. Reconstitute to 1 to 10 mU/ μl per manufacturer's instructions. Store for ~ 6 months at 4°C .

***Vibrio cholerae* sialidase:** Supplied in solution. Store per manufacturer's instructions.

Newcastle disease virus sialidase: Available commercially. Alternatively, prepare as per Paulson et al. (1982). Store stocks in 5- to 10- μl aliquots at -70°C . Thaw only once and store on wet ice at 4°C until use.

COMMENTARY

Background Information

Sialidases from many viral and bacterial strains have been described (Drzeniek, 1973). In general, bacterial enzymes have the broadest spectrum of activity, although the limited specificity of the viral enzymes can be an advantage for certain analyses.

Sialic acid is found in $\alpha(2-3)$ or $\alpha(2-6)$ linkages to neutral sugars (e.g., galactose, *N*-acetylgalactosamine, *N*-acetylglucosamine) or in $\alpha(2-8)$ linkage to another sialic acid. The $\alpha(2-3)$ - and $\alpha(2-6)$ -linked sialic acid residues are found in glycoproteins (both N- and O-linked) and in glycolipids. $\alpha(2-8)$ -linked residues are found in glycolipids, colominic acid (from *E. coli*), and a few mammalian glycoproteins (e.g., neural cell adhesion molecule). As outlined in Table 17.12.2, not all sialidases are active towards all linkages, and these differences can be exploited in structural analyses. Sialidases are only active against α -linked sialic acids. The only natural β -linked sialic acid is in CMP (cytidine monophosphate)-sialic acid.

The common sialic acid *N*-acetylneuraminic acid (Neu5Ac) can carry modifications (primarily *O*-acetylation but also glycolylation, sulfation, and methylation; see Varki, 1992, and Table 17.12.2). Sialidases differ in their activities towards these modified sialic acids. Unfortunately, the distribution of sialic acids containing these modifications has not been well-characterized in most mammalian systems.

Critical Parameters

Several caveats must be kept in mind in using sialidases.

Cleavage. The relative catalytic rates of the different enzymes for the various linkage types—i.e., $\alpha(2-3)$, $\alpha(2-6)$, and $\alpha(2-8)$ —are not of much consequence in most instances, because the enzymes are usually used in excess. Important exceptions to this include: (1) The Newcastle disease virus sialidase preferentially cleaves $\alpha(2-3)$ and $\alpha(2-8)$ linkages. However, $\alpha(2-6)$ -linked sialic acid will be hydrolyzed slowly if an excessive amount of enzyme is employed or if incubations are continued >30 min. (2) The *Vibrio cholerae* enzyme does not cleave the $\alpha(2-3)$ -linked “internal” sialic acid of extended gangliosides (e.g., G_{M1}), although it is active against the oligosaccharide if ceramide is removed. (3) The $\alpha(2-8)$ linkages of colominic acid and b series gangliosides are relatively resistant to release. Combined treatments with sialidases and endosialidases (Troy, 1992) may be used for polysialic acids with more than five sialic acid units. (4) Ganglioside-bound sialic acids may require detergents for complete release. Deoxycholate and cholate work the best.

Effect of substitution. Substitutions have variable effects upon release depending on the enzyme used, as summarized in Table 17.12.2. The decrease in rate with the *N*-glycolyl modification is not relevant in using any of the enzymes. The decrease in rates for the 9- or 7-mono-*O*-acetyl substitutions are also not practically relevant, except for the *Vibrio* enzyme, and particularly with gangliosides. On the other hand, the 4-mono-*O*-acetyl substitution causes complete resistance to all known sialidases. The effects of di- and tri-*O*-acetyl

substitutions have not yet been carefully studied, and it is not safe to extrapolate from data on mono-*O*-acetyl molecules. Likewise, combinations of substitutions (e.g., *N*-glycolyl and *O*-acetyl) have not been studied carefully. Finally, there is no information on the rarer types of sialic acids (e.g., *O*-methyl and *O*-sulfate substituted). If *O*-acetylation is suspected, prior treatment of the glycoconjugates with base (UNIT 17.15) will cause de-*O*-acetylation and improve release.

Controls. Whenever possible, controls such as the sample without enzyme and the enzyme alone must be studied in parallel to be sure that the sialic acids detected are actually released from the sample. This is particularly important when ultrasensitive methods (such as TBA with HPLC detection or DMB derivatization; UNIT 17.16) are employed. These methods are so sensitive that “environmental contamination” with sialic acids can become a problem.

Analysis of results. It is useful to compare the amount of sialic acid released (UNIT 17.16) by sialidase with the amount released by mild acid hydrolysis (UNIT 17.15). If the amount released by the sialidases is significantly less than that released by mild acid, then the sialic acid residues may be resistant due to (1) incorrect choice of sialidase, (2) modification of the sialic acid residues, (3) steric hindrance, or (4) suboptimal conditions for digestion.

It may be important to demonstrate that the observed effect produced by sialidase treatment (e.g., shift in isoelectric point on a focusing gel or a functional response) is in fact due to the sialidase activity. Treatment with heat-inactivated enzyme (prepared by boiling for 5 min) or inhibition with 1 mM 2,3-dehydro-2-deoxy-*N*-acetylneuraminic acid, a specific inhibitor of sialidases, can be used. The reaction should be titrated so that just enough sialidase is being used for the observed result, and then the effect of the inhibitor assessed.

Sialidase inhibitors. Inhibitors of sialidases do exist. Dextran sulfate inhibits the *Vibrio cholerae* sialidase. Other polyanions (e.g., DNA, RNA, and proteoglycans) may also inhibit this or other sialidases. Free sialic acid also can inhibit the *Vibrio cholerae* enzyme, with a K_i of ~5 mM.

Agglutination. Treating intact cells with Newcastle disease virus can cause agglutination of cells. This effect should not be confused with clumping due to cell death.

Buffer systems. The sialidases are compatible with several different buffer systems, with some differences in pH optima noted (Table

17.12.1). *Vibrio cholerae* sialidase works well in sodium acetate and Tris/maleate at pH 5.0 to 6.0 but is considerably more active in Tris/maleate at pH >5.0. *Clostridium perfringens* sialidase has pH optima of 4.5 in sodium acetate but 5.5 in citrate phosphate. *Arthrobacter ureafaciens* sialidase digestion proceeds maximally at pH 5.5, yet retains >50% of activity at pH 4.5 and 7.0. For all sialidases, alternative choices include sodium acetate, ammonium acetate, Tris, HEPES, phosphate, and cacodylate. Acetate interferes with HPLC on AX-5 resin (UNIT 17.12) and β -hexosaminidase digestion (UNIT 17.13).

Troubleshooting

Failure to digest a known sialoglycoconjugate to completion could be due to failure to add sufficient sialidase, use of an old or improperly reconstituted and/or stored enzyme aliquot, or inactivation of the enzyme after addition. If the sample is an unknown but potentially contains >1 nmol of releasable sialic acid, a titration comparing increasing amounts of sialidase versus sialic acid released is useful. Sialidases can lose activity rapidly (e.g., <1 hr) after dilution into an assay mix; inclusion of BSA will help prevent this inactivation. Some manufacturers recommend that the *Arthrobacter ureafaciens* and *Clostridium perfringens* sialidases be reconstituted with BSA for stability on storage.

Anticipated Results

If the type of sialidase used is tailored to the type of sialic acid and linkage, it should be possible to obtain nearly complete release of these residues.

Time Considerations

Once the appropriate buffers and standards are made, the actual digestions will take 30 min to 4 hr or longer (especially for gangliosides). Time required for analysis of the digested product(s) will depend on the specific analytical method employed (as listed in step 6 of the basic protocol).

Endoglycosidase and Glycoamidase Release of N-Linked Oligosaccharides

Carbohydrate chain modifications are often used to monitor glycoprotein movement through the secretory pathway. This is because stepwise sugar-chain processing is unidirectional and generally corresponds to the forward or anterograde movement of proteins. This unit offers a group of techniques that will help analyze the general structure of carbohydrate chains on a protein and, therefore, oligosaccharide processing mileposts. The minimum requirements are that the protein can be labeled metabolically (UNIT 10.18) and immunoprecipitated (UNIT 10.16) and clearly seen on a gel or blot (UNIT 10.8). The sugar chains themselves are not analyzed, but their presence and structure are inferred from gel mobility differences after one or more enzymatic digestions. This approach is most often used in combination with [³⁵S]Met pulse-chase metabolic labeling protocols, but they can be applied to any suitably labeled protein (e.g., biotinylated or ¹²⁵I-labeled). As the oligosaccharide chains mature, they become either sensitive or resistant to highly specific glycosidases. Some of these enzymes cleave intact oligosaccharide chains from the protein—e.g., endo H, endo F₂, endo F₃, peptide:N-glycosidase F (PNGase F), endo D, and O-glycosidase. Others strip only terminal sugars (e.g., sialidase) or degrade a selected portion of the chain (e.g., endo-β-galactosidase). The techniques can be adapted to count the number of N-linked oligosaccharide chains on a protein. One unusual protease, O-sialoglycoprotease, degrades only proteins containing tight clusters of O-linked sialylated sugar chains. These techniques work best on average size proteins (<100 kDa) that contain a few percent carbohydrate by weight, where a gel shift of 1 kDa can be seen. A summary of the enzymes and their applications is shown in Table 17.13A.1.

This unit provides information on how to measure changes in carbohydrate structure and how these changes relate to protein trafficking. Fortunately, the techniques are independent of mechanistic views, although it should be borne in mind that the organization and distribution of many of these indicator enzymes are cell type dependent.

Table 17.13A.1 Enzymes Described in This Unit

Enzyme	Indications and uses	Monitors ^a
Endo D	Transient appearance of highly processed, sensitive forms prior to addition of GlcNAc by GlcNAc transferase I	Cis to medial Golgi
Endo F ₂	Presence of biantennary chains ± core fucose	Medial Golgi
Endo F ₃	Presence of core fucosylated biantennary α chains and/or triantennary chains ± core fucosylation	Medial Golgi
Endo-β-galactosidase	Presence of poly lactosamines	Trans-Golgi and TGN
Endo H	Conversion of high mannose to complex type N-linked chains	Cis to medial Golgi
O-Glycosidase	Presence of Galβ1,3GalNAc-α-Thr/Ser O-linked chains	Cis to medial Golgi
PNGase F	Presence of N-linked chains cleaves; nearly all N-linked chains; only enzyme that cleaves tetrantennary chains	Medial Golgi
Sialidase	Acquisition of sialic acids	Trans-Golgi and TGN
O-Sialoglycoprotease	Presence of mucin-like proteins with cluster of sialylated oligosaccharides	Trans-Golgi and TGN

^aAbbreviation: TGN, trans-Golgi network.

The starting material for these protocols is assumed to be [³⁵S]Met-labeled, immunoprecipitated protein bound to ~20 μl of protein A–Sepharose beads (as described in *UNIT 10.16*). The trace amount of protein is eluted by heating in a small volume of 0.1% SDS, diluted in the appropriate buffer and then digested with one or more enzymes in a small volume. The digest is analyzed on an appropriate SDS-PAGE system that can detect a 1- to 2-kDa size change. A change in the mobility of the protein after digestion is evidence that the carbohydrate chain was sensitive to the enzyme and therefore, that the protein had encountered a certain enzyme in the processing pathway. Alternatively, the analysis can be done by two-dimensional isoelectric focusing (IEF)/SDS-PAGE or two-dimensional nonequilibrium pH gradient electrophoresis (NEPHGE)/SDS-PAGE (*UNIT 10.4*) to see the loss of charged sugar residues or of anionic oligosaccharide chains. The same digestions and SDS-PAGE analysis also apply to proteins that are radioiodinated or biotinylated, or to immunoprecipitates derived from subcellular fractions separated on sucrose or Percoll gradients.

It is important to present the glycosylation pathways, as a detailed description of the pathways is needed to appreciate how they will be used in this unit. A single protein can have more than one kind of oligosaccharide (N-linked and O-linked), and each individual N-linked chain can mature into a different final form. The same is true for O-linked chains. Each is described below.

THE N-LINKED PATHWAY

The N-linked oligosaccharide maturation pathway is most frequently used for tracking protein movement through the Golgi complex. A common feature of all N-linked chains is the core region pentasaccharide shown in Figure 17.13A.1, which consists of three mannose units and two *N*-acetylglucosamine units. The mannose units comprise the trimannosyl core, and two of these residues are α-linked to the only β-linked mannose in the molecule. The β-linked mannose is bound to one of the two *N*-acetylglucosamines. Because they are β1-4 linked to each other, resembling the polysaccharide chitin, this is called a chitobiose disaccharide. Initially, all *N*-glycosylated proteins begin life when a preformed, lipid-associated oligosaccharide is transferred within the lumen of the endoplasmic reticulum (ER) to Asn of proteins having an Asn-X-Thr/Ser sequence. This precursor oligosaccharide contains three glucose (Glc), nine mannose (Man), and two *N*-acetylglucosamine (GlcNAc) sugar residues, and has the structure shown in Figure 17.13A.1. There are several ways to depict this structure. The short-hand symbol method used in Figure 17.13A.1 is the most convenient, but be sure to note the linkages of the individual sugars, as they are important. The α and β symbols denote the anomeric configuration of the sugar, and the number indicates which hydroxyl group of the next sugar is involved in the glycosidic linkage. In all cases, the anomeric position is 1, except in sialic acid where it is 2.

The details of the pathway are presented in Figures 17.13A.2 and 17.13A.3, along with the sensitivity to each endoglycosidase or glycoamidase. The figures show the steps between high-mannose and hybrid types (Fig. 17.13A.2) and complex types (Fig. 17.13A.3). The three Glc residues (filled triangles) are removed from properly folded proteins within the ER by two different oligosaccharide-processing α-glucosidases. The first α1-2Glc is cleaved by α-glucosidase I, and the next two α1-3Glc residues by α-glucosidase II (Fig. 17.13A.2, step 1). An ER-associated α-mannosidase removes one Man residue (open circle; Fig. 17.13A.2, step 2). The protein then moves on to the first step in Golgi-localized processing—the removal of the three remaining α1-2 Man units by Golgi α-mannosidase I to produce Man₅GlcNAc₂ (Fig. 17.13A.2, steps 3 and 4). Many proteins have only high-mannose-type oligosaccharides with five to nine Man residues,

Figure 17.13A.1 Symbol structures for the core region and precursor of N-linked sugar chains. Each sugar is given a symbol and abbreviation at the bottom of the figure. Each one except sialic acid uses its anomeric carbon (C-1) for linking to other sugars. Sialic acid uses C-2 for glycosidic linkage to other sugars. Glycosidases and glycosyltransferases are anomeric specific and distinguish α or β configurations of each sugar. The core structure (**A**) is common to all N-linked chains and is composed of three Man and two GlcNAc residues. The α or β configuration of each sugar is indicated, and the OH group to which that sugar is linked is shown on the bar linking the two symbols. Thus, GlcNAc β 1-4GlcNAc β is represented by two filled squares with β and 4 between them. When a structure is first presented, it will have full display such as that on the left side; if it is repeated, only the symbols will be used as shown immediately to the right. The precursor oligosaccharide (**B**) for all N-linked chains is synthesized in the ER and transferred cotranslationally to the peptide containing an available Asn-X-Thr/Ser sequon.

and no further processing occurs. Alternatively, one to five GlcNAc residues (filled squares) can be added to the trimannosyl core, and these are usually extended with galactose (Gal; filled circles) and sialic acid (Sia; filled diamonds) residues. These extensions, called antennae, are the hallmarks of complex-type oligosaccharides. The transformation of the precursor sugar chain into various high-mannose or complex types is called oligosaccharide processing (Kornfeld and Kornfeld, 1985).

Man₅GlcNAc₂ is an important intermediate because it can have several fates. The first is the well-established addition of one GlcNAc residue by GlcNAc transferase I (Fig. 17.13A.2, step 6). This is the first step toward the formation of complex chains. However, simply adding Gal and Sia to the terminal GlcNAc of this oligosaccharide forms a hybrid structure (Fig. 17.13A.2, steps 12 and 13), where the left side of the molecule looks like a complex chain having one antenna, and the right side still resembles a high-mannose chain. The GlcNAc₁Man₅GlcNAc₂ structure is the *required* substrate for α -mannosidase II, which removes the two terminal Man units from the upper branch of the chain (i.e., the α 1-3Man and α 1-6 Man units; Fig. 17.13A.2, step 7). This enzyme only works after the addition of the first GlcNAc.

Figure 17.13A.2 N-linked oligosaccharide maturation pathway for high-mannose and hybrid types, and sensitivities to various enzymes (see Fig. 17.13A.1 for key). Brackets (top) show the structures designated as high-mannose and hybrid chains. The boxes indicate ER or Golgi localization. The pathway begins with the precursor oligosaccharide (see Figure 17.13A.1). Each successive numbered step in circles represents a glycosidase or glycosyl transferase that generates a new sugar chain with different sensitivities to the various endoglycosidases or PNGase F. (1) precursor oligosaccharide is trimmed by α -glucosidases I and II, removing three Glc. (2) ER mannosidase removes one Man. (3) α -Mannosidase I in Golgi complex removes two Man to make $\text{Man}_6\text{GlcNAc}_2$, with a single remaining α 1-2Man. (4) The final α 1-2Man is removed by a Golgi complex α -mannosidase I. (5) α -Mannosidase III removes the α 1-3 and α 1-6Man units to make $\text{Man}_3\text{GlcNAc}_2$. (6) GlcNAc transferase I adds GlcNAc to either $\text{Man}_5\text{GlcNAc}_2$ or $\text{Man}_3\text{GlcNAc}_2$. (7) α -Mannosidase II removes the α 1-3 and α 1-6Man units to make $\text{GlcNAc}_1\text{Man}_3\text{GlcNAc}_2$. Sensitivity to various enzymes (bottom) changes when moving from left to right, but remains the same within vertical columns. *NOTE:* This continued maturation to form complex chains is shown in Figure 17.13A.3. Additionally, these figures are not comprehensive; many glycosylation steps have not been included, but they do not affect the sensitivities to the enzymes listed.

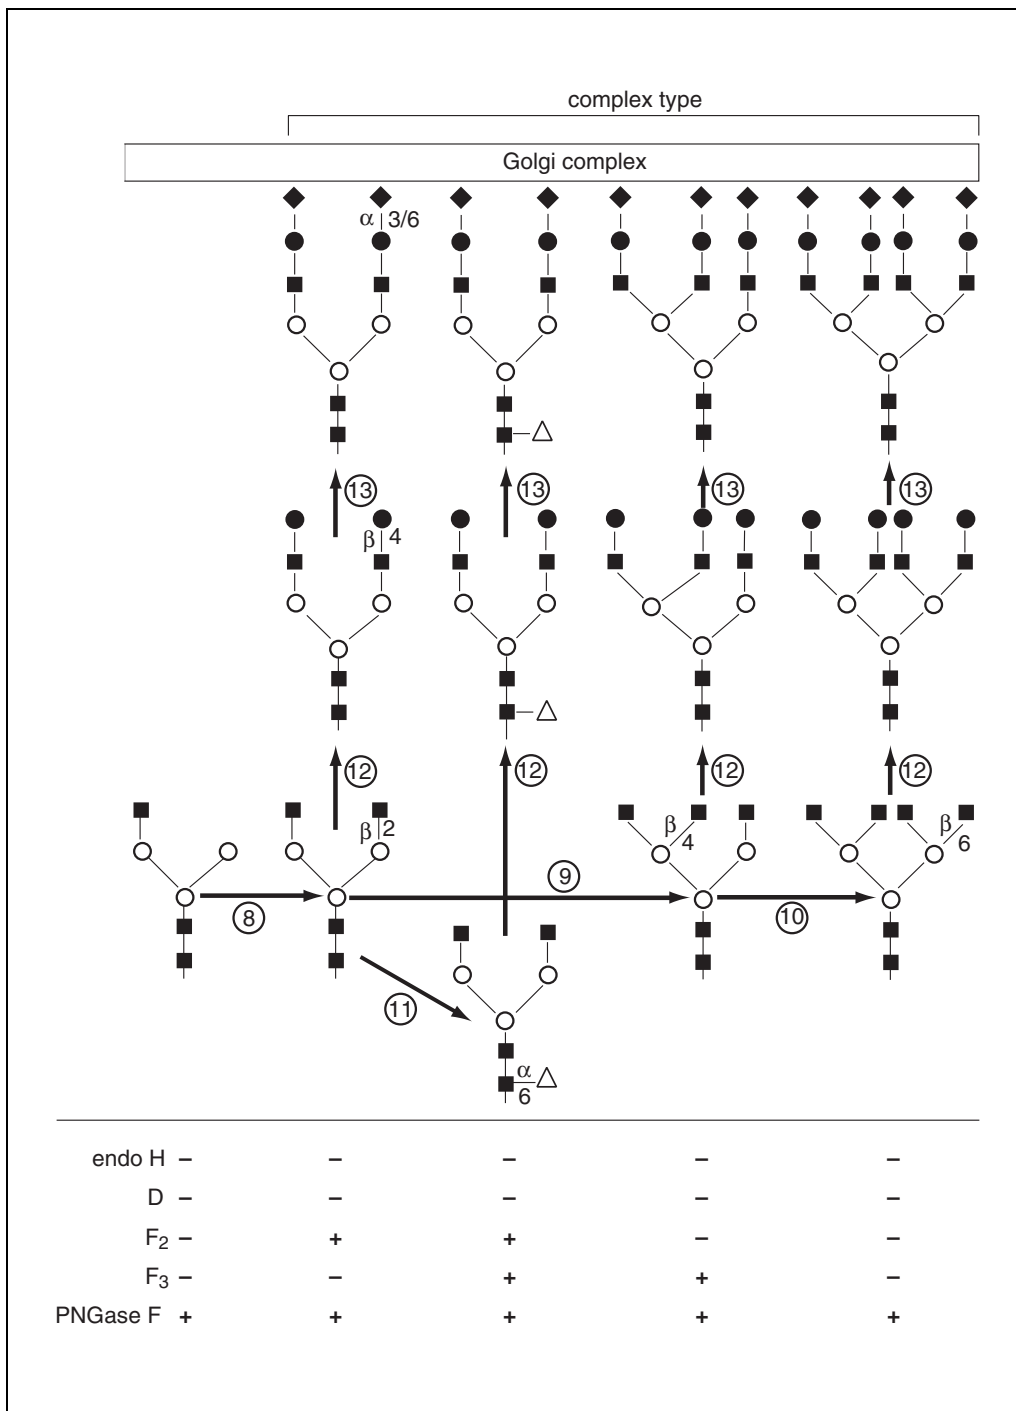

Figure 17.13A.3 N-linked oligosaccharide maturation pathway for complex types, and sensitivities to various enzymes (see Fig. 17.13A.1 for key; see Fig. 17.13A.2 for additional details). **(8)** GlcNAc transferase II adds a second GlcNAc to initiate a biantennary chain. **(9)** GlcNAc transferase IV adds a third GlcNAc to initiate a triantennary chain. **(10)** GlcNAc transferase V adds a fourth GlcNAc to initiate a tetraantennary chain. **(11)** Fucosyltransferase adds α 1-6Fuc to the core region of complex chains. **(12)** β 1-4Gal is added to available GlcNAc residues of hybrid and complex chains. **(13)** α 2-3 or α 2-6Sia is added to Gal residues of hybrid and complex chains.

The other fate for the $\text{Man}_5\text{GlcNAc}_2$ chain is to act as a substrate for the newly identified α -mannosidase III (Chui et al., 1997), which removes the same two Man units as α -mannosidase II, but does not require the prior addition of the first GlcNAc (Fig. 17.13A.2, step 5). α -Mannosidases II and III show partial overlap in the Golgi complex, but α -mannosidase III may occur preferentially in an earlier compartment. The $\text{Man}_3\text{GlcNAc}_2$ product of α -mannosidase III is also a substrate for GlcNAc transferase I. Thus, the same product, $\text{GlcNAc}_1\text{Man}_3\text{GlcNAc}_2$ can be formed in two ways: first, by the sequential action of α -mannosidase III and GlcNAc transferase I (Fig. 17.13A.2, steps 5 and 6) or, second, by GlcNAc transferase I and α -mannosidase II (Fig. 17.13A.2, steps 6 and 7). Sensitivity to specific enzyme digestions (endo H and endo D) can distinguish which route was taken (Fig. 17.13A.2).

GlcNAc transferase II now adds a second GlcNAc to the α 1-6-linked Man (Fig. 17.13A.3, step 8). This molecule can also have several fates. First, fucose (Fuc) can be added to GlcNAc residue linked to the Asn of the protein (Fig. 17.13A.3, step 11). Second, one to three more GlcNAc residues can be added to the core mannose residues to initiate tri- and tetraantennary chains (Fig. 17.13A.3, steps 9 and 10), and even pentaantennary chains (not shown). GlcNAc additions are considered to occur in the medial Golgi regions. Each GlcNAc-based branch can be individually modified, but they are usually extended by one Gal (Fig. 17.13A.3, step 12) and terminated by a Sia (Fig. 17.13A.3, step 13). Both of these sugars are usually thought to be added in *trans*-Golgi cisternae or in the *trans*-Golgi network (TGN). Sometimes selected antennae are also fucosylated in the TGN. One or more terminal Gal residues can be extended by variable-length polylactosamines (Gal β 4-GlcNAc repeats) capped by a Sia. GlcNAc and Gal can be sulfated as a late, perhaps even final, step of processing. These extensions/modifications are thought to occur in the late Golgi complex and TGN, but their order and compartmental segregation are not well understood. Other modifications of N-linked sugar chains are known, but there are fewer tools available to analyze their biosynthetic localization.

THE O-LINKED PATHWAY

For practical purposes, only a portion of the O-linked pathway—i.e., the addition of the first few sugars—will be presented. However, it is very important to remember that some of the same outer chain structures such as Sia, polylactosamines, and Fuc residues are common to both N- and O-linked oligosaccharides.

α -N-Acetylgalactosamine (α -GalNAc; open square) is the lead-off sugar for the O-linked pathway (Fig. 17.13A.4; also see Fig. 17.13A.1 for symbols). It is added to Ser/Thr residues that occur in the proper configuration, generating a broad variety of acceptor sequences. These sequences often cluster as repeats within mucin-like domains. GalNAc is added in the earliest parts of the Golgi complex, not cotranslationally. GalNAc can be further extended by at least six different sugars. The most common is the addition of a β 1-3Gal (Fig. 17.13A.4, step 1), forming a disaccharide that is one of the few O-linked chains that can be diagnosed by enzymatic digestions. This disaccharide is often capped by a Sia (Fig. 17.13A.4, step 2). Additional sugars such as Sia (Fig. 17.13A.4, step 3) or GlcNAc followed by Gal (Fig. 17.13A.4, steps 4 and 5) can be added. Structural analysis can be done by sequential exoglycosidase digestion, but given the complexity and heterogeneity of the sugar chains, such analysis is not a very useful indicator for tracking protein movement through the Golgi complex. Many O-linked chains have terminal Sia residues and, when tightly clustered on Ser/Thr residues, these chains promote proteolysis by O-sialoglycoprotease regardless of the structure of the underlying sugar chain.

Another type of O-linked glycosylation is the addition of glycosaminoglycan (GAG) chains to form proteoglycans. This occurs by a different pathway than the α -GalNAc

Figure 17.13A.4 A small portion of the O-GalNAc pathway (see Fig. 17.13A.1 for key). The first step of the O-linked pathway occurs in the early Golgi complex with the addition of α -GalNAc. There are at least six other sugars that can be added at this point in this complex pathway. Often β 1-3Gal is added (1), quickly followed by α 2-3Sia (2). The presence of these structures can be detected with a combination of O-glycosidase and sialidase. Additional sugars can be added as shown. α 2-6Sia (3) or β 1-6GlcNAc (4) followed by β 1-4Gal (5) and α 2-3Sia (6) on Gal. Each of these sugars must be removed before O-glycosidase can cleave the disaccharide.

linkage. Instead, the chains begin by addition of a β -Xylose (Xyl; open inverted triangle) residue to Ser and are then elongated by two Gal residues and a glucuronic acid (GlcA; half-filled diamond) residue. This core structure can be further elongated by the addition of GlcA β 1-3GalNAc β disaccharides to form the backbone of chondroitin/dermatan sulfate chains, or by GlcA β 1-3GlcNAc α to form the backbone of heparan sulfate chains. Biosynthesis and movement of these proteins have also been followed through the Golgi complex. Initiation begins in late ER/early Golgi complex, and the core tetrasaccharide is probably finished within the medial Golgi, but the addition of chondroitin chains appears to be confined to the TGN. In addition to the well-known O-linked GAG chains, there is clear evidence for the existence of a class of N-linked GAG chains.

ENDOGLYCOSIDASE H DIGESTION

Endoglycosidase H (endo H) cleaves N-linked oligosaccharides between the two *N*-acetylglucosamine (GlcNAc) residues (Fig. 17.13A.5) in the core region of the oligosaccharide chain (Fig. 17.13A.1) on high-mannose and hybrid, but not complex, oligosaccharides. In this protocol, a fully denatured protein is digested with endo H to obtain complete release of sensitive oligosaccharides.

Materials

- Immunoprecipitated protein of interest (UNIT 10.16)
- 0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
- 0.5 M sodium citrate, pH 5.5
- 1% (w/v) phenylmethylsulfonyl fluoride (PMSF) in isopropanol
- 0.5 U/ml endoglycosidase H (endo H; natural or recombinant; Sigma, Glyko, or Boehringer Mannheim)
- 10 \times SDS sample buffer (UNIT 10.2A)
- Water baths, 30 $^{\circ}$ to 37 $^{\circ}$ C and 90 $^{\circ}$ C

BASIC PROTOCOL 1

Preparation and Analysis of Glycoconjugates

17.13A.7

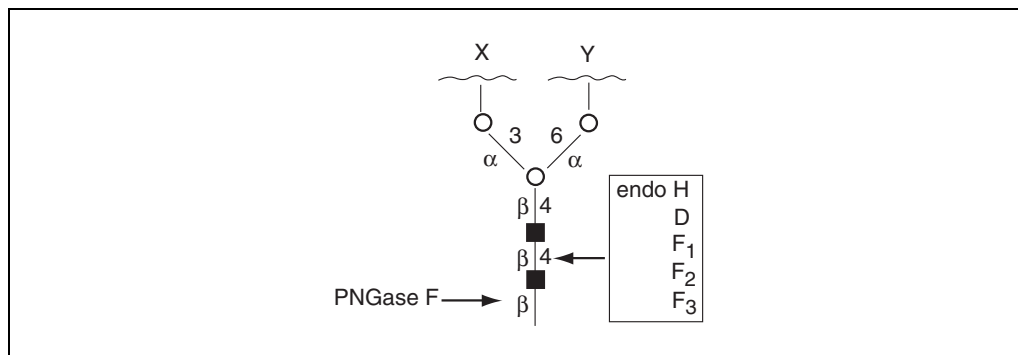

Figure 17.13A.5 PNGase F and endoglycosidase-sensitive bonds in the core of N-linked oligosaccharides (see Fig. 17.13A.1 for key). PNGase F is a glycoamidase that severs the bond between GlcNAc and Asn, liberating the entire sugar chain and converting Asn into Asp. The endoglycosidases (H, D, and Fs) cleave the bond between the two GlcNAc residues in the core region, leaving one GlcNAc still bound to the protein. The differential specificity of the endoglycosidases is based on the structure of the sugar chain in a fully denatured protein. Incomplete denaturation may not expose all sensitive linkages. X and Y are unspecified sugar residues.

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Add 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS to immunoprecipitate in a microcentrifuge tube, mix well, and heat denature 3 to 5 min at 90°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

Protein solubilization in nonionic detergents such as Triton X-100 or Nonidet P-40 is not always sufficient to completely expose all susceptible cleavage sites. Only strong denaturation with SDS exposes all sites for maximum cleavage.

2. Cool and microcentrifuge for 1 sec at 1000 \times g to collect condensed droplets in the bottom of the tube.
3. Place 10- μ l aliquots of solubilized, denatured protein (supernatant) in each of two clean microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

6 μ l 0.5 M sodium citrate, pH 5.5
 20 μ l H₂O
 2 μ l 1% PMSF (in isopropanol)
 1 μ l 0.5 U/ml endo H (enzyme digest only; substitute with water in control).

The PMSF prevents proteolysis. Nonionic detergent is not required to prevent inactivation of endo H as long as high-purity SDS is used.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate overnight at 30°C to 37°C.
6. Immediately prior to electrophoresis, inactivate endo H by adding 4 μ l of 10 \times SDS sample buffer and heating 5 min at 90°C.

7. Analyze protein by one-dimensional SDS-PAGE (UNIT 10.2) and autoradiography (APPENDIX 3A).

The presence of high mannose and/or hybrid N-linked oligosaccharide chains will be evidenced by increased mobility of the digested proteins on SDS-PAGE.

ENDOGLYCOSIDASE D DIGESTION

Like endo H, endo D also cleaves between the two GlcNAc residues in the core of the N-linked sugar chains (Fig. 17.13A.5). However, its narrow substrate specificity makes it useful for detecting the transient appearance of just a few early processing intermediates. It requires that the 2 position of the α 1-3-linked core Man be unsubstituted. This intermediate arises after processing by either α -mannosidase I or III, but prior to addition of the first GlcNAc or action of α -mannosidase II (see Fig. 17.13A.2, steps 3 to 5). Cells with a defect in GlcNAc I transferase (e.g., Lec 1 CHO cells) do not add the first GlcNAc residue (Fig. 17.13A.2, step 6), and N-linked oligosaccharides will remain sensitive to endo D because they cannot modify the α 1-3Man residue.

Materials

Immunoprecipitated protein of interest (UNIT 10.16)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M NaH₂PO₄, pH 6.5
10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
0.5 U/ml endoglycosidase D (endo D; Boehringer Mannheim)
10× SDS sample buffer (UNIT 10.2A)
Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS by heating for 3 to 5 min at 90°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge at 1000 \times g for 1 sec to collect condensed droplets in the bottom of the tube.
3. Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

2 μ l 10% Triton X-100 or NP-40 (20-fold excess over SDS)
2 μ l 0.5 M NaH₂PO₄, pH 6.5
5 μ l H₂O
1 μ l 1 IU/ml endo D (enzyme digest only; substitute with water in control).

The 20-fold excess of nonionic detergent is essential to prevent inactivation of endo D by SDS.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.

6. Immediately prior to electrophoresis, inactivate by adding 2 μ l of 10 \times SDS sample buffer and heating for 5 min at 90°C to 95°C.
7. Analyze protein by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

Endo D sensitivity is detected by increased electrophoretic mobility of the digested proteins on SDS-PAGE.

ENDOGLYCOSIDASE F₂ DIGESTION

Endo F₂, like endo H and endo D, cleaves between the two GlcNAc residues in the chitobiose core (Fig. 17.13A.5). It preferentially releases biantennary complex-type oligosaccharide chains from glycoproteins, but does not cleave tri- or tetraantennary chains.

Materials

Immunoprecipitated protein of interest (UNIT 10.16)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium acetate, pH 4.5 (APPENDIX 2)
10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
0.1 M 1,10-phenanthroline in methanol
200 mU/ml endoglycosidase F₂ (endo F₂; Glyko)
4 \times SDS sample buffer (UNIT 10.2A)
Water baths, 30° to 37°C and 90°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS by heating for 3 to 5 min at 90°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge at 1000 \times g for 1 sec to collect condensed droplets in the bottom of the tube.
3. Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

15 μ l 0.5 M sodium acetate, pH 4.5
3 μ l 0.1 M 1,10-phenanthroline in methanol
2 μ l 10% Triton X-100 or NP-40 (20-fold excess over SDS)
1 μ l 200 mU/ml endo F₂ (enzyme digest only; substitute 0.5 M sodium acetate in control).

A 10- to 20-fold excess of nonionic detergent is required to stabilize the enzyme.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate the mixture at 30° to 37°C overnight.

Some inactivation of the enzyme occurs at 37°C, even with nonionic detergent present; however, if the enzyme is present in sufficient excess, incubation can generally be carried out successfully at 37°C.

6. Immediately before electrophoresis, inactivate by adding 8 μ l of 4 \times SDS sample buffer and heating for 5 min at 90°C to 95°C.
7. Analyze the protein by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

Sensitivity to endo F₂ is detected by increased electrophoretic mobility on SDS-PAGE.

ENDOGLYCOSIDASE F₃ DIGESTION

Endoglycosidase F₃ (endo F₃) is another endoglycosidase with a narrow substrate range and, therefore, high specificity: it cleaves triantennary chains, but not high-mannose, hybrid, nonfucosylated biantennary or tetraantennary chains. A core-fucosylated biantennary chain is the only other demonstrated substrate. When both endo F₃ and endo F₂ digestions are done in parallel on a sample, it can provide evidence for chain branching and core fucosylation. The approach is essentially the same as for the other endoglycosidases.

Materials

Immunoprecipitated protein of interest (UNIT 10.16)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium acetate, pH 4.5 (APPENDIX 2)
10% (w/v) Triton X-100 or NP-40
0.1 U/ml endoglycosidase F₃ (endo F₃; Glyko)
10 \times SDS sample buffer (UNIT 10.2A)
Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS and heat denature 3 to 5 min at 90°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge for 1 sec at 1000 \times g to collect condensed droplets at the bottom of the tube.
3. Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

2 μ l 10% Triton X-100 or NP-40 (20-fold excess over SDS)
4 μ l 0.5 M sodium acetate, pH 4.5
5 μ l H₂O
1 μ l 0.1 U/ml endo F₃ (enzyme digest only; substitute with water in control).

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.

BASIC PROTOCOL 4

Preparation and Analysis of Glycoconjugates

17.13A.11

6. Immediately prior to electrophoresis, inactivate by adding 2 μ l of 10 \times SDS sample buffer and heating for 5 min at 90°C to 95°C.
7. Analyze by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

Sensitivity to endo F₃ is detected by increased mobility on SDS-PAGE.

PEPTIDE:N-GLYCOSIDASE F DIGESTION

PNGase F is a glycoamidase that cleaves the bond between the Asp residue of the protein and the GlcNAc residue that joins the carbohydrate to the protein (Fig. 17.13A.5). Because it liberates nearly all known N-linked oligosaccharides from glycoproteins, it is the preferred enzyme for complete removal of N-linked chains. It is the only enzyme that releases tetra- and pentaantennary chains. The glycoprotein sample must be denatured and digested with PNGase F to remove N-linked oligosaccharides completely.

Materials

Immunoprecipitated protein of interest (UNIT 10.16)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M Tris·Cl, pH 8.6 as determined at 37°C (APPENDIX 2)
10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
200 to 250 mU/ml peptide:N-glycosidase F (PNGase F; Sigma or Glyko)
10 \times SDS sample buffer (UNIT 10.2A)
Water baths, 30° to 37°C and 90°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 90°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge for 1 sec at 1000 \times g to collect condensed droplets in the bottom of the tube.
3. Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

3 μ l 0.5 M Tris·Cl, pH 8.6
5 μ l H₂O
2 μ l 10% NP-40 or Triton X-100
5 μ l 200 to 250 mU/ml PNGase F (enzyme digest only; substitute with 0.5 M Tris·Cl in control).

Sodium phosphate or HEPES buffer, pH 7.0, can be used instead of Tris·Cl. Avoid potassium buffers because these may cause precipitation of a potassium SDS salt. Use of a nonionic detergent is essential, because SDS inactivates PNGase F. A 10-fold weight excess of any of the above nonionic detergents over the amount of SDS will stabilize the enzyme.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate overnight at 30° to 37°C.

6. Immediately prior to electrophoresis, inactivate the enzyme by adding 2.5 μl of 10 \times SDS sample buffer and heating 3 to 5 min at 90°C.
7. Analyze the protein by one-dimensional SDS-PAGE (UNIT 10.2) and autoradiography (APPENDIX 3A).

The presence of N-linked oligosaccharide chains will be evidenced by increased electrophoretic mobility on SDS-PAGE.

ESTIMATING THE NUMBER OF N-LINKED OLIGOSACCHARIDE CHAINS ON A GLYCOPROTEIN

SUPPORT PROTOCOL

One widely used application of endo H or PNGase F digestion is estimation of the number of N-linked oligosaccharide chains on a given glycoprotein. This is done by creating a ladder of partially digested molecules that each differ by only one N-linked sugar chain. The number of separate bands in a one-dimensional polyacrylamide gel (less one for the totally deglycosylated protein) provides an estimate of the number of N-linked chains. The conditions used to generate partially deglycosylated protein must be determined for each protein studied, because the sensitivity of each chain may be different, even when all of them are completely exposed by denaturation. For this protocol, either the incubation time or the amount of enzyme can be varied to determine the best conditions to produce a ladder of partial digests. Usually five or six points are enough to provide a reasonable estimate (Fig. 17.13A.6). Of course, it is important to use enough enzyme to obtain complete deglycosylation. This is best done by monitoring the effects of endo H or PNGase F on newly synthesized [^{35}S]Met pulse-labeled protein just after synthesis, but before any N-linked oligosaccharide processing has occurred. Pulse labeling of protein

Figure 17.13A.6 Data from the estimation of the number of glycosylation sites on lysosome-associated membrane protein 1 (LAMP-1; Viitala et al., 1988). LAMP-1 contains eighteen potential N-linked sites. Graded digestion with increasing amounts of PNGase F was used to generate this ladder of glycoforms. Each band contains at least one less N-linked chain than the band above it. An average N-linked carbohydrate chain has an apparent mass of ~1.5 to 3 kDa. Lysosomal membrane glycoprotein was immunoprecipitated from [^{35}S]Met-labeled cells and the sample was digested with PNGase F for 0 min (lane 1), 5 min (lane 2), 20 min (lane 3), 45 min (lane 4), and 24 hr (lane 5). Figure courtesy of Dr. Minoru Fukuda.

Preparation and Analysis of Glycoconjugates

17.13A.13

for 10 min with [³⁵S]Met followed by digestion is the best way to be sure that all chains are removed.

1. Add 0.1 M 2-ME/0.1% SDS solution to the total volume of immunoprecipitated protein required and heat denature by incubating 3 to 5 min at 90°C.

Each digestion reaction requires 20 μl of immunoprecipitate. Thus, 120 to 140 μl is sufficient for one control plus five or six digests.

2. Cool and centrifuge for 1 sec at 1000 × g to collect condensed droplets at the bottom of the tube.
3. Aliquot 10 μl supernatant to the number of microcentrifuge tubes required to cover the concentration range (e.g., 0.01 to 1 mU/ml PNGase F) or incubation times (e.g., 5 to 60 min) plus one for an undigested control.
4. Add remaining reagents as specified for endo H (see Basic Protocol 1, step 4) or PNGase F (see Basic Protocol 5, step 4), adjusting the enzyme concentration as desired.
5. Incubate at 30°C for the desired length of time.

High enzyme concentration (10 mU/ml) and prolonged incubation (16 hr) must be among the conditions included, in order to ensure that there is a data point for maximum deglycosylation.

For varying enzyme concentrations, incubate for the same amount of time, but the duration of incubation should be shorter than what would give complete digestion because the goal is to obtain increasing extent of incomplete cleavage.

6. After the desired incubation time, inactivate enzyme by adding 0.1 volume of μl of 10× SDS sample buffer and heating 5 min at 90° to 95°C.
7. Analyze the sample from each concentration/time point, including undigested sample, by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

Most newly formed N-linked chains will have a molecular weight in the range of 1500 to 2200, and loss of one chain is sufficient to change the migration of a protein. This procedure has been used to count up to eighteen N-linked sites on one molecule. A sample result is shown in Figure 17.13A.6.

BASIC PROTOCOL 6

SIALIDASE (NEURAMINIDASE) DIGESTION

Sialic acids are the terminal sugars on many N- and O-linked oligosaccharides. The great majority are released with broad-specificity sialidases (neuraminidases) such as that from *Arthrobacter ureafaciens*. Because sialic acids are charged, their loss usually changes the mobility on one-dimensional SDS polyacrylamide gels, but it will always change the mobility on a two-dimensional gel. Since one-dimensional analysis is easier, it can be tried first.

Materials

- Immunoprecipitated protein of interest (UNIT 10.16)
- 0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
- 10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
- 0.5 M sodium acetate, pH 5.0 (APPENDIX 2)
- 1 IU/ml neuraminidase from *Arthrobacter ureafaciens* (Sigma or Glyco)
- 10× SDS sample buffer (UNIT 10.2A)
- Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A), for IEF/SDS-PAGE (UNIT 10.3), or NEPHGE/SDS-PAGE (UNIT 10.4), and for autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 90°C.

Denaturation is less important here, because the sialic acids are exposed at the ends of the sugar chains. In most instances, the denaturation step can probably be omitted and the digestion done while the protein is still bound to the beads.

2. Cool and microcentrifuge for 1 sec at 1000 \times g to collect condensed droplets in the bottom of the tube.
3. Transfer 10- μl aliquots of supernatant to two clean microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

2 μl 10% Triton X-100 or NP-40 (20-fold excess over SDS)

4 μl 0.5 M sodium acetate, pH 5.0

5 μl H₂O

1 μl 1 IU/ml neuraminidase (enzyme digest only; substitute with water for control).

This amount of neuraminidase should be in great excess. Addition of nonionic detergent is not needed if the digestion is done while the protein was still bound to the beads.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.

This time can be shortened to 2 hr, if necessary, but longer incubations are better.

6. Immediately prior to electrophoresis, inactivate the enzyme by adding 2 μl of 10 \times SDS sample buffer and heating 3 to 5 min at 90°C.

If the protein will be analyzed by IEF or NEPHGE, addition of sample buffer is replaced by lysis buffer used for these techniques.

7. Analyze the protein using either the appropriate one-dimensional SDS-PAGE system (UNIT 10.2A) or a two-dimensional IEF/SDS-PAGE or NEPHGE/SDS-PAGE system (UNITS 10.3 & 10.4), and detect by autoradiography (APPENDIX 3A).

Removal of sialic acids usually results in a decrease in apparent molecular weight on one-dimensional gel analysis, or an increase in the isoelectric point of the protein analyzed by two-dimensional gel analysis.

ENDO- β -GALACTOSIDASE DIGESTION

The endo- β -galactosidase from *Bacillus fragilis* degrades polylactosamine chains (Gal β 1-4GlcNAc β 1-3)_n found on both N- and O-linked oligosaccharides. The variable length of these repeating units usually causes the protein to run as a broad band or a smear on the gel. Although not all linkages are equally cleaved by this enzyme (see Fig. 17.13A.7), sensitive proteins that often run as broad bands or smears on gels—e.g., lysosome-associated membrane protein 1 (LAMP-1)—produce both sharper bands and lower molecular weight species after digestion.

**BASIC
PROTOCOL 7**

**Preparation and
Analysis of
Glycoconjugates**

17.13A.15

Figure 17.13A.7 Endo- β -galactosidase-sensitive linkages in polylectosamines (see Fig. 17.13A.1 for key). Linear, unsubstituted polylectosamine units (GlcNAc β 1-3Gal β 1-4) are sensitive to digestion with endo- β -galactosidase, while substitutions—such as sulfate esters (S) or branches starting with GlcNAc (not shown)—completely block digestion. Substitution of neighboring GlcNAc with Fuc or sulfate esters slows the rate, but does not block cleavage. Sensitive sites are shown with bold arrows, slowly hydrolyzed sites with a lighter arrow, and resistant bonds are struck out. Various substitutions are possible, leading to broad bands on gels. This will create variable sensitivities, but even partial sensitivity should give a sharper, more defined band.

Materials

Immunoprecipitated protein of interest (*UNIT 10.16*)
 0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
 0.5 M sodium acetate buffer, pH 5.8 (*APPENDIX 2*)
 10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
 100 mU/ml endo- β -galactosidase (Boehringer Mannheim, Oxford GlycoSystems, Sigma)
 10 \times SDS sample buffer (*UNIT 10.2A*)
 Water baths, 37 $^{\circ}$ and 95 $^{\circ}$ C

Additional reagents and equipment for SDS-PAGE (*UNIT 10.2A*) and autoradiography (*APPENDIX 3A*)

- Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95 $^{\circ}$ C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

- Cool and microcentrifuge 1 sec at 1000 \times g to collect condensed droplets in the bottom of the tube.
- Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

- Add in the following order, mixing after each addition:

2 μ l 10% Triton X-100 or NP-40 (20-fold excess over SDS)
 4 μ l 0.5 M sodium acetate, pH 5.8
 5 μ l H₂O
 1 μ l 100 mU/ml endo- β -galactosidase (enzyme digest only; substitute with water in control).

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 3 μ l of 10 \times SDS sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (UNIT 10.2) and autoradiography (APPENDIX 3A).

If the protein has poly lactosamine chains, its mobility should increase after digestion.

ENDO- α -N-ACETYL GALACTOSAMINIDASE DIGESTION

This enzyme (also known as O-glycosidase or O-glycanase) has limited utility because it is highly specific for cleaving only one O-linked disaccharide, Gal β 1-3GalNAc α -Ser/Thr. Adding any more sugars, including sialic acid, renders the molecule resistant to cleavage and requires removal of each residue before the enzyme will work. Prior sialidase digestion is sometimes used (see Basic Protocol 6), and this can be done while the protein is still bound to the immunoprecipitation beads.

Materials

- Immunoprecipitated protein of interest (UNIT 10.16)
- 0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
- 0.5 M sodium citrate phosphate buffer, pH 6.0, containing 500 μ g/ml BSA (complete buffer supplied with enzyme)
- 10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
- 300 mU/ml endo- α -N-acetylgalactosaminidase (5 \times concentrate from Glyko; use according to directions)
- 10 \times SDS sample buffer (UNIT 10.2A)
- Water bath, 37° and 95°C
- Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 μ l of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95°C.

Use the larger amount of reagent ($\geq 30 \mu$ l) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge 1 sec at 1000 \times g to collect condensed droplets in the bottom of the tube.
3. Transfer 10- μ l aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

- 2 μ l 10% Triton X-100 or NP-40 (20-fold excess over SDS)
- 4 μ l 0.5 M sodium citrate phosphate buffer, pH 6.0, with 500 μ g/ml BSA
- 3 μ l H₂O
- 1 μ l 300 mU/ml endo- α -N-acetylgalactosidase (enzyme digest only; substitute with water in control).

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2 µl of 10× SDS sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

If the protein contains the disaccharide unit, the mobility of the protein should increase. Presence of only a single unit (mol. wt. ~400 Da) may be difficult to detect unless a high-resolution gel is used.

O-SIALOGLYCOPROTEASE DIGESTION

Digestion with O-sialoglycoprotease requires that the substrate have a tight cluster of sialylated O-linked oligosaccharides. Proteins with a single O-linked chain or a few widely spaced chains will not be cleaved. This property makes the enzyme a valuable diagnostic tool.

Materials

- Immunoprecipitated protein of interest (UNIT 10.16)
- 0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
- 0.4 M HEPES buffer, pH 7.4
- 10% (w/v) Triton X-100 or Nonidet P-40 (NP-40)
- 2.4 mg/ml O-sialoglycoprotease (O-sialoglycoprotein endoglycoprotease; Accurate Chemical & Scientific; reconstituted according to directions)
- 10× SDS sample buffer (UNIT 10.2A)
- Water baths, 37° and 95°C

Additional reagents and equipment for SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95°C.

Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.
2. Cool and microcentrifuge 1 sec at 1000 × g to collect condensed droplets in the bottom of the tube.
3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:
 - 2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
 - 4 µl 0.4 M HEPES buffer, pH 7.4
 - 5 µl H₂O
 - 2 µl 2.4 mg/ml O-sialoglycoprotease (enzyme digest only; substitute with water in control).

O-Sialoglycoprotein endopeptidase is a partially purified enzyme, and the specific activity is relatively low. A quantity of 1.0 µg of this enzyme preparation will cleave 5 µg of sensitive substrate per hour at 37°C. Human glycophorin A can serve as a positive control.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2.5 μl of 10× SDS sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A).

If the digestion was successful, the target protein will be undetectable or may be cleaved into small fragments.

COMMENTARY

Background Information

The results of digestion of a hypothetical protein with two N-linked carbohydrate chains as it moves through the ER and Golgi complex with various enzymes are shown in Figure 17.13A.8. At 0 min, both N-linked chains are high-mannose type. They have lost their Glc residues and one Man residue in the ER. Both are sensitive to endo H and PNGase F digestion, yielding a protein with only two remaining GlcNAc residues in the case of endo H diges-

tion, and no carbohydrate at all in the case of PNGase F digestion. These sugar chains are resistant to the other enzyme digestions.

At 45 min, the protein is in the medial Golgi complex and both sugar chains have been processed by Golgi α-mannosidase I. However, one of the chains (left) has been partially processed by Golgi α-mannosidase III to an endo H-resistant/endo D-sensitive chain. The other chain (right) has received a GlcNAc residue from GlcNAc transferase I, but has not encountered

Figure 17.13A.8 Schematic diagram showing results that could be obtained for a hypothetical protein with two N-linked glycosylation sites as it moves through the Golgi complex. Assume that the protein has been biosynthetically labeled with an amino acid precursor (such as [³⁵S]Met) for 10 min and chased in the absence of label for 45 min and 120 min. The protein is then precipitated with a specific antibody. At each time point, equal amounts of the sample are analyzed by fluorography after one-dimensional SDS-PAGE, either without any digestion (control; C) or following digestion with endo H (H), endo D (D), endo F₂ (F₂), PNGase F (PNG), or sialidase (Sia). Oligosaccharide structures consistent with the banding patterns are shown below the schematic gel pattern.

Golgi α -mannosidase II. This chain is still endo H sensitive and endo D resistant. Both chains are sensitive to PNGase F, but neither is sensitive to endo F₂ or sialidase digestion.

At 120 min, both chains have fully matured to complex-type chains. One is a sialylated biantennary chain and the other is a sialylated triantennary chain. Note that each sialic acid is marked \pm , indicating that not all molecules are fully sialylated, accounting for the broader bands. Neither sugar chain is sensitive to endo H or endo D digestion. The biantennary chain (left) is sensitive to endo F₂ cleavage, leaving one GlcNAc residue on the protein, but the triantennary chain (right) is not sensitive to this enzyme. Both chains are cleaved by PNGase F. All sialic acids are removed by sialidase to produce a sharp band, but the underlying sugar chains remain.

Endoglycosidase H

Endo H from *Streptomyces plicatus* cleaves the bond between the two GlcNAc residues in the core of N-linked oligosaccharides. One GlcNAc residue remains attached to the protein or peptide and the remainder of the chain is released as an intact unit (Tarentino et al., 1989). The oligosaccharide structures cleaved by endo H are shown schematically in Figure 17.13A.5. Substrates for endo H include all high-mannose oligosaccharides and certain hybrid types, but not bi-, tri-, tetra- or pentaantennary (complex) chains. Endo H also cleaves oligosaccharides that have α 1-6 fucose residues bound to the reducing (protein to carbohydrate linkage) GlcNAc residue (Tarentino et al., 1989).

Endo H sensitivity is the most common way to trace the movement of newly synthesized glycoproteins from the endoplasmic reticulum (ER) into the Golgi complex. Proteins remain sensitive to endo H while they are in the ER and in early regions of the Golgi complex; they become endo H-resistant after they are processed by enzymes located in the medial Golgi complex. Endo H cleaves the N-linked oligosaccharides from proteins as long as they have not lost the α 1-3Man residue cleaved by Golgi mannosidase II or mannosidase III (Fig. 17.13A.2). After removal of that mannose, the oligosaccharide becomes endo H resistant. Endo H is the best enzyme for identifying high-mannose and hybrid chains and their general transition toward complex chains.

Using endo H alone gives an incomplete map of subcellular trafficking. The resolution of this picture can be enhanced by combining it with endo D digestions. In general, N-linked

chains become endo H resistant at about the same time they become transiently sensitive to endo D. However, the discovery of the alternative pathway for complex N-glycan processing using α -mannosidase III now gives a different perspective. Both α -mannosidase II and III are expressed in most mouse tissues except for hematopoietic cells, which seem to have only α -mannosidase II. So it is conceivable that some proteins, and even different N-linked chains on a single protein, can be processed by α -mannosidase II and others by α -mannosidase III, yielding complex digestion patterns and kinetics of endo H and endo D sensitivity.

Endoglycosidase D

The narrow substrate specificity of endo D makes it useful for detecting a very restricted set of processing intermediates, particularly for distinguishing α -mannosidase II from α -mannosidase III processing. When the results of endo D digestion are combined with the results of an endo H digestion of the same sample, it can help determine which of the two alternate processing pathways is being used. The key requirement for endo D cleavage is an unsubstituted 2 position on the α 1-3Man that forms the trimannosyl core (Fig. 17.13A.1). This window of endo D sensitivity occurs only *after* removal of the α 1-2Man residue by α -mannosidase I and *before* the addition of a GlcNAc residue to this same position by GlcNAc transferase I (Beckers et al., 1987; Davidson and Balch, 1993). The immediate precursor of both pathways is Man₆GlcNAc₂, which is endo D resistant/endo H sensitive. The better-known α -mannosidase II pathway involves the removal of the last α 1-2Man residue by α -mannosidase I (making the oligosaccharide endo D sensitive/endo H sensitive), and then the addition of GlcNAc via GlcNAc transferase I (making it endo D resistant/endo H sensitive). This product, and only this one, is the substrate for α -mannosidase II, which removes two of the remaining five Man residues, specifically the α 1-3Man and α 1-6Man that form the upper branch. Once this occurs, this endo D-resistant molecule also becomes endo H resistant. This structure is also a substrate for GlcNAc transferase II on the way to forming a biantennary chain.

The second pathway involves α -mannosidase III, which was identified as a functionally important enzyme in nearly all tissues when the α -mannosidase II pathway was ablated in mice (Chui et al., 1997). After α -mannosidase I removes the final α 1-2Man from

Man₆GlcNAc₂ to generate Man₅GlcNAc₂, α -mannosidase III cleaves the same two Man residues as α -mannosidase II; however, α -mannosidase III cleavage does not require addition of the first GlcNAc that α -mannosidase II requires. α -Mannosidase III creates the endo D-sensitive/endo H-resistant trimannosyl core. This sugar chain serves as an acceptor for GlcNAc transferase I to form an endo D-resistant/endo H-resistant molecule that can be modified by GlcNAc transferase II, and then on to biantennary chains. As summarized in Figure 17.13A.2, using the two endoglycosidases together will distinguish whether the oligosaccharide was processed by α -mannosidase II or α -mannosidase III. This may be important since there is evidence that distribution of the two enzymes in the Golgi complex is different with α -mannosidase III in an earlier compartment. It is important to point out that all chains of even a single protein are not necessarily processed using all the same enzymes.

Mutant cell line CHO Lec1 lacks GlcNAc transferase I activity and cannot synthesize either complex or hybrid chains. These cells can be used to measure the kinetics of acquiring endo D sensitivity (Beckers et al., 1987). This cell line can be obtained through ATCC (CRL-1735). The chains become permanently endo D sensitive, because they lack GlcNAc transferase I and cannot be converted back to an endo D-resistant form. These chains will also remain endo H sensitive, because α -mannosidase II requires GlcNAc transferase I. However, if any chains are processed by α -mannosidase III, they would become endo H resistant. Again, the combination of endo D and endo H digestions can reveal which pathway was used.

CHO Lec1 cells are also useful for tracking the movement of a protein from the ER into the earliest Golgi compartment where α -mannosidase I is located. Acquisition of endo D sensitivity requires the action of this enzyme. The advantage of using Lec1 cells is that the proteins remain permanently endo D sensitive and there is no risk of kinetically missing that small window of sensitivity before the sugar chain might become endo D resistant once again. Even if α -mannosidase III acts on the protein, it would still remain endo D sensitive, and no further processing would occur.

Endoglycosidase F and peptide N-glycosidase F

Elder and Alexander (1982; Alexander and Elder, 1989) made a landmark discovery when they identified an enzyme in culture filtrates of the bacterium *Flavobacterium meningosepticum* that cleaved N-linked oligosaccharides from glycoproteins. This preparation had a broad substrate specificity. The endoglycosidase activity in this preparation (endo F) was actually due to a set of enzymes, each with a more restricted substrate range. Like endo H, the endo F enzymes cleave the sugar chains between the two core GlcNAc residues (Fig. 17.13A.5). Endo F was originally thought to be a single enzyme, but it is now known that each of the three enzymes has a distinct specificity (Plummer and Tarentino, 1991). The specificity of endo F₁ is very similar to that of endo H, while endo F₂ prefers biantennary chains, and endo F₃ will cleave core fucosylated biantennary and triantennary, but not tetraantennary, chains (Fig. 17.13A.2 and Fig. 17.13A.3). All are commercially available from Glyko.

Plummer et al. (1984) carefully analyzed *Flavobacterium* filtrates and found that the very broad substrate range was actually due to a glycoamidase activity rather than an endoglycosidase activity. The glycoamidase releases the entire carbohydrate chain from the protein by cleaving the Asp-GlcNAc bond (Fig. 17.13A.5). The enzyme is called by various names, including peptide:N-glycosidase F (PNGase F), glycopeptidase F, and N-glycanase (previously available from Genzyme), but the proper name is peptide N-4(N-acetyl- β -glucosaminyl)asparagine amidase F. PNGase F has the broadest specificity, and it releases most of the N-linked oligosaccharide chains from proteins.

Endo F₂ and Endo F₃

Endo F₂ prefers biantennary chains over high-mannose chains by ~20 fold. Thus, endo H and PNGase F are better choices for broadly distinguishing high-mannose from complex chains as described above in the endo H protocol (Tarentino and Plummer, 1994).

Many proteins have core-fucosylated N-linked glycans, and the addition of fucose can be used as an additional trafficking marker. Endo F₃ will hydrolyze triantennary chains, but endo F₂ will not. Endo F₂ hydrolyzes biantennary chains; however, endo F₃ will also hydrolyze core-fucosylated biantennary chains only

a bit more slowly than it does triantennary chains. Thus, if all the chains on a protein are sensitive to endo F₂ (biantennary) and to endo F₃, this is evidence for the presence of a core fucose on those chains.

The enhancement of endo F₃ activity on biantennary chains with a core α 1-6Fuc points out that some specificities are really a matter of relative rates of cleavage. If both endo F₂ (biantennary) and endo F₃ (triantennary and biantennary with core fucose) cleave the protein, they may be acting on different chains on the same molecule. If there is only a single chain, repeat the experiment under the same conditions using 10- to 20-fold dilutions of each enzyme. If both still cleave the chain about equally, it is evidence for core fucosylation of a biantennary chain.

PNGase F

PNGase F has the broadest specificity of all the enzymes that cleave N-linked oligosaccharides. It is indifferent to all extended structures on the chains, such as sulfate, phosphate, polylactosamines, polysialic acids, and even the occasional glycosaminoglycan chain. Most of the modifications in the Man₃GlcNAc₂ core region also make no difference in chain cleavage. The only oligosaccharide structural feature that confers PNGase F resistance is the presence of an α 1-3Fuc on the GlcNAc bound to Asn (Tretter et al., 1991). This modification is commonly found in plants and in some insect glycoproteins, but it is rare in most mammalian cell lines. However, caution is warranted, as there is evidence that some mammalian cells do have the critical α 1-3Fuc transferase, and some studies show that a majority of N-linked chains of bovine lung are actually PNGase F resistant! It is not known how common this resistance may be. It is thus important to document N-glycosylation with proteins still in the ER (see Support Protocol) before they might be processed to a PNGase F-resistant form.

Sialidase

Sialidases are also called neuraminidases because the most common form of sialic acid is *N*-acetylneuraminic acid. The sialic acids are a family with over forty different members, but fortunately the very great majority of them can be removed from the oligosaccharides by the broad-spectrum sialidase from *Arthrobacter ureafaciens* (AUS). It can even digest polysialic acids, a rare modification found on only a few proteins such as neuronal cell adhesion molecule (NCAM). Sialidases with selected speci-

ficities from other sources are available but would not usually be needed. AUS has an optimum pH of 5.0, with ~30% of maximum activity at pH 7.

Because sialic acids are charged, they affect gel mobility of proteins more than would be expected from their nominal molecular weight. The magnitude of the gel shift depends on the number of residues. It is difficult to estimate their number by sialidase digestion, but the mobility change is usually sufficient if there are several sialic acid residues. On the other hand, if a protein has only one sialic acid, its presence could be missed using standard one-dimensional SDS-PAGE. To be certain of the effects of sialidase, the sample can be analyzed by a two-dimensional system, using IEF or NEPHGE in the first dimension (UNITS 10.3 & 10.4). The loss of even a single sialic acid will be evident because it changes the isoelectric point.

AUS will remove sialic acids from both N- and O-linked chains, so the type of chain carrying them must be determined independently using PNGase F or possibly O-glycosidase in combination with sialidase. A protein will generally be partially or completely resistant to O-glycosidase because the required disaccharide, Gal β 1-3GalNAc, is usually extended and often sialylated. Until the sialic acid is removed, it will be resistant.

The presence of sialic acid (sialidase sensitivity) is often used as an indication of the transport of a protein into the *trans*-Golgi network (TGN). This may be true in general, but it is important to remember that the distribution of Golgi enzymes is cell type dependent. For instance, α -mannosidases I and II, which are typically considered *cis*/medial Golgi enzymes, are strongly expressed on the brush border of enterocytes—hardly a Golgi compartment. There are other similar examples of various distributions of sialyl transferase. Moreover, there are different sialyl transferases and each may have its own unique distribution. Although one should be cautious, it is probably safe to place sialyl transferase in the late Golgi compartment rather than an early one.

Endo- α -N-acetylgalactosaminidase

This enzyme from *Diplococcus pneumoniae* also goes by various names, including O-glycosidase and O-Glycanase. The last name is a trade name from Genzyme, which no longer sells enzymes; the enzyme is now available from Glyko. This enzyme has a narrow substrate range and cleaves only Gal β 1-3GalNAc α -Ser/Thr. These are only the first two

sugars added in the diverse O-linked pathway that can produce glycans with a dozen or more sugar units. A portion of the pathway is shown in Figure 17.13A.4. Fortunately, many, but far from all, O-linked chains have the simple trisaccharide structure and would be sensitive to cleavage after removing the Sia. Thus, sequential individual digestions or mixed digestions can be used. As both Gal and GalNAc (and probably Sia) are added in the early Golgi complex, sensitivity to the enzyme shows that the protein carries O-linked chains, but matching enzyme sensitivity and a Golgi compartment to further chain extension is difficult. Combining a battery of exoglycosidases (sialidase, α -fucosidase, α -*N*-acetylgalactosaminidase, and β -hexosaminidase) with endo- α -*N*-acetylgalactosaminidase will probably remove most O-linked sugar chains, except sulfated ones. The bottom line is that it is easy to use the enzyme in combination with sialidase to show that a protein has simple O-linked chains, but it is difficult to conclude much more concerning either the structure of the sugar chain or intracellular trafficking.

Endo- β -galactosidase

Bacterioides fragilis endo- β -galactosidase is one of several enzymes that specifically degrade polyactosamines by cleaving linear chains of GlcNAc β 1-3Gal β 1-4 repeats at the Gal β 1-4 linkage. Any substitution on the galactose itself blocks cleavage; however, modifications of the neighboring sugars can slow hydrolysis (Fig. 17.13A.7). For instance, fucosylation and/or sulfation of nearby GlcNAc slows cleavage, but chain branching or sulfation at Gal block it. Even with these potential complexities, digestion with endo- β -galactosidase will sharpen a broad band even if it does not cleave every linkage. The repeating GlcNAc β 1-3Gal β 1-4 units can be found on both N- and O-linked chains, so sensitivity to PNGase F digestion can potentially distinguish the location. Lysosome-associated membrane protein 1 (LAMP-1) has polyactosamine repeats on N-linked chains. Remember that glycosylation is not template driven, so oligosaccharides often exist as a continuum of different structures on individual proteins. For example, heavily sulfated polyactosamine repeats are also known as keratan sulfate and are degraded by keratanases.

O-Sialoglycoprotease

O-Sialoglycoprotease (also called O-glycoprotease or O-sialoglycoprotein endopepti-

dase; Mellors and Lo, 1995) is a neutral metalloprotease produced by *Pasteurella haemolytica*. This enzyme requires clusters of sialylated oligosaccharides on Ser or Thr residues (Norgard et al., 1993). Having a single sialylated O-linked sugar chain on a protein will not lead to degradation, nor will having a nonsialylated sugar chain. Therefore, this enzyme can be used in a typical pulse-chase experiment to indicate whether there are tightly grouped O-linked chains and when they are sialylated. Adding the initial α -GalNAc in the early Golgi complex is insufficient to cause proteolysis; sialylation is specifically required, and this may occur in a later Golgi compartment. Proteolysis can generate smaller fragments of a target protein that are still visible on gels, or the fragments may be so small that they are not even seen on the gels. It depends on the protein. Many leukocyte antigens such as the P-selectin ligand, or others such as CD43, CD44, CD45, and CD34 found on hematopoietic stem cells, are all substrates. As sialic acids are found on both N- and O-linked chains (in clusters and not), sequential digestions using PNGase F, sialidase, and O-sialoglycoprotease endopeptidase in different orders can reveal different kinds of sialylated glycans. If used as part of a pulse-chase protocol, they can reveal different kinetic subcompartments. Not all sialyl transferases are necessarily within the same Golgi compartment.

Critical Parameters

For nearly all of the digestions, complete denaturation of the protein can be important, as maximum deglycosylation occurs only when the sugar chains of glycoproteins are completely exposed. This is not important for sialidase digestions since sialic acids are exposed. Usually endo H digestions will work without full denaturation, but the unprocessed high-mannose chains remain unprocessed because they are often less exposed to the processing enzymes. This may or may not be true of the target protein, but it is better to be safe and denature it completely before digestion. Heating the immunoprecipitate with 0.1 M 2-mercaptoethanol/0.1% SDS is the best way to release the protein in a denatured state. Assuming that the immunoprecipitate contains <10 μ g of protein, 30 μ l of 0.1% SDS still provides a three-fold excess over the protein. Adding SDS presents another problem: free SDS may denature the digesting enzyme before it has a chance to finish its job. For most enzymes, be sure that the free SDS concentration is <0.01%. The best

way to do this is to add a 10- to 20-fold weight excess of nonionic detergent with a low critical micellar concentration (e.g., Triton X-100 or NP-40). These detergents will form mixed micelles with the free SDS and keep it from denaturing the added enzymes.

The amount of enzyme and the incubation time recommended in the protocols are in excess and should be sufficient to cleave any of the sensitive linkages. The incubation times can be shortened, if necessary, but it is better to keep the enzyme concentration as indicated.

Many of the digestions (e.g., sialidase, O-sialoglycoprotease) can be adapted for use on membrane preparations or on live cell surfaces by simply omitting the ionic and nonionic detergents and decreasing the incubation time. The problem is that some linkages may not be exposed and/or sensitive to the digestion. Thus, the usefulness of this approach needs to be determined on a case-by-case basis.

Endo H

Endo H has a broad pH optimum between 5.5 and 6.5, and phosphate or citrate/phosphate buffers can be used in place of citrate. Endo H is very stable to proteases, freezing and thawing, and prolonged incubations. No additives are required for storage of the enzyme. At concentrations below 5 to 10 $\mu\text{g/ml}$ (200 to 400 mU/ml), endo H will bind to glass, so it should be stored in plastic vials (e.g., screw-cap microcentrifuge tubes).

Endo D

Endo D has a broad pH optimum of 4 to 6.5. One unit of enzyme activity will cleave 1 μmole of a $\text{Man}_5\text{GlcNAc}_3$ glycopeptide per min at 37°C. It is supplied from Boehringer Mannheim as a powder containing 0.1 U of activity. Adding 0.1 ml of water gives a 20 mM phosphate buffer, pH 7, 0.05% sodium azide, and 5 mg/ml BSA. It is stable for 3 months at 4°C or at -20°C, but freezing and thawing should be avoided. There may be a slight contamination (<0.2%) with β -N-acetylglucosaminidase activity.

Endo F

Commercial endo F preparations are mixtures of endo F₁, F₂, and F₃. Endo F preparations should not be used for routine deglycosylation or to draw conclusions about the structure of the released oligosaccharides unless the specificity is clearly defined.

Endo F₂

Endo F₂ has a broad pH optimum of 4 to 6 and retains >50% of its activity at pH 7. The enzyme is sensitive to SDS, but adding nonionic detergents prevents denaturation of the enzyme by SDS. Although the enzyme is stable at 4°C for months, it can be frozen in aliquots at -70°C as long as repeated freeze/thaw cycles are avoided. The 1,10-phenanthroline can be used to inhibit a trace of a zinc metalloprotease that may be present.

PNGase F

The pH optimum for PNGase F is 8.6, but 80% of full activity occurs between 7.5 to 9.5 with a range of buffers including phosphate, ammonium bicarbonate, Tris-Cl, and HEPES. Borate buffers inhibit the enzyme. Commercial PNGase F is endo F free and is stable for 6 months at 4°C, or indefinitely at -70°C. However, it should be stored in small aliquots and repeated freeze/thaw cycles should be avoided. PNGase F will bind to glass and plastic surfaces and should not be stored in dilute solutions (<0.1 mU/ml). All of the unit activities of commercial preparations are based on cleavage of dansylated glycopeptides; they are expressed in nmoles/min, which are actually mU, not true International Units (1 International Unit = 1 $\mu\text{mole/min}$). SDS inactivates PNGase F, but adding a ten-fold weight excess of nonionic detergents protects the enzyme (Tarentino et al., 1989; Tarentino and Plummer, 1994).

Sialidase

AUS is available as a lyophilized powder from typical commercial sources such as Sigma, Boehringer Mannheim, and Glyko. It should be reconstituted in water at 1 to 10 mU/ μl according to manufacturer's directions. It is stable for 6 months at 4°C. Treatment with sialidase is also used in assays of protein transport to the cell surface.

Endo- α -N-acetylgalactosaminidase (O-glycosidase)

Endo- α -N-acetylgalactosaminidase has a pH optimum of 6.0 and has 50% activity at 5.5 to 7.0. The thiol inhibitor parachloromercuric benzoate (PCMB; 1 mM) inactivates the enzyme, and 1 mM EDTA inhibits it (63%), as do Mn^{2+} and Zn^{2+} (50%). Chloride also inhibits the enzyme, so HCl-containing buffers should be avoided. The enzyme will have full access to the sugar chains only after denaturing the protein with SDS, but the excess SDS needs to be removed by forming mixed micelles with

nonionic detergents. The enzyme is stable at 4°C and at -20°C, but freeze/thaw cycles should be avoided.

Endo-β-galactosidase

The enzyme is supplied by several commercial sources, including Glyko and Sigma. The enzyme is free of contaminating endo- and exoglycosidases. It has a pH optimum of 5.8 and should be stored at -20°C, but is stable for ≥2 months at 4°C. Glyko supplies the enzyme as a lyophilized powder with BSA for stability. EDTA, Ca²⁺, Mn²⁺, and Mg²⁺ do not affect stability or activity, but PCMB inactivates it.

O-Sialoglycoprotease

The partially purified enzyme is supplied by Accurate Chemical and Scientific as a lyophilized powder containing nonsubstrate bovine serum proteins and HEPES buffer. The enzyme should be reconstituted according to the manufacturer's instructions, divided into aliquots appropriate for a single use, and stored at -20°C. Freeze/thaw cycles inactivate the enzyme, and it is inhibited by EDTA or 1,10-phenanthroline. It is possible to check the activity with a positive control of glycoporphin A, which is available through Sigma.

Troubleshooting

Most of the procedures should work as described, but there is a chance that the enzyme is inactive because of a variety of factors such as age, poor storage, or excess SDS. To check activity, it is worthwhile to run a positive control digestion using the same solutions including SDS and nonionic detergents as for the samples. Since the positive controls are simply glycoproteins that are visualized by Coomassie or silver staining, this requires running a separate gel for staining. This should not be required on a routine basis if the enzymes are used and stored as directed. The most likely culprit in failed digestions is using SDS solutions that are too old or too impure.

Anticipated Results

If the digestions are effective, the labeled band will usually show increased mobility on the gel. In rare instances, digestions can actually decrease mobility. The amount of change will depend on the contribution of that component to the overall mass of the protein. As mentioned before, a gel system that allows visualization of a 1-kDa change should be used. Proteins that are >100 kDa may cause problems for fine resolution. Here are a few numbers to keep in mind.

1. The smallest N-linked chain (Man₃GlcNAc₂) will have a mass of ~0.9 kDa.

2. Two sialic acids on a single N-linked biantennary chain will have a mass of ~0.6 kDa, but their loss may appear larger. If they occur on clustered O-linked chains (sialoglycoprotease sensitive), the apparent size difference will be even larger.

3. Most polylectosamines are three or more repeats, and therefore their mass would be ~1 kDa. The protein will probably run as a heterogeneous smear or broad band before digestion.

4. A single O-glycosidase-sensitive disaccharide (0.4 kDa) may be below detection limits.

Time Considerations

All digestions can be done overnight for convenience, but the amount of enzymes should be sufficient for complete digestion in less time. The gels are run the next day, but the time needed for the development of autoradiograms will depend on the strength of the signal. A low-abundance protein labeled for 10 to 30 min with [³⁵S]Met may give a weak signal and require long exposures (e.g., 2 weeks). Trafficking of abundant glycoproteins such as viral coat proteins require only short exposure times (e.g., a few hours).

Analysis of Glycosaminoglycans with Polysaccharide Lyases

Polysaccharide lyases are a class of enzymes useful for analysis of glycosaminoglycans (GAGs) and the glycosaminoglycan component of proteoglycans (PGs). These enzymes cleave specific glycosidic linkages present in acidic polysaccharides and result in depolymerization (Linhardt et al., 1986). These enzymes act through an eliminase mechanism resulting in unsaturated oligosaccharide products that have UV absorbance at 232 nm. The lyases are derived from a wide variety of pathogenic and nonpathogenic bacteria and fungi (Linhardt et al., 1986). This class of enzymes includes heparin lyases (heparinases), heparan sulfate lyases (heparanases or heparitinases), chondroitin lyases (chondroitinases), and hyaluronate lyases (hyaluronidases), all of which are described in this unit.

Polysaccharide lyases can be used, alone or in combinations, to confirm the presence of GAGs in a sample as well as to distinguish between different GAGs (see Table 17.13B.1 and Commentary). The protocols given for heparin lyase I are general and, with minor modifications (described for each lyase and summarized in Table 17.13B.2), can be used for any of the polysaccharide lyases.

The basic protocol describes depolymerization of GAGs in samples containing 1 μg to 1 mg of GAGs. The alternate protocol describes depolymerization of GAGs in samples containing <1 μg of radiolabeled GAG. Two support protocols describe assays to confirm and quantitate the activity of heparin and chondroitin ABC lyases. It is recommended that enzyme activity be assayed before the enzyme is used in an experiment to be sure it is active and has been stored properly.

The standard definition of a unit (U), 1 μmol product formed/min, is used throughout this article. Some lyases are sold in nonstandard units (e.g., 0.1 $\mu\text{mol/hr}$, $\Delta A_{232}/\text{min}$), and these should either be converted to standard units or the activity should be determined using the appropriate support protocol.

Table 17.13B.1 Polysaccharide Lyases Used to Identify Glycosaminoglycans

Glycosaminoglycan	Enzyme
Heparin, heparan sulfate, chondroitin sulfate, dermatan sulfate, hyaluronate	Heparin lyases I, II, III, and chondroitin ABC, AC lyases
Heparin, heparan sulfate, chondroitin sulfate, dermatan sulfate	Heparin lyases I, II, III, and chondroitin ABC lyase
Heparin, heparan sulfate	Heparin lyases I, II, III
Chondroitin sulfate, dermatan sulfate, hyaluronate	Chondroitin ABC, AC lyases
Chondroitin sulfate, dermatan sulfate	Chondroitin ABC lyase
Heparin	(Heparin lyase I–heparin lyase III) ^a
Heparan sulfate	Heparin lyase III
Chondroitin sulfate	Chondroitin AC lyase (or chondroitin ABC lyase–chondroitin B lyase) ^a
Dermatan sulfate	Chondroitin B lyase (or chondroitin ABC lyase–chondroitin AC lyase) ^a
Hyaluronate	Hyaluronate lyase

^aSample is divided into two portions and each is treated with a different lyase. The amount of depolymerization (i.e., counts moving from V_o to V_t of a gel-filtration column) is determined for each portion, and the difference gives a measure of the amount of glycosaminoglycan.

OVERVIEW OF HEPARIN LYASES

There are three well-characterized polysaccharide lyases that act endolytically on heparin and heparan sulfate (Jandik et al., 1994); these enzymes are called heparin lyases. Heparin and heparan sulfate GAGs are structurally related, linear sulfated polysaccharides. Heparin's major sequence (representing 70% to 90% of its structure) is as follows:

Heparan sulfate is composed primarily of equal proportions of the following:

and

These disaccharide sequences are found in differing amounts in both heparin and heparan sulfate (Desai et al., 1993a,b). Substrates for heparin lyases are illustrated in Figure 17.13B.1.

The nomenclature of the three heparin lyases is somewhat confusing. However, heparin lyase I and III have enzyme commission (EC) numbers to facilitate their identification. The decision as to which enzyme should be used for a particular application is based on both the specificity desired and the reaction conditions required. The activity of these lyases toward specific glycosidic linkages has been determined using structurally characterized oligosaccharide substrates (Desai et al., 1993a). The primary linkages cleaved by these enzymes and their relative activities toward heparin and heparin sulfate (Desai et al., 1993a, b) are presented in Figure 17.13B.1 and Table 17.13B.3. Information on the optimal conditions for the activity and stability for these enzymes is given under the description of each enzyme and summarized in Table 17.13B.2.

Figure 17.13B.1 Primary glycosidic linkages cleaved by heparin lyases. Abbreviations: X, H or SO_3^- ; Y, CH_3CO or SO_3^- . Heparin lyase II cleaves at either glucuronic or iduronic acid residues.

Table 17.13B.2 Reaction Conditions for Polysaccharide Lyases with Optimum Buffers and Reaction Temperatures

Lyase	Buffer ^a	Optimum temperature
Heparin I	Sodium phosphate/NaCl, pH 7.1	30°C
Heparin II	Sodium phosphate, pH 7.1	35°C
Heparin III	Sodium phosphate, pH 7.6	35°C
Chondroitin ABC	Tris-Cl/sodium acetate, pH 8	37°C
Chondroitin AC	Tris-Cl/sodium acetate, pH 8	37°C
Chondroitin B	Ethylenediamine/acetic acid/NaCl, pH 8	25°C
Hyaluronate	Sodium acetate/NaCl, pH 5.2	>30°C

^a See Reagents and Solutions for buffer recipes.

HEPARIN LYASE I (Lohse and Linhardt, 1992)

Heparin lyase I (EC 4.2.2.7), from *Flavobacterium heparinum* (*Cytophagia heparinia*), is commonly referred to as heparinase. The enzyme has a molecular weight of 42,800 Da and a pI of 9.1 to 9.2. Heparin lyase I has a random endolytic action pattern—i.e., it randomly acts on any site with the appropriate primary structure within the polymeric substrate (Fig. 17.13B.1; Jandik et al., 1994).

Complete Heparin Lyase–Catalyzed Depolymerization of an Unlabeled Sample

Samples consisting of tissues, biological fluids, PGs, and GAGs (UNIT 17.2) that contain microgram quantities of heparin and are not metabolically labeled can be analyzed using heparin lyase (see Critical Parameters for method to distinguish between heparin and heparan sulfate).

ENZYME

BASIC PROTOCOL

Preparation and Analysis of Glycoconjugates

17.13B.3

Materials

Heparin- or heparan sulfate-containing sample
Sodium phosphate/NaCl buffer (see recipe)
Heparin lyase I solution (see recipe)

Spectropor dialysis membrane, MWCO 1000 (Spectrum)
500- μ l polypropylene microcentrifuge tubes
30° and 100°C water baths

Additional reagents and equipment for polysaccharide dialysis (APPENDIX 3D),
HPLC (UNIT 17.18), and gel-filtration chromatography (UNITS 10.9 & 17.17)

1. Dissolve sample, containing 1 μ g to 1 mg heparin, in 50 μ l sodium phosphate/NaCl buffer. Dialyze sample against sodium phosphate/NaCl buffer using 1000 MWCO dialysis membrane.
2. Thaw and assay activity of a frozen aliquot of enzyme.
3. Thaw 10 μ l heparin lyase I solution at room temperature and add 40 μ l sodium phosphate/NaCl buffer to the 500- μ l tube containing enzyme. Add 50 μ l sodium phosphate/NaCl buffer to another 500- μ l tube to serve as a blank control.

Additional enzyme (10- to 100-fold) may be required to break down small, resistant oligosaccharides (Rice and Linhardt, 1989; Desai et al., 1993a).

For heparin lyase II and III, the chondroitin lyases, and hyaluronate lyase, see alternative conditions listed in Table 17.13B.2 and in descriptions of individual enzymes below.

4. Add 50 μ l sample to each tube and incubate 8 to 12 hr at 30°C.
5. Heat tube 2 min at 100°C to terminate the reaction. Analyze the product by a method appropriate for its purity and concentration.

A pure sample containing >10 μ g of heparin can be analyzed by measuring the difference in absorbance at 232 nm (ΔA_{232}) in 30 mM HCl between enzyme-treated sample and blank ($\epsilon = 5500 M^{-1}$ for oligosaccharide products in 30 mM HCl). Enzyme-treated sample is diluted with measured amounts of 30 mM HCl until the A_{232} is between 1 and 2. The blank is diluted with the same quantity of 30 mM HCl and its A_{232} is measured. The difference between the two measured A_{232} values, ΔA_{232} , is used to calculate the moles of oligosaccharide product formed. Ten moles of oligosaccharide product is obtained for each mole of heparin. If the treated sample contains substantial amounts of protein or other substances that absorb at or near 232 nm, disappearance of polysaccharide substrate can be measured using a dye-binding assay (Grant et al., 1984). Smaller quantities of samples or samples of lower purity can be analyzed by HPLC or gel-filtration chromatography using UV or conductivity detection methods.

Complete Heparin Lyase–Catalyzed Depolymerization of Very Small Amounts of Radiolabeled Glycosaminoglycans

ALTERNATE
PROTOCOL

When attempting to use heparin lyase to depolymerize radiolabeled samples that contain very small quantities of heparin, it is often useful to add cold substrate as a carrier so the activity of heparin lyase can be distinguished from that of trace amounts of chondroitin lyases that are often present in heparin lyase preparations. Chondroitin lyase may pose a problem when using a heparin lyase to distinguish between heparin/heparan sulfate and chondroitin/dermatan sulfate in radiolabeled samples (see Critical Parameters and Table 17.13B.3). Therefore, it is recommended that cold carrier chondroitin/dermatan sulfate be added to block the action of minor chondroitin lyase contaminants. Alternatively, chondroitin ABC lyase from *Proteus vulgaris* (an organism free of enzymes acting on heparin and heparan sulfate) can be used to detect chondroitin sulfate chains specifically (see discussion of chondroitin lyases).

Additional Materials (also see Basic Protocol)

Radiolabeled heparin-containing sample (UNIT 17.4)
20 mg/ml chondroitin sulfate A solution (see recipe)
20 mg/ml chondroitin sulfate C solution (see recipe)
20 mg/ml dermatan sulfate solution (see recipe)

1. Dissolve GAG sample containing radiolabeled heparin in 50 μ l sodium phosphate/NaCl buffer. Dialyze sample against sodium phosphate/NaCl buffer using 1000 MWCO dialysis membrane.
2. Thaw 10 μ l of heparin lyase I solution at room temperature, immediately prior to use.
For heparin lyase II and III, the chondroitin lyases, and hyaluronate lyase, see alternative conditions listed in Table 17.13B.2 and in descriptions of individual enzymes below.

3. Add 30 μ l sodium phosphate/NaCl buffer to the 500- μ l tube containing enzyme.
4. *Optional:* Add 1.7 μ l each of 20 mg/ml chondroitin sulfate A, chondroitin sulfate C, and dermatan sulfate substrate solutions (34 μ g each) to the enzyme in buffer.

This step should be performed if there is any concern that the enzyme contains chondroitin lyase impurities.

5. Add 50 μ l radiolabeled heparin solution and incubate 8 to 12 hr at 30°C.
6. Heat 2 min at 100°C to terminate the reaction.
7. Analyze depolymerized radioactive sample by HPLC or gel-filtration chromatography using radioisotope detection methods.

In gel-filtration chromatography following treatment with heparin lyase, counts in fractions corresponding to an apparent molecular weight <1500 Da confirm the presence of heparin/heparan sulfate. Similar results are obtained with heparin lyase II and III except heparin lyase III does not act on heparin (Table 17.13B.3).

Preparation and
Analysis of
Glycoconjugates

17.13B.5

Assay of Heparin Lyase Activity

Commercial preparations of heparin lyase should be assayed before use, particularly for applications in which the level of enzyme activity is critical—e.g., when trying to distinguish between heparin and heparan sulfate or measure their relative amounts in a sample containing both.

Materials

Sodium phosphate/NaCl buffer (see recipe)
Heparin lyase I solution (see recipe)
20 mg/ml heparin solution (see recipe)
UV spectrophotometer, temperature controlled
1-ml quartz cuvette with 1-cm pathlength

Reaction conditions

A 700- μ l reaction should contain:
50 mM sodium phosphate, pH 7.1
100 mM sodium chloride
10 mU heparin lyase I
1 mg heparin

Protocol

1. Add 640 μ l sodium phosphate/NaCl buffer to a 1-ml cuvette. Warm the cuvette to 30°C in a temperature-controlled UV spectrophotometer.

If a temperature-controlled spectrophotometer is not available, activity can be measured at room temperature, or sample can be incubated in a water bath and absorbance measured at fixed time points.

2. Thaw a 10- μ l aliquot of heparin lyase I solution at room temperature.
3. Take cuvette out of the spectrophotometer, remove 90 μ l warm buffer and transfer it to the tube containing heparin lyase I solution. Immediately transfer the entire 100 μ l of buffer and enzyme back into the warm cuvette.
4. Place cuvette in the spectrophotometer and set the A_{232} to zero.
5. Remove cuvette from the spectrophotometer and add 50 μ l of 20 mg/ml heparin substrate solution to initiate the reaction. Seal cuvette with Parafilm and invert once or twice to mix. Remove Parafilm and return cuvette to spectrophotometer.
6. Within 30 sec after addition of substrate, begin to measure absorbance continuously or at 30 sec intervals for 2 to 10 min. Plot A_{232} versus time.

At room temperature (~20°C) a two-fold decrease in reaction rate is observed; this requires a 4- to 20-min assay time.

7. Calculate the enzyme activity (1 U = 1 μ mol product formed/min) from the initial rate (<5% reaction completion) using $\epsilon = 3800 \text{ M}^{-1}$ for the reaction products in sodium phosphate/NaCl buffer. Each product formed has an unsaturated uronic acid residue at its nonreducing terminus. Enzyme activity is calculated as

$$\text{Enzyme activity} = \frac{(\Delta A_{232}/\text{min}) (700 \mu\text{l})}{3800 \text{ M}^{-1}}$$

The slope of the linear portion of the curve is used to calculate the initial rate of reaction.

HEPARIN LYASE II (Lohse and Linhardt, 1992)

Heparin lyase II (no EC number), an endolytic enzyme from *Flavobacterium heparinum*, has a molecular weight of 84,100 Da and a pI of 8.9 to 9.1. The substrate for heparin lyase II is indicated in Table 17.13B.3 and Figure 17.13B.1.

Protocols for the assay and use of heparin lyase II are identical to those for heparin lyase I, with the following modifications (see Table 17.13B.2):

1. Prepare enzyme and substrate solutions in sodium phosphate buffer, pH 7.1 (see recipes).
2. Carry out the reaction at 35°C.
3. Use 20 mg/ml heparan sulfate solution (see recipe) in Support Protocol 1 to assay for enzyme activity.

HEPARIN LYASE III (Lohse and Linhardt, 1992)

Heparin lyase III (EC 4.2.2.8), an endolytic enzyme from *Flavobacterium heparinum*, is commonly referred to as heparitinase and has a molecular weight of 70,800 Da and a pI of 9.9 to 10.1. Heparin lyase III can be used to confirm the presence of heparan sulfate in a sample (Fig. 17.13B.1 and Tables 17.13B.1 and 17.13B.3).

Protocols for the assay and use of heparin lyase III are identical to those of heparin lyase I, with the following modifications (see Table 17.13B.2):

1. Prepare enzyme and substrate solutions in sodium phosphate buffer, pH 7.6 (see recipes).
2. Carry out the reaction at 35°C.
3. Use 20 mg/ml heparan sulfate solution (see recipe), instead of heparin, as the substrate to assay for enzyme activity in Support Protocol 1.

OVERVIEW OF CHONDROITIN SULFATE LYASES

There are several polysaccharide lyases that act on chondroitin sulfates, dermatan sulfate, and hyaluronate. Chondroitin sulfate galactosaminoglycans are structurally related, sulfated, alternating 1→3, 1→4 linked, linear polysaccharides. The structure of the major disaccharide linkage found in each chondroitin sulfate and the enzyme that acts at each linkage are shown in Figure 17.13B.2. Hyaluronate has the same backbone structure, except that it is not sulfated and contains *N*-acetylglucosamine in place of *N*-acetylgalactosamine (Fig. 17.13B.3).

The decision of which chondroitin lyase to use should be based on both the specificity desired and the reaction conditions required (Tables 17.13B.1 & 17.13B.2).

CHONDROITIN ABC LYASE (Yamagata et al., 1968)

Chondroitin ABC lyase (chondroitinase ABC, EC 4.2.2.4), from *Proteus vulgaris*, has a molecular weight of 150,000 Da. This enzyme acts endolytically on chondroitin sulfates A-E (Fig. 17.13B.2; Jandik et al., 1994), slowly on hyaluronic acid, and not at all on heparin, heparan sulfate, or keratan sulfate.

**Preparation and
Analysis of
Glycoconjugates**

17.13B.7

Figure 17.13B.2 Glycosidic linkages cleaved by chondroitin lyases. Abbreviation: Ac, CH_3CO .

The basic and alternate protocols for chondroitin ABC lyase are identical to those described for heparin lyase I with the following modifications:

1. Prepare enzyme and substrate solutions in Tris-Cl/sodium acetate buffer, pH 8 (see recipe).
2. Carry out the reaction at 37°C .
3. When using the alternate protocol for depolymerization of very small amounts of radiolabeled GAGs, omit step 4.

Figure 17.13B.3 Glycosidic linkage in hyaluronate cleaved by hyaluronate lyase and chondroitin AC and ABC lyases. Abbreviation: Ac, CH₃CO.

A radioactive sample containing chondroitin sulfate or dermatan sulfate can be analyzed, following chondroitin ABC lyase treatment, by HPLC (UNIT 17.18) or gel-filtration chromatography (UNITS 10.9 & 17.17) using radioisotope detection methods. In gel-filtration chromatography following treatment with chondroitin ABC lyase, counts in fractions corresponding to a molecular weight <1000 Da confirm the presence of chondroitin sulfate or dermatan sulfate.

Assay of Chondroitin ABC Lyase Activity

Commercial preparations of chondroitin lyase should be assayed before use, particularly for applications in which the level of enzyme activity is critical.

Materials

- Tris·Cl/sodium acetate buffer, pH 8.0 (see recipe)
- Chondroitin ABC lyase solution (see recipe)
- 20 mg/ml chondroitin sulfate A (see recipe), chondroitin sulfate C solution (see recipe), or dermatan sulfate solution (see recipe)
- UV spectrophotometer, temperature controlled
- 1-ml quartz cuvette with 1-cm path length

Reaction conditions

- A 700- μ l reaction should contain:*
- 50 mM Tris·Cl, pH 8
 - 60 mM sodium acetate
 - 10 mU chondroitin lyase
 - 1 mg chondroitin sulfate A or C, or dermatan sulfate

Protocol

1. Add 640 μ l Tris·Cl/sodium acetate buffer to a 1-ml quartz cuvette. Warm the cuvette to 37°C in a temperature-controlled spectrophotometer.

If a temperature-controlled spectrophotometer is not available, activity can be measured at room temperature or the sample can be incubated in a water bath and the absorbance measured at fixed time points.

2. Thaw a 10- μ l aliquot of chondroitin ABC lyase solution at room temperature.
3. Take cuvette out of the spectrophotometer, remove 90 μ l warm buffer, and transfer it to enzyme solution. Immediately transfer entire 100 μ l buffer plus enzyme back to the warm cuvette.
4. Place cuvette in spectrophotometer and set the absorbance at 232 nm (A_{232}) to zero.

SUPPORT PROTOCOL 2

Preparation and Analysis of Glycoconjugates

17.13B.9

5. Remove cuvette from spectrophotometer and add 50 μl of 20 mg/ml chondroitin A or C or dermatan sulfate solution to initiate reaction. Seal cuvette with Parafilm and invert once or twice to mix. Remove Parafilm and return cuvette to spectrophotometer.

To assay for chondroitin AC lyase activity, use chondroitin A or C as substrate. To assay for chondroitin B lyase activity, use dermatan sulfate as substrate (see Table 17.13B.1 and description of individual enzymes below).

6. Within 30 sec after adding substrate begin to measure the absorbance continuously or at 30-sec intervals for 2 to 10 min. Plot A_{232} versus time.
7. Calculate the enzyme activity (1 U = 1 μmol product formed/min) from the initial rate (<5% reaction completion) using $\epsilon = 3800 \text{ M}^{-1}$ for reaction products at pH 8. Enzyme activity is calculated as

$$\text{Enzyme activity} = \frac{(\Delta A_{232}/\text{min})(700 \mu\text{l})}{3800 \text{ M}^{-1}}$$

Calculate the number of product molecules formed per substrate molecule from the A_{232} measured at reaction completion.

ENZYME

CHONDROITIN AC LYASE (Yamagata et al., 1968; Hiyama and Okada, 1975; Michelacci and Dietrich, 1975)

Two chondroitin AC lyases from *Arthrobacter aurescens* and *Flavobacterium heparinum* share the same enzyme commission number (EC 4.2.2.5). Chondroitin AC lyase from *A. aurescens* has a molecular weight of 76,000 Da (Hiyama and Okada, 1975) and a pI of 5.46. It acts exolytically on chondroitin sulfate A and C (Jandik et al., 1994) and exhibits a three-fold higher activity on hyaluronate. It can act at the glucuronic acid residues in dermatan sulfate (Fig. 17.13B.2) but does not act on heparin or heparan sulfate (Fig. 17.13B.1). Chondroitin AC lyase from *F. heparinum* acts endolytically on chondroitin sulfates A and C (Jandik et al., 1994), on hyaluronate, and at the glucuronate residues of dermatan sulfate (Fig. 17.13B.2; Gu et al., 1993). It does not act on heparin, heparan sulfate, or keratan sulfate (Yamagata et al., 1968).

The protocols for chondroitin AC lyase are identical to those described for chondroitin ABC lyase except chondroitin A or C should be used as substrate in Support Protocol 2 for assaying chondroitin lyase activity.

ENZYME

CHONDROITIN B LYASE (Michelacci and Dietrich, 1975)

Chondroitin B lyase (no EC number), from *Flavobacterium heparinum*, has a molecular weight of 55,000 Da. Chondroitin B lyase acts only on dermatan sulfate and not on the glucuronate residues of chondroitin sulfates A, C, and hyaluronate, and not on heparin or heparan sulfate (Fig. 17.13B.2).

This enzyme can be assayed as described for chondroitin ABC lyase using dermatan sulfate as substrate. The heparin lyase I protocols are used for sample analysis with this enzyme, with the following modifications (see Table 17.13B.2):

1. Prepare enzyme and substrate solutions in ethylenediamine/acetic acid/NaCl buffer, pH 8 (see recipe).
2. Carry out the reaction at 25°C.
3. Use dermatan sulfate solution (see recipe) as substrate in Support Protocol 2.

HYALURONATE LYASE (Vesterberg, 1968; Rautela and Abramson, 1973; Sasaki et al., 1982)

ENZYME

Hyaluronate lyases (EC 4.2.2.1 and EC 4.2.99.1) act only on hyaluronate (Hiyama and Okada, 1975) allowing hyaluronate (Fig. 17.13B.3) to be distinguished from chondroitin sulfate (Fig. 17.13B.2 and Table 17.13B.1). The enzyme from *Streptomyces hyalurolyticus* has been purified and has a pI <7 (Sasaki et al., 1982). Homogeneous *Staphylococcus aureus* hyaluronate lyase has a molecular weight of 84,000 Da (Rautela and Abramson, 1973) and a pI of 7.4 to 7.9 (Vesterberg, 1968).

Reaction conditions

A 700- μ l reaction should contain:

- 50 mM sodium acetate, pH 5.2
- 125 mM sodium chloride
- 10 mU hyaluronate lyase
- 1 mg hyaluronate

The basic, alternate, and support protocols for hyaluronate lyase are identical to those described for heparin lyase with the following modifications (see Table 17.13B.2):

Protocol

1. Use sodium acetate/NaCl buffer, pH 5.2 (see recipe), to prepare enzyme (hyaluronate lyase; see recipe) and substrate solutions.
2. Perform the reaction at 30° to 60°C.

Higher temperatures can be useful to reduce substrate viscosity—hyaluronic acid is very viscous. Higher temperatures will also increase the reaction rate, and they can be used to inhibit the activity of other lyases that may be present as contaminants of the hyaluronate lyase preparation.

3. Use hyaluronate solution (see recipe), instead of heparin solution, as substrate to assay enzyme activity (see Support Protocol 1).
4. When using the Alternate Protocol for depolymerization of very small amounts of radiolabeled GAGs, omit step 4.

Following treatment with hyaluronate lyase, a radioactive sample containing hyaluronate can be analyzed by HPLC (UNIT 17.18) or gel-filtration chromatography (UNIT 17.17) using radioisotope detection methods. In gel-filtration following treatment with hyaluronate lyase, counts in fractions corresponding to a molecular weight <500 Da confirm the presence of hyaluronate.

Testicular hyaluronidase is a hydrolase (EC 3.2.1.35) that also acts on hyaluronate (also on chondroitin sulfates A and C). Because it is not a polysaccharide lyase, testicular hyaluronidase cannot be assayed with the support protocol, but it can be used in the basic and alternate protocols with the modifications described above.

Preparation and
Analysis of
Glycoconjugates

17.13B.11

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Chondroitin lyase solutions, 1 mU/ μ l

Dissolve 0.1 U lyophilized enzyme in 100 μ l Tris-Cl/sodium acetate buffer (see recipe) for chondroitin ABC lyase (chondroitinase ABC; Sigma or Seikagaku) and chondroitin AC lyase (chondroitinase AC from *Arthrobacter aurescens* and *Flavobacterium heparinum*; Sigma or Seikagaku) or ethylenediamine/acetic acid/NaCl buffer (see recipe) for chondroitin B lyase (chondroitinase B; Sigma or Seikagaku). Store in 10-mU aliquots in 500- μ l polypropylene tubes <1 year at -70°C .

Different suppliers use different definitions for units of enzyme activity. Enzyme activity levels should be assayed and standardized, as described in the support protocols, in the laboratory before the enzymes are used in analytical studies.

Chondroitin sulfate A or C solution, 20 mg/ml

Dissolve 20 mg chondroitin sulfate A or C, sodium salt (Sigma or Seikagaku) in 1 ml Tris-Cl/sodium acetate buffer, pH 8 (see recipe) or other buffer appropriate to enzyme/substrate pair (see Table 17.13B.2). Store 1 year at $<0^{\circ}\text{C}$.

Dermatan sulfate solution, 20 mg/ml

Dissolve 20 mg dermatan sulfate, sodium salt (Sigma or Seikagaku) in 1 ml ethylenediamine/acetic acid/NaCl buffer, pH 8 (see recipe) or other buffer appropriate to enzyme/substrate pair (see Table 17.13B.2). Store 1 year at $<0^{\circ}\text{C}$.

Ethylenediamine/acetic acid/NaCl buffer

Dissolve 3.0 g ethylenediamine (50 mM final) and 1.7 g NaCl (30 mM final) in 900 ml H_2O . Adjust pH with glacial acetic acid to pH 8, and bring volume to 1 liter with H_2O . Store <1 month at 4°C .

Heparan sulfate solution, 20 mg/ml

Dissolve 20 mg heparan sulfate, sodium salt from bovine kidney (Seikagaku) in 1 ml sodium phosphate buffer, pH 7.6 (see recipe). Store 1 year at 0°C .

Heparin lyase solutions, 1 mU/ μ l

Dissolve 0.1 U lyophilized enzyme in 100 μ l sodium phosphate/NaCl buffer (see recipe) for heparin lyase I or sodium phosphate buffer (see recipe) for heparin lyase II and III adjusted to the appropriate pH. Store enzyme in 10 mU aliquots in 500- μ l polypropylene tubes <1 year at -70°C .

*Heparin lyase I from *Flavobacterium heparinum* is sold as heparinase I (Sigma) and heparinase (Seikagaku). Heparin lyase II is sold as heparinase II (Sigma) and heparitinase II (Seikagaku). Heparin lyase III from *Flavobacterium heparinum* is sold as heparinase III (Sigma) and heparatinase or heparatinase I (Seikagaku).*

Different suppliers use different definitions for units of enzyme activity. Enzyme activity levels should be assayed and standardized, as described in the support protocols, in the laboratory before the enzymes are used in analytical studies.

Heparin solution, 20 mg/ml

Dissolve 20 mg heparin, sodium salt (140 to 180 USP U/mg), from porcine intestinal mucosa or bovine lung (Sigma) in sodium phosphate/NaCl buffer, pH 7.1 (see recipe). Store 1 year at 0°C .

Different suppliers use different definitions for units of enzyme activity. Enzyme activity levels should be assayed and standardized, as described in the support protocols, in the laboratory before the enzymes are used in analytical studies.

Hyaluronate lyase solution, 1 mU/μl

Dissolve 0.1 U lyophilized enzyme (hyaluronidase from *Streptomyces hyalurolyticus*; Sigma or Seikagaku) in 100 μl sodium acetate/NaCl buffer, pH 5.2 (see recipe). Aliquot 10 mU to 500-μl polypropylene tubes and store <1 year at -70°C.

Different suppliers use different definitions for units of enzyme activity. Enzyme activity levels should be assayed and standardized, as described in the support protocols, in the laboratory before the enzymes are used in analytical studies.

Hyaluronate solution, 1.4 mg/ml

Dissolve 1.4 mg hyaluronate in 1 ml sodium acetate/NaCl buffer, pH 5.2 (see recipe). Store 1 year at <0°C.

Hyaluronate of high molecular weight is very viscous. It is best to use a hyaluronate of low to medium molecular weight to measure activity.

Sodium acetate/NaCl buffer

Dissolve 4.1 g sodium acetate (30 mM final) and 7.3 g NaCl (125 mM final) in 900 ml H₂O. Adjust pH with glacial acetic acid to pH 5.2 and bring volume to 1 liter with H₂O. Store <1 month at 4°C.

Sodium phosphate buffer

Dissolve 7.1 g dibasic sodium phosphate (50 mM final) in 900 ml H₂O. Adjust pH with concentrated phosphoric acid to pH 7.1 for heparin lyase II and pH 7.6 for heparin lyase III. Bring volume to 1 liter with H₂O. Store <1 month at 25°C.

Sodium phosphate/NaCl buffer

Dissolve 7.1 g dibasic sodium phosphate (50 mM final) and 5.8 g sodium chloride (100 mM final) in 900 ml H₂O. Adjust pH with phosphoric acid to pH 7.1 and bring volume to 1 liter with H₂O. Store <1 month at 25°C.

Tris·Cl/sodium acetate buffer

Dissolve 6.05 g Tris base (50 mM final) and 8.17 g sodium acetate (60 mM final) in 900 ml H₂O. Adjust pH to 8.0 with concentrated hydrochloric acid, and bring volume to 1 liter with H₂O. Store <1 month at 4°C.

COMMENTARY

Background Information

Proteoglycans (PGs) are primarily found in the extracellular matrix and are important in cell-cell interaction. Glycosaminoglycans (GAGs) are the dominant physical, chemical, and biological features of PGs. Lyases cleave specific glycosidic linkages at C4 of uronic acid residues present in GAGs (Figs. 17.13B.1, 17.13B.2, and 17.13B.3) through an eliminase mechanism, resulting in unsaturated oligosaccharide products that have UV absorbance spectra maxima at 232 nm (Linhardt et al., 1986). An eliminase catalyzes an elimination reaction that results in the formation of a double bond. In contrast, a hydrolase (the most common class of enzymes acting on polysaccharides) breaks down polysaccharides through the addition of water and does not result in the formation of a double bond. Lyases are useful for identifying and distinguishing the GAGs

present in unlabeled or radiolabeled samples (see Table 17.13B.1).

Critical Parameters and Troubleshooting

Lyases are primarily of microbial origin and often a single organism produces multiple lyases acting on a variety of PGs and GAGs. Thus, it must be recognized that despite the high level of purity of the commercially available enzymes, they may contain small amounts of enzymatic impurities. These impurities can cause misleading results, particularly when large quantities of enzyme are used to treat very small quantities of sample—e.g., when these enzymes are used to analyze radiolabeled samples.

Protease contamination can also be present in the enzyme preparation. Commercial enzymes often contain bovine serum albumin

(BSA) for stabilization during lyophilization, and this greatly reduces potential problems associated with proteolytic contamination.

Complete degradation of a GAG. Table 17.13B.1 shows how the polysaccharide lyases can be used, alone or in combination, to determine the content of a GAG. All three heparin lyases used in combination (at equal-unit concentrations in 50 mM sodium phosphate buffer, pH 7, at 30°C) will degrade heparin or heparan sulfate to disaccharides, although a small quantity of lyase-resistant tetrasaccharide may remain. Chondroitin ABC lyase can be used to completely digest a mixture of chondroitin sulfates. If hyaluronate and chondroitin sulfate are both present, it is advisable to use an equal-unit mixture of chondroitin ABC and AC lyases. For complete degradation of GAGs, except keratan sulfate (see UNIT 17.2), it is advisable to treat the sample with an equal-unit mixture of heparin lyases I, II, and III and chondroitin ABC and AC lyases in sodium phosphate/NaCl buffer, pH 7, 30°C.

Heparin lyase III can be used to distinguish between samples containing heparan sulfate and those containing heparin. Although heparin lyase I (heparinase) has been used by investigators to demonstrate the presence of heparin in a sample, it also acts at some linkages present in heparan sulfate (Table 17.13B.3). Gel-filtration analysis can help distinguish between heparin and heparan sulfate because the large oligosaccharides formed from heparan sulfate elute in the void volume. In addition, oligosaccharide product compositional analysis (UNIT 17.19) is useful in distinguishing heparin from heparan sulfate when using heparin lyase I.

Caution is required when attempting to distinguish heparin/heparan sulfate from chondroitin/dermatan sulfate using heparin lyases. *Flavobacterium heparinum* produces both heparin and chondroitin/dermatan sulfate lyases; thus, minor contaminating activities can result in false positives. Step 4 of the Alternate Protocol for the use of heparin lyase on radiolabeled samples—incubation in the presence of nonspecific substrate—is included to eliminate false positives. The use of chondroitin ABC lyase, which contains no heparin lyase activity, is complicated by heparin's inhibition of chondroitin ABC lyase (Nakada and Wolfe, 1961). This inhibition is overcome by using excess enzyme (Linhardt et al., 1991).

Chondroitin sulfate is routinely distinguished from dermatan sulfate using chondroitin AC and ABC lyases (Saito et al., 1968). This can give slightly different results from those

obtained using chondroitin AC and B lyases (Linhardt et al., 1991). Chondroitin AC lyases from *F. heparinum* and *Arthrobacter aureescens* both act at glucuronate-containing linkages in dermatan sulfates (Gu et al., 1993) and are useful for analysis of the glucuronic acid content of dermatan sulfate (Linhardt et al., 1991).

Hyaluronate content can be determined using hyaluronate lyase, which is specific for hyaluronate. Although hyaluronate lyases are inhibited by chondroitin sulfates, the addition of salt (150 mM NaCl) overcomes this inhibition (Nakada and Wolfe, 1961; Yamagata et al., 1968).

Contaminants in samples. The presence of certain metals (particularly divalent metals), proteases, polyanions, detergents (SDS and Triton X-100), and denaturants (urea and guanidine) can interfere with the activity of lyases. Before using these enzymes, detergents should be removed by precipitation with potassium chloride or by using a detergent-removal column such as Biobeads (Bio-Rad). Urea and guanidine should be removed by exhaustive dialysis using controlled-pore dialysis membrane (MWCO 1000).

Reaction conditions. Lyases are compatible with a wide range of buffers including succinate, acetate, ethylenediamine acetate, Tris-Cl, bis-Trispropane-HCl, sodium phosphate, MOPS, TES, and HEPES (Lohse and Linhardt, 1992). The presence of calcium may either enhance or reduce lyase activity. Its effect is probably due to changes calcium causes in the GAG substrate conformation and not through direct interaction with the enzyme. Because calcium is incompatible with certain buffers, e.g., phosphate, and can lead to variable results, its use is not recommended. The pH optima for lyases are broad—between pH 5 and 9. Hyaluronate lyase works best at pH <7, and chondroitin and heparin lyases work best at pH ≥7. Lyases can be used at temperatures between 20° and 40°C. Optimum temperatures are always a compromise between activity and stability considerations. If enzyme instability is a concern due to elevated temperature or prolonged incubation time, heparin lyase II should be used to degrade heparin or heparan sulfate, chondroitin ABC lyase should be used to degrade chondroitin sulfates and dermatan sulfates, and hyaluronate lyase should be used for hyaluronate. Optimal reaction conditions for the polysaccharide lyases are summarized in Table 17.13B.2.

Removal of lyase and lyase activity. Following the use of a lyase, residual lyase activity can

be destroyed by heating the reaction mixture to 100°C or by adding denaturants or detergents. Most lyases are cationic proteins and can be removed from anionic oligosaccharide products by passing the reaction mixture through a small cation-exchange column, such as SP-Sephadex (Sigma), adjusted to an acidic pH. The oligosaccharide products (void volume) are then readjusted to neutral pH and analyzed (UNITS 17.17 & 17.19). This method can also be used to remove BSA, an excipient found in many of the commercial enzymes, from the oligosaccharide products.

Enzyme stability during storage. These enzymes can be stored in their lyophilized or reconstituted states at -20° or -70°C for ≤1 year. Once an enzyme is reconstituted, it should be aliquoted and frozen immediately. Single aliquots can be thawed to assay the enzyme or for use in an experiment. Heparin lyase II is very stable but heparin lyase III is unstable and should be used immediately after removing from frozen storage. The heparin lyases, particularly heparin lyase III, are sensitive to freeze-thawing and lyophilization. Among the chondroitin lyases, chondroitin AC lyase is most susceptible to thermal inactivation (Michelacci and Dietrich, 1975). Lyase storage stability is enhanced by high (>2 mg/ml) protein concentrations. This is often accomplished by addition of BSA.

Anticipated Results

When used correctly, an active lyase should specifically catalyze the breakdown of its GAG substrates. The types of GAGs present in a sample can be easily identified by using multiple lyases. The amount of product formed, and thus the amount of GAG in the sample, can be determined. Accuracy of analysis depends on a number of factors including the complexity of the sample and the types and concentrations of GAGs present. For a sample containing one GAG in high concentration with no contaminating proteins, salts, detergents, etc., GAG concentration can be determined to ±5%. For a complex sample containing many different GAGs at low concentrations in the presence of high levels of contaminants, it may only be possible to estimate GAG concentration to ±100%.

Time Considerations

It takes about half a day to prepare buffers and solutions and to reconstitute, aliquot, and freeze the enzyme. One aliquot of frozen enzyme can be thawed and assayed to ensure that

the enzyme is active and has been stored properly. Application of the enzyme to determine the presence or type of GAG in a sample requires ~3 days for sample preparation, overnight treatment with enzyme, and analysis.

Preparation of Glycopeptides

UNIT 17.14A

Generation of glycopeptides from glycoproteins is frequently useful when analyzing a protein's oligosaccharide side chains. Freed from the bulk of the polypeptide backbone by proteolysis, glycopeptides can be characterized by a variety of techniques. This approach is especially useful for proteins with multiple glycosylation sites, but it is also applicable when concern exists that the protein's structure and solubility will interfere with particular techniques such as gel-filtration and lectin-affinity chromatography (UNIT 17.1), glycosyltransferase assays (UNIT 17.6), and colorimetric assays (UNIT 17.9).

Extensive proteolysis with pronase or proteinase K results in oligosaccharides with one or a few amino acid residues attached. These glycopeptides are suitable for compositional analyses (UNIT 17.16), exo- and endoglycosidase digestions (UNITS 17.12 & 17.13), and lectin-affinity chromatography (UNIT 17.1). This technique, detailed in the first basic protocol, is often employed as a first step in characterizing oligosaccharides on very large glycoproteins such as proteoglycans and mucins.

Limited proteolysis with a specific endoproteinase (e.g., trypsin, α -chymotrypsin, and V8 protease), as described in the second basic protocol, leaves a larger peptide attached to the oligosaccharide. The resulting glycopeptides are generally suitable substrates for Peptide:N-glycosidase F (PNGase F; UNIT 17.13), an enzyme useful in defining oligosaccharide-peptide linkages. Additionally, they can be separated by C₁₈ reversed-phase chromatography, resulting in a glycopeptide map that is analogous to a peptide map (UNIT 10.12), and used for detection of glycosylation sites (UNIT 17.14B).

Alternative approaches for removing oligosaccharide side chains from the peptide include β -elimination (UNIT 17.15), endoglycosidases (UNIT 17.13), phospholipases (for GPI-anchored proteins; UNIT 17.8), or hydrazinolysis (Takasaki et al., 1982).

EXTENSIVE PROTEOLYTIC DIGESTION OF GLYCOPROTEINS

In this protocol, glycoproteins are applied to a Sephacryl S-200 gel-filtration column to separate them from any lower-molecular-weight material that may be present (e.g., degradation products or other low-molecular-weight contaminants). Denatured glycoproteins in SDS will generally elute in the void volume (V_0); the contaminants elute after the V_0 . The glycoproteins pooled from the V_0 are then digested with pronase or proteinase K and rechromatographed on the same column. Glycopeptides are recovered in the material that now elutes after the V_0 and are desalted before further use.

If the sample has already been purified by techniques such as immunoprecipitation (UNIT 10.16), dialysis (APPENDIX 3), or gel filtration (UNIT 10.9) which reliably remove low-molecular weight contaminants, it can be digested directly with pronase or proteinase K. After boiling to terminate the protease reaction, the glycopeptides can be desalted. Thus, the use of SDS and passage over Sephacryl S-200 can be completely avoided.

Generation of glycopeptides from a sample metabolically labeled with a radioactive sugar precursor (UNIT 17.4) is described and radioactivity is followed for each gel-filtration run. However, the same approach can be employed with unlabeled glycoproteins, following the column profiles with a carbohydrate-specific colorimetric assay (UNITS 17.9 & 17.16) if sufficient mass is present (see specific units for detection limits). Suitable samples range from total cellular lysates (containing multiple different glycoproteins together with degradation products and precursors) to highly purified protein samples.

Supplement 32

Materials

Radiolabeled glycoprotein sample (UNIT 17.4)
20% (w/v) sodium dodecyl sulfate (SDS)
1 M 2-mercaptoethanol (2-ME)
Sephacryl S-200 gel-filtration column (50- to 75-ml bed volume; Sigma or Pharmacia Biotech), equilibrated (UNIT 10.9) in ammonium formate/azide solution containing 0.1% (w/v) SDS (see recipe)
100% and 85% (v/v) acetone (HPLC or ACS grade), ice-cold
0.1 M Tris-Cl, pH 7.5 (APPENDIX 2), without or with 10 mM CaCl₂ (Tris/CaCl₂)
Pronase or proteinase K stock solution
Phenylmethylsulfonyl fluoride (PMSF), in 100% ethanol
Sephadex G-15 (Sigma or Pharmacia Biotech) or Bio-Gel P-2 (Bio-Rad) columns (30- to 60-ml bed volume), equilibrated in ammonium formate/azide solution
15- or 50-ml conical polypropylene tubes
Beckman TJ-6 centrifuge or equivalent
Water bath, 50°C

Additional reagents and equipment for preparation and standardization of gel-filtration columns and sample desalting (UNIT 10.9), quantitation of proteins (UNIT 10.1), and acetone precipitation (UNIT 17.10)

Purify the protein sample

1. Place radiolabeled glycoprotein sample in a 15-ml conical polypropylene tube. Add $\frac{1}{10}$ vol of 20% SDS and $\frac{1}{50}$ vol of 1 M 2-ME and boil 5 min. Cool to room temperature and centrifuge 10 min at $1000 \times g$ (2000 rpm in a Beckman TJ-6), room temperature to remove any precipitate. Save the supernatant.

The protein sample should contain <1 μg to several mg, depending on the source. The sample volume should be ≤1 ml. If the volume of the initial sample is >1 ml, lyophilize and resuspend it in 1 ml water (or less, if solubility permits). Large amounts of protein may require a larger volume, depending on the protein's solubility. If a larger volume is used, the volume of the Sephacryl S-200 column should be increased so that the sample volume is no more than 5% of the bed volume of the column.

Boiling ensures that any endogenous proteases or glycosidases are inactivated. For proteins known to be soluble without SDS, the addition of SDS can be eliminated. After boiling, the sample can be freed of low-molecular-weight contaminants, if necessary, by chromatography directly on Sephacryl S-200 (step 2) using a buffer in which the sample is known to be soluble.

2. Apply supernatant to Sephacryl S-200 column (50- to 75-ml bed-volume) equilibrated in ammonium formate/azide solution containing 0.1% (w/v) SDS. Collect 1.0- to 1.5-ml fractions and count 2% to 5% of each eluted fraction in a scintillation counter to determine the elution profile.

Sephacryl S-200 is utilized because almost all glycoproteins will elute in the V_0 in the presence of SDS. The profile should contain a peak eluting at V_0 . Additional peak(s) eluting after the V_0 , resulting from degradation products or unincorporated isotope, may or may not be present, depending on the source of the sample and its preparation (see critical parameters).

3. Pool the V_0 into a 15- or 50-ml polypropylene tube and determine the amount of protein present. Lyophilize the sample, resuspend in $\frac{1}{10}$ the original volume with water, and add 8 vol of ice-cold 100% acetone. Precipitate overnight at -20°C .

It is only necessary to determine the amount of protein in the sample if >20 μg may be present, so that sufficient protease may be added.

4. Centrifuge 15 min at $3000 \times g$, 4°C . Wash pellet gently with ice-cold 85% acetone and centrifuge as before. Remove supernatant with a Pasteur pipet and save pellet.

The second wash step is necessary to remove residual SDS which may interfere with the digestion. If desired, transfer the sample to a smaller polypropylene or a 5- or 10-ml screw-cap glass tube prior to the addition of acetone.

Digest with protease

- 5a. *For pronase digestion:* Add 200 μl of Tris/ CaCl_2 buffer to the pellet. If the total protein is $<20 \mu\text{g}$, add 20 μl pronase stock solution. Tightly cap the tube and incubate 2 to 4 hr at 50°C .

- 5b. *For proteinase K digestion:* Add 200 μl of 0.1 M Tris·Cl, pH 7.5, to the pellet. If the total protein is $<20 \mu\text{g}$, add 20 μl proteinase K stock solution. Tightly cap the tube and incubate 2 to 4 hr at 50°C .

See commentary for a discussion on the choice and uses of the two proteases. If the sample contains $>20 \mu\text{g}$ glycoprotein, add sufficient protease stock to give a protease:sample ratio of 1:20 (w/w). If larger amounts of protein are present, add larger amounts of digestion buffer. Depending on the protein sample, concentrations $\leq 100 \text{ mg/ml}$ are acceptable.

6. Add a second aliquot of protease (equal to that added in steps 5a or 5b) and continue the 50°C digestion for 12 to 16 hr.

The pellet should be completely solubilized during the digestion. If not, continue digestion for 48 or 72 hr. Inclusion of 2-ME to 20 mM (final) may increase solubility.

If a 50°C water bath is unavailable, the digestion may proceed equally well at 37°C . However, because microbial growth may be a problem at 37°C , 0.02% sodium azide should be added to the reaction if the digestion is done at this temperature.

7. Add $\frac{1}{10}$ vol of 20% SDS to completely solubilize any residual aggregated material. Boil 10 min, cool, and centrifuge 10 min at $1000 \times g$, room temperature.

Any protease not destroyed by boiling may contaminate the Sephacryl S-200 column and act to digest samples applied subsequently, resulting in obvious confusion if nondigested samples are applied. Inactivation of proteinase K can be augmented by phenylmethylsulfonyl fluoride (PMSF). Add $\frac{1}{100}$ vol of 0.1 M solution in 100% ethanol to the sample and incubate 20 to 30 min at room temperature prior to boiling.

8. Apply the supernatant to the Sephacryl S-200 column, collect fractions, and determine the elution profile as in step 2.

Recover glycopeptides

9. Compare the elution profiles before and after protease digestion. Material that elutes after the V_0 (often a broad peak) represents glycopeptides released from the glycoproteins that eluted in the V_0 of the first column. Pool the glycopeptides and add $\frac{1}{50}$ vol saturated KCl. Incubate 4 to 12 hr at 4°C .

The KCl treatment removes the bulk of the SDS.

10. Remove the insoluble K^+ -SDS precipitate by centrifuging 10 min at $1000 \times g$, 4°C . Collect the supernatant, concentrate by lyophilizing, and resuspend in 0.5 to 1.0 ml water.

Some residual K^+ -SDS precipitate may be apparent after resuspension and can be removed by repeating the centrifugation step as above.

11. Desalt glycopeptides on a Sephadex G-15 or Bio-Gel P-2 column (30- to 60-ml bed volume) equilibrated in ammonium formate/azide solution. Collect fractions that are

~5% of the total bed volume and determine the elution profile as in step 2. Pool the glycopeptides eluting in the V_0 and lyophilize. Store at -20°C .

The samples may be stored frozen indefinitely.

BASIC PROTOCOL

PROTEOLYTIC DIGESTION OF PURIFIED GLYCOPROTEINS WITH ENDOPEPTIDASES

Glycoproteins labeled metabolically with a radioactive sugar (UNIT 17.4) are first reduced and alkylated to increase solubility and prevent the cross-linking of peptides by disulfide bonds, and then digested with a site-specific endoproteinase. Unlike digestion with pronase or proteinase K, the resulting glycopeptides will generally be attached to a larger peptide of a defined length.

Materials

Radiolabeled protein sample (UNIT 17.4)
Tris/SDS solution
Dithiothreitol (DTT)
Iodoacetamide
1N sodium hydroxide (NaOH), prepared fresh every 4 weeks
2-mercaptoethanol (2-ME), undiluted
Sephadex G-50 column (30- to 60-ml bed volume; Sigma or Pharmacia Biotech) column, equilibrated in ammonium formate/azide solution containing 0.1% (w/v) SDS (UNIT 10.9)
100% and 85% (v/v) acetone, ice-cold
Nitrogen (N_2) stream
Protease digestion buffer
Protease stock solution
5- to 15-ml Pyrex or polypropylene tubes
Aluminum foil
pH paper, range pH 7 to 12
10-ml round-bottomed polypropylene tubes
Beckman TJ-6 centrifuge or equivalent
1.5-ml polypropylene microcentrifuge tubes
Additional reagents and equipment for preparation and standardization of gel-filtration columns and sample desalting (UNIT 10.9) and acetone precipitation (UNIT 17.10)

1. Place the purified radiolabeled protein sample in a 5- to 15-ml Pyrex or polypropylene tube and dissolve in 700 μl Tris/SDS solution.

Recovery of radiolabeled glycopeptides proteins can be aided by the addition of a carrier protein (e.g., 50 μg of ovalbumin, bovine immunoglobulin, or fetuin), which should be added before the reduction step.

In principle, any denaturing and strongly buffered solution similar to the reducing buffer can be employed. For instance, if the protein is in a PBS/NP-40 buffer, $1/10$ vol of 3 M Tris-Cl, pH 8.6/20% SDS stock solution could be added to approximate the reduction buffer. Alternatively, the protein sample can be exchanged into reducing buffer by gel-filtration chromatography (UNIT 10.9), dialysis (APPENDIX 3), or acetone precipitation (UNIT 17.10).

2. Add 11.9 mg DTT and boil 3 min. Incubate 1 hr at 37°C .
3. Remove the sample from the water bath and wrap tube in aluminum foil to protect from light. Add 32.3 mg of iodoacetamide. *Immediately* check the pH with pH paper

and adjust to pH 8 to 9 by adding 50- μ l aliquots of 1 N NaOH (5 to 10 aliquots may be needed). Continue the incubation for 1 hr at room temperature, shielded from light.

Alkylation of the free sulfhydryl groups prevents the reformation of disulfide bonds. Improper pH during this procedure will inhibit the alkylation. Exposure to light can produce unwanted side reactions, but dim light is acceptable to use.

4. Terminate the reaction with 50 μ l of undiluted 2-ME and apply to a Sephadex G-50 column (30- to 60-ml bed volume) equilibrated in ammonium formate/azide solution containing 0.1% (w/v) SDS. Collect 1.0- to 1.5-ml fractions and count 2% to 5% of each eluted fraction in a scintillation counter to locate the glycoprotein eluting in the V_0 . Pool the appropriate fractions into a 10-ml round-bottomed polypropylene tube and lyophilize.
5. Redissolve the reduced and alkylated protein in 0.3 to 0.4 ml water. Add 8 vol of ice-cold 100% acetone and precipitate overnight at -20°C .
6. Centrifuge 15 min at $3000 \times g$, 4°C , and discard the acetone. Rinse the walls of the tube and the pellet with 1 ml of 85% ice-cold acetone, and centrifuge as before. Use a Pasteur pipet to carefully aspirate most of the acetone, leaving all precipitated material behind, and dry with a gentle stream of N_2 .

The pellet must be dry because any remaining acetone will interfere with the endopeptidase reaction.

7. Add 200 μ l of protease digestion buffer and a small stirbar. Add 10 μ l protease stock, rotate the tube gently to coat the liquid over the walls where the sample has been in contact, and stir gently at room temperature. Add another 10 μ l protease after 8 to 12 hr and digest for a total of 24 hr.

See commentary for choice of protease. For radiolabeled proteins, generally present in microgram quantities or less, the amount of protease (2 mg) used here should represent a considerable excess over the sample. If carrier protein has been added, or the mass of the sample is known, sufficient protease should be added to ensure at least a 1:1 protease:sample (w/w) ratio. For nonradiolabeled proteins, protease:sample ratios of 1:10 to 1:30 are employed.

8. Terminate the reaction by boiling 5 min. Use a large magnetic stirbar on the outside of the tube to pull the small stirbar halfway up the side. Rinse the small stirbar with 0.2 to 0.4 ml water, then remove it. Centrifuge the sample 10 min at $2000 \times g$, room temperature, and transfer the supernatant to a 1.5-ml microcentrifuge tube. Wash the large tube and pellet once with water, centrifuge as before, and combine supernatants.
9. Resuspend the pellet in 0.5 ml digestion buffer and count an aliquot ($\sim 5\%$) in a scintillation counter. Likewise, count an aliquot ($\sim 5\%$) of the supernatant. Calculate the percent release of radioactivity as soluble peptides by:

$$100 \times \text{cpm in supernatant} / (\text{cpm in supernatant} + \text{cpm in pellet})$$

If a significant amount of material remains insoluble, redigest with more of the same or another protease (e.g., α -chymotrypsin or V8 protease). Store samples frozen.

Soluble material will represent both digested sample (i.e., peptides and glycopeptides) and possibly undigested sample (e.g., if no appropriate sites of proteolysis are present or accessible). Likewise, insoluble material may represent undigested sample (insoluble because of denaturation and acetone precipitation) and perhaps glycopeptides and peptides as well. Some peptides and glycopeptides are insoluble in aqueous solutions at neutral pH and are only soluble in dilute acid (e.g., 25 mM sodium phosphate, pH 2.5), alkali (e.g., ammonium hydroxide), organic solvents (e.g., acetonitrile), or denaturants (e.g., SDS or guanidine). The choice of buffer used to resuspend the digested material in this step may

be altered depending on the next analytical step planned. For example, if the sample is to be analyzed by SDS-PAGE (UNIT 10.2), the digested material can be resuspended directly in sample buffer containing SDS. If reverse-phase liquid chromatography is planned, the sample can be resuspended in TFA or TFA containing 6M guanidine buffer. Thus, the demonstration that the endopeptidase added in step 7 has cleaved the sample depends not on the solubility of the sample but rather on direct biochemical evidence of proteolysis, such as a change in size as detected by SDS-PAGE, gel-filtration chromatography, or reverse-phase peptide mapping. The calculation of percent release of soluble radioactivity is essential to determine if insolubility and thus sample loss at this point is a problem.

REAGENTS AND SOLUTIONS

Ammonium formate/azide solution

1.58 g ammonium formate (25 mM)
0.2 g sodium azide (NaN_3 ; 0.2% w/v)
 H_2O to 1 liter
Store indefinitely at room temperature

Prepare the Sephacryl S-200 and Sephadex G-50 column equilibration buffers by adding 1.0 g sodium dodecyl sulfate (SDS; 0.1% w/v) to this solution.

Protease digestion buffers

Trypsin or α -chymotrypsin digestion buffers

0.79 g ammonium bicarbonate
 H_2O to 100 ml
Titrate with NH_4OH to pH 8.0. Filter through a 0.45- μm membrane and store at -20°C .

V8 protease digestion buffer

74.4 mg Na_2EDTA (2 mM)
0.39 g ammonium bicarbonate (50 mM) or 0.71 g sodium phosphate (50 mM)
 H_2O to 100 ml
Titrate with NH_4OH to pH 7.8
Store at -20°C

In the presence of ammonium acetate or bicarbonate, V8 protease cleaves on the carboxyl side of Asp residues; in the presence of phosphate, it cleaves after both Asp and Glu residues (Drapeau, 1977).

Protease stock solutions

For α -chymotrypsin: Dissolve 10 mg in 100 μl of 1 mM HCl. Store unused portion at 4°C for the second addition (step 8, alternate protocol). Do not use >1 day old.

For pronase: Dissolve 10 mg/ml pronase in Tris/ CaCl_2 and incubate 2 hr at 50°C to destroy contaminating glycosidases. Store at 4°C ; use within 48 hr.

For proteinase K: Resuspend 2 mg/ml proteinase K in 0.1 ml of 0.1 M Tris-Cl, pH 7.5, containing 2 mM calcium chloride (22 mg anhydrous CaCl_2 in 100 ml buffer). Store stock solution ≤ 2 weeks at 4°C or ≤ 1 month at -20°C without loss of activity.

Calcium reduces autolysis of the protease. Proteinase K is also available in solution.

For trypsin: Dissolve 10 mg TPCK-treated trypsin (Worthington) or DPCC-trypsin (Sigma) in 100 μl of 1 mM HCl. Store unused portion at 4°C for the second addition (step 8, alternate protocol). Do not use TPCK-treated trypsin if the second digestion is planned to be done with α -chymotrypsin. Do not use >1 day old.

For V8 protease (endoproteinase Glu-C or staphylococcal V8 protease): Make a 10 mg/ml stock in V8 protease digestion buffer. Store at 4°C . Do not use >1 day old.

Saturated KCl

45 g KCl
100 ml H₂O

Mix to saturation by stirring overnight, or by boiling for 5 min and allowing solution to cool to room temperature. Store indefinitely at room temperature.

Tris/CaCl₂ solution

0.11 g anhydrous calcium chloride (CaCl₂; 10 mM)
100 ml 0.1 M Tris·Cl, pH 7.5
Store indefinitely at room temperature

Tris/SDS solution

To 90 ml H₂O add:
6.05 g Tris·Cl (0.5 M)
2.0 g sodium dodecyl sulfate (SDS; 2% w/v)
Titrate with HCl to pH 8.6
Add H₂O to 100 ml
Store indefinitely at room temperature

COMMENTARY

Background Information

Pronase is widely utilized to generate glycopeptides with minimal peptide content, irrespective of the nature of the oligosaccharide-peptide linkage (Spiro, 1966). This is of obvious advantage when the nature of the glycosidic linkage is not known. Thus, the total oligosaccharide population from a sample can be released and characterized either functionally or structurally by serial lectin-affinity chromatography (UNIT 17.18) or endoglycosidase digestion (UNIT 17.13). Gel-filtration chromatography is limited by potential heterogeneity of the peptides remaining attached to the oligosaccharide. For the same reason, ion-exchange chromatography can not be used to determine the number of charged groups, such as sialic acid or sulfate, although similarly prepared samples can be compared with one another.

Pronase is a mixture of several proteases of differing specificities that are capable (in principle) of removing all amino acid residues except the linkage residue from a glycopeptide. However, in some applications, more than one amino acid residue is left attached. Although there are few published applications of proteinase K in the generation of glycopeptides, it offers several advantages over pronase. These include equally broad activity, wider pH range (pH 4 to 12), greater tolerance of SDS and urea, lack of divalent cation requirement, and inactivation by PMSF (Ebeling et al., 1974). Also, contaminating glycosidases and phosphatases do not appear to be a problem, eliminating the need for the predigestion step required for pro-

nase. Like pronase, proteinase K will digest a protein into small fragments, showing a preference for cutting after hydrophobic amino acid residues. The generation of oligosaccharides linked to single amino acids probably does not occur with great efficiency because proteinase K is not active against dipeptide substrates with unblocked amino groups.

Studies specifically directed at proteoglycan analyses often start with pronase digestion of [³H]glucosamine and ³⁵SO₄⁻²-labeled material. A useful overview of this approach, including steps on sample preparation, can be found in Britz and Hart (1983).

Glycopeptides prepared with pronase or proteinase K are not reliable substrates for PNGase F (UNIT 17.13), which requires a peptide linkage on both sides of the glycosylated Asn residue for activity. Glycopeptides derived from a site-specific endopeptidase are generally suitable substrates for PNGase F. Occasionally glycopeptides resistant to PNGase F may be encountered, if the endoprotease happens to cleave adjacent to the glycosylated Asn residue. Digestion with a different endoprotease should circumvent this problem.

Endopeptidases (Judd, 1990; Swiedler et al., 1983) that require a slightly alkaline pH are suitable for work with glycoproteins. Digestion buffers requiring an acidic pH and chemical cleavage techniques may degrade some oligosaccharide structures. Trypsin, α-chymotrypsin, and V8 protease are active between pH 7.5 to 8.5 and in 0.1% SDS, and represent a reasonable first choice. O-acetyl groups on

sialic acid, however, are stable under acidic but not alkaline conditions (UNIT 17.12).

Critical Parameters and Troubleshooting

The details of sample preparation will largely depend on the source of material, its purity, and the detection method. Total cellular extracts, containing both secreted and integral membrane proteins, require detergents for solubility, as may denatured proteins. In contrast, secreted and plasma glycoproteins do not require detergents. [³H]Mannose will label only N-linked oligosaccharides and GPI anchors (UNITS 17.4 & 17.8), and therefore proteoglycans, glycolipids, and O-linked chains will be mostly invisible. [³H]Glucosamine will label all of these structures, and they are all detected (although with variable sensitivities) by hexose-specific colorimetric assays (UNIT 17.9).

The steps required in sample preparation will depend on the sample source and the specific questions being asked. The following points should be considered:

1. Samples need to be purified away from low-molecular-weight glycopeptides, degradation products, and sugar precursors prior to analysis.

2. Glycolipids can cause problems. Alone or with nondenaturing detergents, they migrate at a high molecular weight by gel filtration (as micelles), but at a low molecular weight in the presence of excess SDS or denaturing solvents. On SDS-PAGE, they can migrate as small proteins (~10,000 MW). They may precipitate with acid, acetone, or ethanol (depending on the amount of salts and protein present), but can be difficult to extract from tissues with acetone. If glycolipids will be a problem, specific steps for their removal should be employed (Finne and Krusius, 1982; Britz and Hart, 1983).

3. The solubility of denatured glycoproteins can be a limiting factor in any of the steps. Occasionally, prolonged incubations at elevated temperatures or the addition of 2-mercaptoethanol to 20 mM (final) will solve problem.

Careful bookkeeping of recoveries at each step is important to detect unexpected losses. The use of polypropylene tubes and a carrier protein with radioactive samples may help decrease these losses.

Both protocols assume that digestion will yield glycopeptides containing single glycosylation sites. This is generally the case for N-linked oligosaccharides, as their sites are spaced far apart on the peptide backbone. O-linked glycosylation sites can be clustered in

regions of high serine (Ser) and/or threonine (Thr) content and be resistant to proteolysis. Heterogeneity in glycosylation (both in terms of the size of the oligosaccharide and whether a particular Ser/Thr residue is glycosylated) may cause a partial block in protease accessibility to certain regions of the peptide, resulting in incomplete and variable proteolysis and heterogeneity in the resulting glycopeptides.

Anticipated Results

Digestion of radiolabeled samples with pronase or proteinase K will yield molecules consisting of the oligosaccharide structure found at a given glycosylation site, plus one or a few amino acids. Such structures can be studied functionally (e.g., in blocking, binding, or adhesion assays) or structurally (UNITS 17.6, 17.13, 17.16, 17.18, & 17.19).

Digestion of purified glycoproteins with site-specific proteases will generate glycopeptides with a larger peptide portion attached. These glycopeptides can be fractionated by reversed-phase chromatography because the peptides are of a defined length (UNIT 10.12), used as substrates for endoglycosidases, or subjected to other biochemical analyses.

Time Considerations

Each individual step (e.g., enzyme digestion, gel filtration, and desalting) will require less than half a day. Lyophilization and acetone precipitation are overnight procedures. The procedure from starting sample to purified glycopeptides can easily be done in five calendar days.

Detection of Individual Glycosylation Sites on Glycoproteins

Many glycoproteins contain multiple sites of glycosylation. They may all have the same oligosaccharide–amino acid linkage (GlcNAc–Asn, GalNAc–Ser/Thr, GlcNAc–Ser/Thr, Xyl–Ser/Thr, or GPI anchor), or different types may be present. Although many of the methods in this unit are directed towards characterizing the total oligosaccharide population on a glycoprotein, for some investigations it may be necessary to determine (1) how many different sites exist, (2) the sugar–amino acid linkage of each site, and (3) the structural characteristics of the oligosaccharides found at the different sites.

Although such an in-depth study is not feasible for all sites on all glycoproteins, a general approach (described in the Basic Protocol) based on peptide mapping techniques has been employed successfully. Glycopeptides generated by endopeptidase digestion (UNIT 17.14A) are separated by reversed-phase chromatography (UNIT 10.12) using C₁₈ resin. Elution times are determined primarily by hydrophobic interactions between the peptide and the resin. However, the presence of hydrophilic, negatively charged oligosaccharides shortens retention times, causing glycopeptides to elute in considerably broader peaks than do peptides. By following the elution profile either radiochemically (for material prepared with radioactive sugar precursors or sulfate; UNIT 17.4) or colorimetrically (using hexose-specific assays; UNITS 17.9 & 17.16), the peaks corresponding to unique glycopeptides can be identified. With proper controls, the number of peaks will correspond to the number of different glycosylation sites. The eluted fractions are suitable for analysis by lectin chromatography (for N-linked oligosaccharides; UNIT 17.1), and the peptide sugar linkage can be defined either by endoglycosidase digestion (see Support Protocol and UNIT 17.13) or chemical cleavage (β -elimination; UNIT 17.15). Oligosaccharides freed from the peptide as described in the Support Protocol can be characterized by size or charge (UNIT 17.17), techniques not generally applicable with glycopeptides.

BASIC PROTOCOL

FRACTIONATION OF GLYCOPEPTIDES BY REVERSED-PHASE HPLC

A highly purified glycoprotein metabolically labeled with a radioactive sugar precursor (UNIT 17.4) is digested with a site-specific protease (UNIT 17.14A). The resulting glycopeptides, each of which contains a single or just a few glycosylation site(s), are fractionated by reversed-phase HPLC. The individual glycopeptide fractions are pooled separately and desalted in preparation for further analytical studies (see Support Protocol).

Materials

Highly purified glycoprotein metabolically labeled with a radioactive sugar precursor (UNIT 17.4)

HPLC buffers A and B (see recipe)

1 M Tris·Cl, pH 8.4 (APPENDIX 2)

Organic solvents: chloroform, DMSO, acetonitrile, and methanol

10 mM ammonium formate in water and in 50% acetonitrile (see recipe)

Ventilated oven, 40° to 45°C

Nitrogen tank

C₁₈ cartridge (e.g., Sep-Pak cartridge, Waters)

1-cc and glass 10-cc syringes

50-ml polypropylene tube

Additional reagents and equipment for peptide isolation by reversed-phase HPLC (UNIT 10.12)

Detection of Individual Glycosylation Sites on Glycoproteins

17.14.10

Contributed by Leland D. Powell

Current Protocols in Molecular Biology (1995) 17.14.10-17.14.15

1. Prepare glycopeptides from purified, labeled glycoprotein sample by reduction, alkylation, and specific endopeptidase digestion (*UNIT 17.14A*). Lyophilize the digested samples.

If the primary sequence of the protein is known, choose a protease or combination of proteases that will result in peptides having a unique glycosylation site. Even if one is only interested in N-linked sites and is working with material labeled with [2-³H]mannose, the potential of other glycosylation sites to interfere with proteolysis must be kept in mind.

If sequence data are not available, several proteases or combinations thereof may need to be compared.

2. Immediately prior to HPLC analysis, resuspend the lyophilized sample in 100 to 200 μ l HPLC buffer A, wetting the walls of the tube exposed to sample to ensure maximal recovery.
3. Microcentrifuge the sample 10 min at 10,000 \times g, 4°C. Using a pipet tip with 2 to 4 mm of the tip cut off, transfer solution and as much of the particulate material as possible to a 1.5-ml microcentrifuge tube on ice. Rinse out the digestion tube again and combine with the first wash. Keep the total volume to less than that of the injector sample loop.

As the HPLC buffers are acidic and sialic acid residues potentially acid labile, minimize the time of exposure of the sample to the buffer and keep it on ice until just before injecting onto the HPLC.

4. Microcentrifuge the sample material 10 min at 10,000 \times g, 4°C. Carefully remove the supernatant fluid, measure the radioactivity of an aliquot by scintillation counting, and inject the rest on the HPLC column. If minimal amounts of the sample are available, wash the insoluble material once in HPLC buffer A, spin as before, and pool the supernatant fluids.

Do not inject particulate material onto the HPLC column.

Depending on the complexity of the pattern and purity of the sample, anywhere from 5,000 to 50,000 cpm of sample are necessary for an adequate analysis.

5. Determine the amount of glycopeptide insoluble in HPLC buffer A (the “core”) by washing the insoluble particulate material once in water, resuspending it in water, and measuring the radioactivity of an aliquot by scintillation counting. If a significant percentage of the total sample remained insoluble after this first proteolytic digestion, redigest the material with the same protease (using a larger amount) or another protease.

If TPCK-treated trypsin was used, chymotrypsin digestion cannot follow. If digestion with chymotrypsin is anticipated, use the highest-grade trypsin available (not TPCK-treated).

6. Perform HPLC exactly as described in *UNIT 10.12*, except starting with the column equilibrated in HPLC buffer A and eluting the peptides with a linear gradient to 100% HPLC buffer B over 90 min, using a flow rate of 1 ml/min, and collecting 1-min fractions.

With experience, adjustments may need to be made in the shape of the gradient used to optimize the fractionation of individual glycopeptides.

7. Collect the effluent into tubes containing 0.2 to 0.5 ml of 1 M Tris·Cl, pH 8.4 (ensure final pH >5). As the run proceeds, remove tubes and mix to assure timely neutralization. Determine the elution profile by measuring the radioactivity of an aliquot of each fraction by liquid scintillation counting.

Analytical runs do not require neutralization. Instead, collect the fractions directly into scintillation vials and dry by placing them (in a cardboard or metal rack) overnight in a ventilated oven at 40° to 45°C, resuspending the salt pellet in 0.2 ml water followed by scintillation cocktail, and counting.

8. Pool the appropriate peaks and dry under a nitrogen stream.

Once most of the organic solvent is removed, the sample can be frozen, dried under vacuum, and stored at -20°C. Samples should be stable at least 1 year.

9. Prepare a C₁₈ cartridge by washing sequentially with chloroform, DMSO, acetonitrile, methanol, and water (10 ml per wash), and finally with 20 ml of 10 mM ammonium formate in water.
10. Resuspend the sample in 1 to 2 ml water and apply to the cartridge using a 1-cc syringe. Rinse the sample tube with 1 ml of 10 mM ammonium formate and apply to the cartridge. Repeat once more, then wash the cartridge with an additional 20 ml of 10 mM ammonium formate, saving all the aqueous washes.
11. Using a glass syringe, elute the cartridge with 6 ml of 10 mM ammonium formate/50% acetonitrile into a 50-ml polypropylene tube and dry under nitrogen as before. Store frozen.

The fractionated glycopeptides can now be analyzed by further digestion (see Support Protocol).

12. Follow the recovery of glycopeptide throughout by measuring the radioactivity of a fixed percentage (1% to 5%) of the initial sample, the aqueous washes, and the acetonitrile-eluted sample by scintillation counting, being careful to mix each sample before removing the aliquots for counting.

Most glycopeptides will be soluble in aqueous solutions in the absence of detergents or organic solvents. However, poor recoveries or unexpected losses when pipetting suggest that solubility may be limiting. To check for "sticky" glycoprotein, rinse tubes and pipet tips that have been exposed to samples with 0.1% SDS and measure the radioactivity of the wash by scintillation counting. Resuspension of the sample, after removal of the acetonitrile, in 0.1% NP-40, 10 mM β-octylglucoside, or another nondenaturing detergent may be necessary.

SUPPORT PROTOCOL

ENDOGLYCOSIDASE DIGESTION OF PURIFIED GLYCOPEPTIDES

Glycopeptides pooled and desalted from a reversed-phase chromatogram (see Basic Protocol) are digested with a specific endoglycosidase (UNIT 17.13A). Sensitivity to digestion is determined by rechromatographing over the same C₁₈ column.

Additional Materials (also see Basic Protocol)

Glycopeptide sample (see Basic Protocol, step 11)

HPLC apparatus with 500-μl injector sample loop

Additional reagents and equipment for endoglycosidase digestion (UNIT 17.13)

1. Resuspend glycopeptide sample in 10 mM ammonium formate in water and transfer to a microcentrifuge tube. Dry in a vacuum concentrator.
2. Add 10 to 50 ml of an appropriate buffer for digestion with PNGase F, endo F, or endo H (UNIT 17.13A) or endo-O-α-N-acetylgalactosaminidase (UNIT 17.17). Add the appropriate enzyme and allow digestion to proceed as specified in the respective unit.

Detergents can be omitted from the enzyme buffer formulations, as most glycopeptides are soluble in aqueous solutions.

3. Terminate the reaction by boiling 3 min.
4. Just prior to HPLC chromatography, dilute with 5 to 10 vol HPLC buffer A (but not exceeding the capacity of the injector loop), microcentrifuge 10 min at $10,000 \times g$, 4°C , and perform HPLC (see Basic Protocol, steps 6 and 7).

A 500- μl injector sample loop is required. Whenever possible, do not load over 400 μl in the loop, as the presence of a stationary phase along the walls of microbore tubing limits their usable volume.

5. Determine the elution time of the sample.

A decrease in elution time relative to that of the undigested glycopeptide indicates that its oligosaccharide was a substrate for the chosen endoglycosidase.

As in Basic Protocol step 7, glycopeptides are retained by the C_{18} column. After removal of the peptide, the free oligosaccharide will elute in the first few minutes of the column run (with or just after the breakthrough volume). Nondigested material will elute at the same time as seen initially in Basic Protocol step 7. The percentage release of the oligosaccharide can be calculated directly. These runs can be performed either analytically or preparatively.

An alternative to HPLC is to fractionate the digested oligosaccharide on a Sep-Pak C_{18} cartridge; glycopeptides will be retained and released oligosaccharides will elute in the water wash (unless the original glycopeptide elutes with water or very early in the HPLC gradient).

Nondigested glycopeptides may be recovered as in Basic Protocol steps 7 to 12. Released oligosaccharides may be desalted on a $1 \times 20\text{-cm}$ column of Sephadex G25 or Bio-Gel P-2, eluted in 10 mM ammonium formate for addition analyses.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

HPLC buffers A and B

2 \times HPLC buffer stock
28.1 g NaClO_4 (HPLC grade)
2.35 ml phosphoric acid
 H_2O to 1 liter

The pH will be 1.7 to 1.9 (do not adjust).

Buffer A: Mix 500 ml of 2 \times stock and 500 ml water.

Buffer B: Mix 500 ml of 2 \times stock and 500 ml HPLC-grade acetonitrile.

Use deionized, distilled water throughout. Filter and degas solvents.

Ammonium formate, 10 mM, in water and in 50% acetonitrile

Prepare 20 mM ammonium formate in water; do not adjust the pH, which will be ~ 6.7 to 6.9 . Dilute 1:1 (v/v) with water (to make 10 mM ammonium formate) or with acetonitrile (to make 10 mM ammonium formate/50% acetonitrile).

COMMENTARY

Background Information

Analysis of protein glycosylation on a site-by-site basis is not widely done, as it requires more time and material than analysis of total protein oligosaccharide. However, as more refined questions in glycobiology are addressed, such detailed structural information will increasingly be needed. Most published reports on this topic have focused on N-linked oligosaccharides, as these are in general more structurally complex than O-linked (mucin-like) oligosaccharides. Additionally, owing to their spacing on the peptide backbone, N-linked oligosaccharides are relatively easily separated into unique peptides by endopeptidase digestion and thus lend themselves to study by this technique. In principle, this approach could be used to identify a C-terminal peptide with a GPI anchor (released by PI-PLC digestion; *UNIT 17.8*). In contrast, O-linked mucin-type structures are frequently, although not always, clustered on the peptide backbone and cannot be separated by this approach. As [2-³H]mannose labels predominantly N-linked and GPI structures, it is often the radiolabel of choice for these analyses.

Two major questions are addressed in a site-by-site analysis.

1. How many sites are glycosylated? The consensus sequence for glycosylation of O-linked sites and proteoglycans is not clearly established. The sequence for N-linked glycosylation (Asn-X-Ser/Thr) is easily identified, yet not all possible acceptor sequences are glycosylated. Thus, direct biochemical methods must be employed to determine the number of glycosylation sites.

2. How do the structures found at the different sites compare? It is widely accepted that for a glycoprotein with a single glycosylation site, multiple different oligosaccharide structures will be found. The various factors responsible for this heterogeneity have been recently reviewed (Kobata and Takasaki, 1992). Moreover, site-specific microheterogeneity is also present: at the different glycosylation sites on a given glycoprotein, different populations of oligosaccharides will be found. These differences can only be assessed if the different sites are first separated and then analyzed independently.

Site-specific glycosylation patterns have been determined for several glycoproteins, including α 1-acid glycoprotein (Treueheit et al.,

1992), murine histocompatibility antigens (Swiedler et al., 1983), and macrophage adhesion molecules (Dahms et al., 1985).

Critical Parameters

Detailed studies such as those outlined in this unit require very clean glycoprotein preparations. Even if, based on SDS-PAGE and fluorographic analysis, a sample appears to be clean, with just low levels of radioactivity migrating diffusely outside of the band of interest, it is still possible for this low-level background to be concentrated by the C₁₈ column and thus turn into a significant contaminant. Thus, it may be useful to purify the radiolabeled sample by SDS-PAGE before proceeding with proteolysis and HPLC. Proteolysis of gel-purified samples can be performed directly in the acrylamide gel slices, on material blotted onto nitrocellulose, or after eluting from the gel slice.

The choice of radioactive precursor for labeling will depend on a variety of factors; see *UNIT 17.4* Commentary for discussion. As indicated in Background Information, [2-³H]mannose is often used for the analysis of N-linked oligosaccharides.

The potential presence of multiple glycosylation sites on each glycopeptide, either from clustered sites or from incomplete proteolysis, is a significant concern. This is most worrisome for O-linked sites, which frequently (but not always) appear in clusters on the peptide backbone.

Large proteins with multiple sites (e.g., >6) can be difficult to analyze owing to the complexity of the resulting chromatogram. An alternative strategy entails separating the protein into large glycopeptides by cleaving with CNBr or by limited proteolysis of nondenatured proteins, resulting in domains that can be fractionated by size, reversed-phase HPLC (*UNIT 10.12*), or ion-exchange chromatography (*UNIT 10.10*) and subsequently subjected to more extensive proteolysis.

Troubleshooting

The possibility of obtaining overly complex reversed-phase chromatograms is one of the most significant limitations of this methodology. Heterogeneously glycosylated peptides will migrate as broad clusters of peaks rather than the discrete peaks seen with peptides; incomplete proteolytic digestion can also result in increased peak complexity. If confronted with a complex or uninterpretable profile, in-

tially rule out incomplete digestion by repeating the process with more protease, longer digestion times, and/or combinations of proteases (trypsin and chymotrypsin). Alternatively, reduce the oligosaccharide heterogeneity (as with sialidase digestion) and repeat the C₁₈ analysis.

Recovery of glycopeptides at each step should be monitored closely to detect unexpected losses and/or solubility problems. As a rule, glycopeptides are very soluble in aqueous buffers, but large proteolytic fragments from denatured proteins may exhibit problematic solubility behavior.

Some large N-linked glycopeptides are resistant to cleavage by PNGase F. The basis of this inhibition has not yet been determined.

Anticipated Results

The C₁₈ chromatogram should contain discrete clusters of peaks representing single peptides with heterogeneous oligosaccharide side chains. Comparison of glycopeptides radiolabeled with different radioactive sugar precursors should indicate the type of oligosaccharide present (N-, O-, or GPI-linked structures). Comparison of the amount of material in each peak will indicate if some sites are underglycosylated. If the procedure is done on a preparative scale, the different glycopeptide fragments are suitable for more detailed structural analysis.

Time Considerations

Preparation of glycopeptides is described (including time considerations) in *UNIT 17.14A*.

Performing the HPLC analysis will require a day's effort. Endoglycosidase digestions require ~1 hr to set up, an overnight digestion, and 2 to 4 hr to analyze. Multiple sites will require proportionally more time.

β -Elimination for Release of O-Linked Glycosaminoglycans from Proteoglycans

UNIT 17.15A

**BASIC
PROTOCOL**

O-linked glycosaminoglycan (GAG) chains in proteoglycans are readily released from their core proteins by treatment with alkali at room temperature. This β -elimination is the same type of reaction as that for releasing O-linked oligosaccharides from their core proteins. Under the reaction conditions described here, N-linked oligosaccharides remain attached to the core protein, but any O-linked oligosaccharides will be released along with the GAG chains. The procedure can be used to isolate the free GAG chains, the free O-linked oligosaccharides, and the core protein (which will still have any N-linked oligosaccharides that were originally present).

Materials

Proteoglycan solution to be analyzed
Alkaline borohydride reagent (see recipe)
2 M HCl
1 M NaOH

Additional reagents and equipment for dialysis (*APPENDIX 3*)

1. Dialyze proteoglycan solution exhaustively against water to remove all buffer salts. Transfer to small test tube or centrifuge tube and dry in gentle stream of air or by lyophilization.
2. Dissolve dried proteoglycan sample in minimal volume of alkaline borohydride reagent and incubate 24 hr at room temperature.

The reaction tube should not be capped because evolution of hydrogen gas may result in pressure buildup.

3. Add 2 M HCl at room temperature, monitoring acidity with pH paper until the pH of the solution is 0 (to convert excess borohydride to hydrogen gas).
4. When evolution of hydrogen has ceased, add 1 M NaOH until pH is 6 to 8 as measured with pH paper.

For detailed discussion of further treatment of the products, see Commentary.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Alkaline borohydride reagent

Dissolve 22.4 mg sodium borohydride (NaBH_4) in 2 ml of 0.4 M NaOH just before use.

The resulting solution contains 0.3 M NaBH_4 .

Supplement 31

COMMENTARY

Background Information

Chondroitin sulfate, dermatan sulfate, and heparan sulfate are glycosaminoglycans (GAGs) occurring in cell-surface proteoglycans, in which they are O-linked to their core proteins through a xylosyl→serine linkage. Cartilage keratan sulfate is also O-linked to proteins in proteoglycans (through *N*-acetylgalactosamine, or GalNAc), whereas corneal keratan sulfate occurs as an N-linked polysaccharide. Hyaluronic acid, however, does not occur linked to a protein. Although heparin is synthesized in the mast cell as a proteoglycan, it is cleaved from its core protein in the final stages of synthesis and occurs, for the most part, as a mixture of free polysaccharide chains that are released from the cells only when the cells degranulate.

The basic protocol gives essentially complete release of O-linked GAGs, along with any O-linked oligosaccharides attached to the core protein. This is accomplished in 24 hr without removal of N-linked oligosaccharides (Mayo and Carlson, 1970; Seno and Sekizuka, 1978). The serine residues to which the GAGs are O-linked are converted to dehydroalanine residues, but the core protein is not cleaved. Thus, the molecular weight of both the core protein and the released GAG chains can be estimated by gel electrophoresis or gel filtration (Bienkowski and Conrad, 1985; Fedarko and Conrad, 1986). Sodium borohydride (NaBH_4) is included in the reaction mixture to prevent alkaline cleavage of the newly formed xylosyl or GalNAc reducing terminals from the rest of the GAG chain (known as the peeling reaction). If desired, tritiated sodium borohydride (NaB^3H_4) can be used in the reaction to label the reducing-terminal xylose of the GAG chains (as well as the reducing-terminal residues of the O-linked oligosaccharides, if present). If NaB^3H_4 is used, all reactions must be carried out in a designated radioactive fume hood because oxidation of NaB^3H_4 yields $^3\text{H}_2$ gas. N-linked oligosaccharides remain attached to the core protein under the mild reaction conditions described here.

This protocol is useful for demonstrating the proteoglycan nature of an unknown sample containing GAGs, as the molecular weight of proteoglycans will be reduced, but that of free GAG chains will not (Bienkowski and Conrad, 1984; Fedarko and Conrad, 1986). It is also a necessary step for characterizing the proteoglycan and its constituent core protein and GAG

chain(s) after the GAGs are separated from the smaller O-linked oligosaccharides that are also released in the reaction. If NaB^3H_4 is used in the reaction to label the reducing-terminal xylosyl, the molar ratio of total disaccharides in the GAG chains to [^3H]xylosyl can be used to estimate the size of the GAG chains. In addition, the linkage region can be recovered from an ^3H -labeled GAG chain by trimming away the main chain with lyases (*UNIT 17.14B*) or nitrous acid (for heparan sulfate), leaving the labeled linkage region. If the starting proteoglycan contains both O-linked GAGs and O-linked oligosaccharides, the products will consist of core protein, polysaccharides, and oligosaccharides. After the reaction the products can be separated from each other by gel filtration to resolve the oligosaccharides from the core protein and GAG chains. The polymeric fraction can then be resolved by DEAE-cellulose chromatography in a salt gradient to separate the core protein from the more highly charged GAG chains (Bienkowski and Conrad, 1984).

Critical Parameters

Although the reaction can be run at higher temperatures (35° to 50°C) to increase the reaction rate, loss of sulfate residues, cleavage of N-linked oligosaccharides (Ogata and Lloyd, 1982), or cleavage of the polypeptide chain may result. Under the milder conditions described here, these side-reactions appear to be minimal, and both the carbohydrate chains and the core proteins can be recovered intact. These conditions release both xylose-linked glycosaminoglycans (GAGs), GalNAc-linked keratan sulfate, and O-linked oligosaccharides, and there seems to be little difference in the rates of β -elimination of these different carbohydrates. No comparisons of these rates, however, have been reported. Sodium borohydride must be present to reduce the new reducing terminals of the carbohydrate chains as they are released from the core protein, so that alkaline degradation of the carbohydrate chains cannot occur. It is advisable to free the proteoglycan from oxyanions such as phosphate prior to reaction because these will catalytically destroy sodium borohydride (Conrad et al., 1973).

The procedure described in this unit does not include palladium chloride (PdCl_2), which has been used by other workers (Seno and Sekizuka, 1978) to reduce dehydroalanine to alanine as it is formed during the elimination.

PdCl_2 may be useful to stabilize the core protein when more harsh conditions are used for the β -elimination, and to allow amino acid analysis of the resulting core protein by observing the conversion of serine to alanine. It is not, however, necessary for the reaction, and the colloidal Pd formed in the reaction may interfere with recovery of the reaction products. It should be noted that the number of moles of serine converted to alanine is a reflection of the number of moles of carbohydrate chains originally O-linked to the core protein.

Anticipated Results

The β -elimination reaction is virtually stoichiometric. Assuming that the proteoglycan is pure before the reaction is run, the products of this reaction will be the intact core protein, the intact glycosaminoglycan chains, and any O-linked oligosaccharides that were also attached to the core protein.

Time Considerations

This reaction can be run ≥ 24 hr without any serious side reactions. Normally, a 24-hr incubation is sufficient to obtain complete cleavage of the proteoglycan.

β -Elimination for Release of O-GalNAc-Linked Oligosaccharides from Glycoproteins and Glycopeptides

This unit describes release of oligosaccharides that are attached to polypeptides through an *N*-acetylgalactosamine (GalNAc) linkage to the hydroxyl groups of serine or threonine. The β -elimination procedures described here can be used to recover the oligosaccharide chains (also called glycans) and/or identify the serine or threonine residues involved in the linkage.

β -elimination (Fig. 17.15.1) is usually carried out in the presence of a reducing agent such as sodium borohydride (NaBH_4) under alkaline conditions (Basic Protocol; see also UNIT 17.15A). The reducing agent immediately converts released oligosaccharides into reduced oligosaccharides, which is necessary because free oligosaccharides can be degraded under alkaline conditions by further β -elimination (peeling reaction; see Background Information). This method provides quantitative release of the oligosaccharides but does not yield intact polypeptides (see Critical Parameters).

An alternative method is to employ only alkaline conditions without a reducing agent (Alternate Protocol 1). The extent of conversion of serine and threonine residues in the polypeptide after oligosaccharide release indicates the number of such residues involved in linkage to O-glycans. However, this method does not allow quantitative recovery of the released glycans.

Another alternative is to use sodium sulfite (Na_2SO_3 ; see Alternate Protocol 2), which converts serines and threonines that are attached to O-glycans into cysteic acid and α -amino- β -sulfonylbutyric acid, respectively. This method, however, does not allow quantitative recovery of released glycans because further β -elimination of O-glycans (known as the peeling reaction; Fig. 17.15.2) cannot be prevented. The two products of the second alternate protocol (cysteic acid and α -amino- β -sulfonylbutyric acid) cannot be resolved using an amino acid analyzer, as they will elute in the same peak, so they must be quantitated using paper chromatography (Support Protocol).

β -elimination is not restricted to oligosaccharides attached through GalNAc but may also be used for release of oligosaccharides linked through other residues, including *N*-acetylglucosamine and xylose. For release of glycosaminoglycans linked through xylose, see UNIT 17.15A.

BASIC PROTOCOL

β -ELIMINATION IN THE PRESENCE OF SODIUM BOROHYDRIDE

β -elimination is achieved by reducing the sample under alkaline conditions using NaBH_4 (Carlson, 1968; Fukuda, 1989). Products are resolved by passing the reaction mixture through a Sephadex column. This procedure allows quantitative recovery of the O-glycans that are released.

Materials

- Glycopeptide or glycoprotein sample
- 1 M NaBH_4 /0.05 M NaOH (prepare fresh)
- 1 M acetic acid in methanol (prepare fresh, cool to room temperature before use)
- Nitrogen gas stream
- Methanol (HPLC grade)
- 0.2% orcinol/2 M H_2SO_4 (store at 4°C)
- 9-ml screw-cap conical glass test tubes

β -Elimination for Release of Oligosaccharides

17.15.4

Contributed by Minoru Fukuda

Current Protocols in Molecular Biology (1995) 17.15.4-17.15.9

Copyright © 2000 by John Wiley & Sons, Inc.

25° to 30°C and 45°C water baths
1 × 30–cm Sephadex G-15 column (Pharmacia Biotech) equilibrated in H₂O
Silica gel–coated thin-layer chromatography (TLC) plate
150° to 200°C oven

1. Mix 1 to 500 µg glycopeptide or glycoprotein sample and 5 to 100 µl of 1 M NaBH₄/0.05 M NaOH in a 9-ml screw-cap conical glass test tube.

The volume of solution used should be minimal but enough to dissolve the sample.

2. Close test tube loosely with screw cap and incubate 24 to 36 hr in a 45°C water bath.
3. Open test tube in a vented hood and slowly add 3 ml of 1 M acetic acid in methanol. Place tube in a 25° to 30°C water bath and dry contents in a nitrogen gas stream.
4. Repeat step 3.
5. Add 3 ml methanol, dry as in step 3, then dissolve in ~200 µl water. Either proceed to step 6 or freeze at –20°C until ready to continue.
6. Apply to a 1.0 × 30–cm Sephadex G-15 column and elute with water. Collect 1-ml fractions using a fraction collector.
7. Spot an aliquot from each fraction on a silica gel–coated TLC plate and allow to dry. Spray plate with orcinol/H₂SO₄ reagent and heat 4 min in a 150° to 200°C oven. Identify fractions containing carbohydrates by appearance of a brown color.

Alternatively, other methods for detection of carbohydrates can be used. It is also possible to calibrate the column before the experiment so that the fractions where the oligosaccharides will elute are known in advance. Those fractions are then collected and pooled.

8. Dry carbohydrate-containing fractions by evaporation and freeze at –20°C until ready for further analysis.

RAPID β-ELIMINATION IN DIMETHYL SULFOXIDE SOLUTION

This procedure facilitates release of O-glycans so that β-elimination can be completed in a short time. It yields oligosaccharides that are not reduced at the reducing terminals, making it possible to add various functional groups such as fluorescent probes.

Additional Materials (also see *Basic Protocol*)

Dimethyl sulfoxide (DMSO)
0.425 M KOH
100% ethanol
0.4 M HCl

1. Dissolve glycoproteins or glycopeptides in 500 µl to 1 ml of DMSO to a final concentration of 5 mg/ml in a 9-ml screw-cap conical glass test tube.
2. Add sufficient 0.425 M KOH and 100% ethanol to give a 0.17 M KOH concentration and a DMSO/water/ethanol ratio of 50:40:10 (v/v/v).

For example, to treat a sample dissolved in 1 ml DMSO, add 800 µl of 0.425 M KOH and 200 µl of 100% ethanol.

3. Incubate 1 hr at 45°C, then neutralize with 0.4 M HCl using pH paper as indicator.
4. Proceed with Basic Protocol, steps 6 to 8, or freeze sample at –20°C until ready to continue.

ALTERNATE PROTOCOL 1

Preparation and Analysis of Glyconjugates

17.15.5

β -ELIMINATION IN THE PRESENCE OF SODIUM SULFITE

This procedure is used (in combination with the Support Protocol) to determine the number of serine and threonine residues involved in O-glycan attachment, which are converted to cysteic acid and α -amino- β -sulfonylbutyric acid, respectively, by Na_2SO_3 .

Additional Materials (also see Basic Protocol)

0.5 M Na_2SO_3 /0.1 M NaOH (prepare fresh)

1 M and 6 M HCl

7-ml conical glass test tube

Vacuum evaporator, 40°C

110°C oven

1. In a 7-ml conical glass test tube, dissolve glycopeptides to a concentration of 1.0 mM or glycoprotein to a concentration of 8 mg/ml in 0.5 M Na_2SO_3 /0.1 M NaOH. Incubate 48 hr at 37°C.

Glycoprotein samples can first be treated by oxidation with performic acid to facilitate determination of serine and threonine residues (see Critical Parameters).

2. Terminate reaction by adjusting pH to ~3 with 1 M HCl. Evaporate to dryness in a 40°C vacuum evaporator.
3. Dissolve in 200 μ l of 6 M HCl and transfer to a test tube. Hydrolyze 24 hr in a 110°C oven with tube sealed.
4. Evaporate hydrolysis reaction mixture (total amino acid mixture) to dryness in a 40°C vacuum evaporator, then proceed to support protocol for quantitation of O-linked serine and threonine residues (see Support Protocol).

The reaction mixture may be dissolved in water and stored at -20°C until ready for analysis.

SEPARATION OF β -ELIMINATION PRODUCTS BY PAPER CHROMATOGRAPHY

In the second alternate protocol, the serine and threonine residues that are linked to O-glycans are converted, respectively, to cysteic acid and α -amino- β -sulfonylbutyric acid. Conventional amino acid analyzers combine the total yield of these two compounds in the same peak. This support protocol employs paper chromatography to separate cysteic acid and α -amino- β -sulfonylbutyric acid for the purpose of determining the number of O-linked serine and threonine residues in a glycoprotein or glycopeptide (Spiro, 1972).

Materials

Dried β -elimination reaction product (see Alternate Protocol 2)

0.05 M NaOH

Dowex AG-1-X8 resin (200 to 400 mesh; formate form; Bio-Rad)

5 mM pyridine formate buffer, pH 4.0 (see recipe)

4 M formic acid

4:1:5 (v/v/v) 1-butanol/acetic acid/water

0.5 \times 5-cm chromatography column

Whatman 3 MM chromatography paper

Paper chromatography chamber

1. Dissolve dried β -elimination product in water and titrate to pH 4.0 with 0.05 N NaOH.

2. Equilibrate Dowex AG-1-X8 resin by suspending in pyridine formate buffer, pH 4.0 for several hours. Pack 0.5 equilibrated resin into a 0.5 × 5-cm column and wash with pyridine formate buffer.
3. Apply sample from step 1 to column. Wash column with 10 ml pyridine formate buffer, then elute acidic amino acids with 5 vol of 4 M formic acid.
4. Dilute eluate with 2 ml water, then lyophilize to remove formic acid and pyridine formate.
5. Separate acidic amino acids in 4:1:5 (v/v/v) 1-butanol/acetic acid/water for 5 days using Whatman 3 MM paper.

The migration relative to aspartic acid (R_{Asp}) in this system is 0.42 for both cysteic acid and α -amino- β -sulfonylbutyric acid.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 5.

Pyridine formate buffer (5 mM), pH 4.0

Prepare 5 mM pyridine formate and adjust to pH 4.0 with 6 M formic acid. Store at room temperature in a sealed glass bottle.

COMMENTARY

Background Information

O-linked oligosaccharides, which are attached to polypeptides through the β -carbon-borne hydroxyl groups of serine or threonine, are abundant in mucin-type glycoproteins. O-linked oligosaccharides can be released from glycoproteins by β -elimination, after which the oligosaccharides can be fractionated and their structures determined. The method relies on β -elimination, shown in Figure 17.15.1, and takes advantage of the presence of the hydroxyl group of serine or threonine at the amino acid's β carbon. Under alkaline conditions, the peptide-group oxygen becomes negatively charged, and a double bond is formed between the peptide carbon and the α carbon. This double bond in turn migrates to make a double bond between the α and β carbons, and the β -carbon oxygen and linked oligosaccharide are released.

During this β -elimination, the released O-glycans are exposed to strong alkaline conditions. Such treatment tends to induce another β -elimination reaction within the released O-glycans (known as a peeling reaction). In particular, if the next sugar residue is attached to C-3 (also known as the β carbon) of *N*-acetylgalactosamine (GalNAc), this additional β -elimination occurs as in Fig. 17.15.2—i.e., presence of alkali introduces a double bond and this induces another β -elimination reaction in which the sugar chain is cleaved and released

from GalNAc. It is therefore necessary to introduce a reducing agent to prevent such further β -elimination. Thus, to prevent further degradation of released oligosaccharides and permit quantitative recovery of the released O-glycans, alkaline degradation is usually carried out in the presence of large amounts of the reducing agent NaBH₄ (Basic Protocol). β -elimination employing NaBH₄, however, does not provide quantitative recovery of alanine or α -aminobutyric acid (produced, respectively, from serine or threonine residues that are involved in O-glycan attachment).

Critical Parameters

The method employing 1 M NaBH₄ in 0.05 N NaOH (Basic Protocol) is most suitable for quantitative release of O-linked oligosaccharides from glycoproteins. This method is, however, not suitable for obtaining intact polypeptides because the sodium borohydride also cleaves peptide bonds and may also often lead to release of N-linked oligosaccharides (Ogata and Lloyd, 1982).

The need for a technique that kept the polypeptide portion as intact as possible led to the invention of the procedure using NaOH in DMSO (Alternate Protocol 1; Downs et al., 1973). However, this method is better suited for release of intact oligosaccharides than intact polypeptides, as cleavage of polypeptides cannot be completely avoided.

Figure 17.15.1 β -elimination for release of *O*-GalNAc-linked oligosaccharides from glycoproteins and glycopeptides. R represents oligosaccharide chain; broken lines represent remainder of polypeptide chain. The double bond formed can be reduced in the presence of sodium borohydride and palladium chloride (also see *UNIT 17.15A*).

Figure 17.15.2 Peeling reaction. R, remainder of GalNAc moiety; R', oligosaccharide chain.

The alkaline sodium sulfite method using 0.5 M Na₂SO₃ in 0.1 M NaOH (Alternate Protocol 2), is best suited for estimating the number of serine and threonine residues involved in O-glycan attachment. However, this method does not give a 100% yield of α -aminobutyric acid because the conversion of threonine to α -amino- β -sulfonylbutyric acid is usually ~75%. This method also does not prevent the peeling reaction involving the O-glycans that are released. It is useful only for determining the amount of serine and threonine involved in O-glycosylation. In order to determine accurately the amount of cysteic acid and α -aminobutyric acid produced in the alkaline sodium sulfite reaction, it is desirable to prepare a control in which the glycoproteins are oxidized with performic acid before β -elimination. This treatment cleaves disulfide cross-linkages in the peptide chain, converting, for example, cystine to cysteine residues. The difference between the amounts of cysteic acid and α -aminobutyric acid obtained before and after the alkaline sodium sulfite reaction represents the amount of serine and threonine involved in O-glycan attachment.

In order to release O-glycans without cleavage of the polypeptide moiety, other chemical methods must be employed—e.g., those employing trifluoromethanesulfonic acid or hydrogen fluoride (Sojar and Bahl, 1987). Attempts to characterize the oligosaccharides released using these methods have not yet been made.

Troubleshooting

Problems occur in β -elimination if the sample is treated with reducing agent under acidic conditions. This lowers the efficiency of the β -elimination reaction and also decreases the effective concentration of reducing agent. If it is not known whether or not the sample is acidic, it should be desalted before carrying out the reaction.

Anticipated Results

β -elimination using the three methods presented in this unit is virtually stoichiometric for release of O-linked oligosaccharides. Of these methods, only the Basic Protocol yields intact

oligosaccharides. Using Alternate Protocol 1, the released oligosaccharides may be degraded, although relatively intact polypeptides may be released. Using Alternate Protocol 2, it is possible to determine the number of serine and threonine residues involved in O-glycan attachment; however, here too the released oligosaccharides may be degraded. Neither of the alternate protocols is therefore suited for oligosaccharide analysis.

Time Considerations

The alkaline borohydride reaction (Basic Protocol and Alternate Protocol 1) can be run 24 to 48 hr without any serious side reactions. Including the time for chromatography, 48 hr is sufficient to obtain a mixture of O-linked oligosaccharides from glycopeptide or glycoprotein. Alternate Protocol 2 (β -elimination with sodium sulfite) will take an additional 24 hr.

Acid Hydrolysis for Release of Monosaccharides

The first step in obtaining a compositional analysis of a glycoconjugate is the release of the individual monosaccharide constituents. How these are released and processed depends on what methods are available for their analysis and identification. When the analysis is to be performed by high-performance liquid chromatography (HPLC), the monosaccharides must be released by acid hydrolysis of the glycoconjugate. Free glucose residues can then be separated using a pellicular-resin anion-exchange column and detected by pulsed amperometry (see UNIT 17.19A). When a gas-liquid chromatography (GLC) approach is to be taken in the analysis—and the glycoconjugate contains amino sugars and/or uronic acids—methanolysis, followed by trimethylsilylation of hydroxyl and carboxyl groups, is the method of choice (UNIT 17.19A). Often a prediction can be made of the type of monosaccharides present in a glycoconjugate by analogy with other glycoconjugates from closely related sources. If the sample is not expected to contain amino sugars or uronic acids—or if only neutral sugars must be measured—acid hydrolysis, followed by reduction and peracetylation (UNIT 17.19A), is preferred.

When an HPLC approach is taken, neutral sugars, hexosamines, and uronic acids can be directly analyzed after strong acid hydrolysis (see Basic Protocol 3). If sialic acids are involved, they must be analyzed separately by submitting an aliquot of the sample to mild acid conditions (see Basic Protocol 2), after which the sialic acids are purified and analyzed by HPLC without derivatization (see UNIT 17.19A) or after derivatization (see UNIT 17.18). In some cases, enzymatic release of sialic acids (see UNIT 17.12) may be chosen to preserve the *O*-acyl substitutions.

Mild acid hydrolysis to release fucosyl residues from glycoconjugates is described in Basic Protocol 1. Mild acid hydrolysis to release sialic acids from glycoconjugates, along with dialysis and column chromatography procedures to purify the sialic acids, are described in Basic Protocol 2. Strong acid hydrolysis to release all monosaccharides from glycoconjugates is described in Basic Protocol 3. Conditions required for successful release of all the different monosaccharides in a glycoconjugate vary to a great extent when hydrochloric or sulfuric acid is used for hydrolysis. However, the conditions required for hydrolysis using trifluoroacetic acid (TFA; see Basic Protocol 3) are considerably more uniform. Apart from sialic acids, which are known to be destroyed under strong acid conditions, all sugar residues—including fucose, hexosamines, and uronic acids—can be confidently determined after optimized treatment with TFA. TFA also has the advantage of being easily eliminated by evaporation without leaving a residue. For the release of sialic acids, however, mild acid hydrolysis using acetic acid (see Basic Protocol 2) and/or enzymatic release (UNIT 17.12) is recommended. The Alternate Protocol describes a harsher acid hydrolysis procedure for 4-*O*-acetylated sialic acids, which are more difficult to release.

A precise quantitative ratio of the different types of monosaccharides in a glycoconjugate is very difficult to obtain. This arises from the fact that all glycosidic bonds must be split while avoiding destruction of the liberated monosaccharides. Susceptibility to acid hydrolysis, as well as stability of the released unit, is different for each monosaccharide—e.g., pyranosides and furanosides hydrolyze at different rates; the presence of substituents affects the rate of hydrolysis; and α and β anomers have different rates of hydrolysis. In some cases, therefore, more than one set of conditions may be required to achieve a complete analysis (see Critical Parameters).

MILD ACID HYDROLYSIS FOR RELEASE OF FUCOSE RESIDUES

This protocol describes mild acid hydrolysis conditions appropriate for the release of terminal nonreducing fucose from a glycoconjugate. These conditions should release the fucose residues without releasing other monosaccharides (except sialic acids). Strong acid hydrolysis (see Basic Protocol 3) should be used to analyze for total monosaccharide composition, including fucose.

Materials

Glycoconjugate-containing sample to be analyzed

Standard: 1 $\mu\text{mol/ml}$ L-fucose (mol. wt. 164.2) in H_2O

0.05 M HCl prepared from constant-boiling HCl (sequencer-grade, Pierce)

99% methanol (anhydrous; e.g., Aldrich)

Small glass culture tubes or 3.5-ml glass vials with Teflon-lined screw caps

Heating block or oven

Nitrogen (N_2) or vacuum evaporation system: e.g., Speedvac (Savant), shaker-evaporator (Baxter Scientific), or lyophilizer

Dialysis tubing (500 MWCO)

Additional reagents and equipment for phenol–sulfuric acid assay for monosaccharides (UNIT 17.9), dialysis (APPENDIX 3C), and compositional analysis of monosaccharides from glycoproteins (UNIT 17.19A)

1. Estimate the total carbohydrate composition of the sample to be analyzed by the phenol–sulfuric acid assay (UNIT 17.9).
2. Using N_2 , a Speedvac system, or a lyophilizer, evaporate three aliquots of the sample to be analyzed (each containing ≥ 10 nmol of carbohydrate) to dryness in small glass culture tubes or 3.5-ml glass vials. Simultaneously evaporate to dryness three 10- μl aliquots of 1 $\mu\text{mol/ml}$ L-fucose for use as standards.

Use brand-new precleaned glass tubes or vials, or clean used ones by heating ≥ 3 hr at 50°C first in concentrated nitric acid, then in 6 M HCl—each time by placing them inside a glass container with a lid and filling the container with acid. Care should be taken to ensure that each tube or vial is completely filled with acid. Rinse the vials thoroughly with Milli-Q purified water or equivalent, then with ethanol, and finally dry in an oven. When < 5 μg total carbohydrates are to be analyzed, it is recommended that the glass vials be silanized by incubating 15 min at room temperature with 2% dichlorodimethylsilane in toluene. The solution is then decanted and the silanized vials rinsed successively with methanol and hot distilled water and allowed to dry.

3. Redissolve each dried sample and standard by adding 0.4 ml of 0.05 M HCl for up to 1 mg of material. Flush samples and standards with nitrogen and cap tubes.

When glass vials are used, nitrogen can be introduced through a needle inserted in the septum and evacuated through a second needle.

4. Using a 100°C heating block or oven, heat one sample and one standard 2 hr, another sample and standard 4 hr, and the remaining sample and standard 8 hr.

When a heating block is used, care must be taken that transfer of heat to the tubes is adequate. This can be achieved by filling the wells with pump oil or using a sand or metallic bath. Most of the tube or vial should be covered with the heating element to avoid distillation of the solvent in the upper part of the tube. When oil is used in the wells, excess oil must be wiped from the vials and the vials washed with hexane and dried before opening.

5. After each sample and standard has been heated for the required time period, evaporate the solution using a nitrogen or vacuum evaporation system. Wash residues twice with 99% methanol, then evaporate again.

CAUTION: This procedure should be carried out in a chemical fume hood.

If this is of interest, a defucosylated glycoconjugate can be prepared following this protocol. After acid hydrolysis under optimal conditions, neutralize reaction mixture with 0.05 M NaOH, dilute, and dialyze at 4°C against 20 vol water using 500-MWCO dialysis tubing to recover defucosylated glycoconjugate. Alternatively, the defucosylated product can be recovered by gel filtration chromatography (UNIT 10.9) on Bio-Gel P2 or Sephadex G-15, using water for elution.

6. Store the dried hydrolysates at -20°C until ready for compositional analysis. Results will indicate the best time for complete hydrolysis with minimal decomposition.

Procedures for compositional analysis are found in UNIT 17.19.

RELEASE OF SIALIC ACIDS (EXCLUDING 4-O-ACETYLATED SPECIES) BY MILD ACID HYDROLYSIS AND PURIFICATION OF THE PRODUCT

**BASIC
PROTOCOL 2**

This procedure allows the quantitative release of most types of known sialic acids, other than those acetylated at the 4 position, with minimal destruction. Subsequent handling of the sialic acid hydrolysate, including purification, is also designed to avoid migration or loss of *O*-acetyl groups. After purification, the mixtures of sialic acids can be analyzed by HPLC with (UNIT 17.18) or without derivatization (UNIT 17.19A). For release of sialic acids acetylated at the 4 position, see Alternate Protocol. This protocol can be used to prepare a mixture of sialic acids from commercially available glycoconjugate standards (e.g., bovine submaxillary mucin) for use as a standard in sialic acid analysis.

Materials

Glycoconjugate-containing sample to be analyzed
Sodium formate buffer, pH 5.5 (see recipe)
0.1 N H₂SO₄
10 M and 2 M acetic acid
1% butylated hydroxytoluene (BHT; Sigma) in ethanol
Dowex AG 50W-X2 ion-exchange resin (200 to 400 mesh, hydrogen form; Bio-Rad)
Dowex AG 3-X4A ion-exchange resin (100 to 200 mesh, hydroxyl form; Bio-Rad)
10 mM and 1 M formic acid (ACS certified), ice-cold
Dialysis tubing (1,000 and 12,000 MWCO; Spectrapor, Spectrum)
Heating block
5-ml glass culture tubes with Teflon-lined screw caps
0.5 × 10-cm glass chromatography columns *or* Pasteur pipets plugged with glass wool
20-ml glass test tubes
Lyophilizer or shaker-evaporator (Baxter Scientific)
Additional reagents and equipment for dialysis (APPENDIX 3C), de-*O*-acetylation of sialic acids and TBA assay (UNIT 17.18), and ion-exchange chromatography (UNIT 10.10)

Prepare sample and determine optimal conditions

1. Thoroughly homogenize sample to be analyzed and dialyze (APPENDIX 3C) overnight at 4°C against a 100-fold excess of sodium formate buffer, pH 5.5, using 12,000-

**Preparation and
Analysis of
Glycoconjugates**

17.16.3

MWCO tubing. Lyophilize dialysate and store frozen at -20°C until ready for analysis.

Dialysis is not necessary for relatively purified biological samples that do not contain low-molecular-weight contaminants. If not to be analyzed immediately, samples should be lyophilized and stored frozen at -20°C .

Crude biological samples may contain O-acetyl esterases, which could cause de-O-acetylation of sialic acids during the isolation procedure. These enzymes can be inactivated by adding a 100 mM stock solution of diisopropyl fluorophosphate (DFP) in isopropanol to a final concentration of 1 mM, then incubating 15 min on ice. As DFP is extremely toxic, safety recommendations should be studied carefully; gloves should be worn and the compound should be used in the fume hood.

2. Dissolve the sample in water. De-O-acetylate an aliquot of sample, release sialic acids with 0.1 N H_2SO_4 , and determine total sialic acid content by the TBA assay (UNIT 17.18).

Although the TBA assay uses harsher conditions for releasing the sialic acids and will cause some destruction, it is used here in a comparative fashion. Therefore, it is a valid indication of the recoveries from step to step.

3. Transfer three aliquots of the sample from step 1 (each containing ~ 10 nmol of sialic acids) to 5-ml glass culture tubes.
4. Add 10 M acetic acid to a final acetic acid concentration of 2 M, then add 1 vol of 1% BHT per 100 vol sample.

The BHT retards lipid peroxidation.

5. Using an 80°C heating block or oven, heat one aliquot 2 hr, another aliquot 4 hr, and the remaining aliquot 5 hr.

When a heating block is used, care must be taken that the transfer of heat to the tubes is adequate. See Basic Protocol 1, step 4 annotation, for proper technique.

6. After each sample has been heated for the required time period, lyophilize and de-O-acetylate, then determine total free sialic acid by the TBA assay (UNIT 17.18). Compare the numbers obtained to determine the time required for maximal release of sialic acids.

Release and purify sialic acids

7. In a 5-ml glass culture tube add 2 M acetic acid to the lyophilized sample from step 1 (0.4 ml for up to 1 mg) and incubate at 80°C for the time determined in steps 5 and 6. Cool to room temperature.
8. Transfer reaction mixture into 1000-MWCO dialysis tubing, then wash the test tube twice with water, each time transferring the washings into the dialysis tubing. Dialyze (APPENDIX 3C) overnight at 4°C against 10 vol water and retain the dialysate (solution outside the tubing).

An MWCO of 1000 is sufficient to allow the passage of free sialic acids. Bigger pores may allow more contamination by permitting bigger molecules to dialyze out.

When total volumes are small (100 μl to 1 ml), the dialysis tubing can be placed inside a test tube. In this case, it must be closed with knots instead of plastic clamps.

Assuming that equilibrium is achieved, a 10% loss (sialic acids remaining in the tubing) should be expected when dialyzing against 10 vol water. The recovery can be improved by repeating the dialysis.

- Using a 0.5 × 10-cm chromatography column or Pasteur pipet plugged with glass wool, prepare a 1-ml column of Dowex AG 50W-X2 ion-exchange resin (see UNIT 10.10) in a cold room or cold box, using ice-cold water to suspend the resin and wash the column.

The resin must be extensively washed with ice-cold water before use. All chromatography steps must be performed at 4°C and eluants must be ice cold.

- Load the dialysate from step 8 directly to the column. Wash column with 6 ml cold water and collect eluant in a 15-ml glass test tube on ice.

For large preparations, every step can be scaled up, but it may be necessary to lyophilize the dialysate and dissolve it in a small volume of water before loading it onto the column. The content of the dialysis tubing (the retentate, containing the desialylated glycoconjugates under study) can also be frozen, lyophilized, and reserved for other analyses.

- Check pH of eluant with pH paper. If >3, go to step 12. If <3, add 10 mM sodium formate buffer, pH 5.5, until pH is >3.

- Using a 0.5 × 10-cm chromatography column or Pasteur pipet plugged with glass wool, prepare a 1-ml column of Dowex 3-X4A ion-exchange resin (hydroxyl form). Convert resin to formate form by equilibrating in 3 vol of 1 M formic acid. Let column stand in contact with formic acid for 15 min, then wash with 10 mM sodium formate (pH 5.5) until effluent pH is stable at 5.5 (see UNIT 10.10).

Large batches of resin can be prepared and stored at 4°C. Always take into consideration the capacity of the resin and calculate the volume of the column required to bind the total sialic acids present in the sample as determined by the TBA assay in step 2.

- Load sample from step 11 on column. Wash column immediately with 7 ml ice-cold 10 mM formic acid, and discard washings.

- Elute sialic acids with 10 ml ice-cold 1 M formic acid. Collect eluant on ice in a 20-ml glass test tube, then evaporate it to dryness by lyophilization or in a shaker-evaporator with the temperature of the water bath maintained at <37°C. Store at -20°C until analysis.

The purified mixture of sialic acids can be analyzed by HPLC (UNIT 17.19A) or derivatized and analyzed by reversed-phase HPLC with fluorometric detection (UNIT 17.18).

RELEASE AND PURIFICATION OF 4-O-ACETYLATED SIALIC ACIDS

A harsher acid hydrolysis procedure is used to liberate 4-O-acetylated sialic acids, which are resistant to release by the method indicated in Basic Protocol 2.

Additional Materials (also see Basic Protocol 2)

23.4 M (concentrated) formic acid
Heating block

- Prepare the sample and determine total sialic acid content in an aliquot of the material by TBA assay (see Basic Protocol 2, steps 1 and 2).
- Adjust dialyzed sample to pH 2.0 by dropwise addition of concentrated formic acid. Heat at 70°C for 1 hr. Cool to room temperature, and centrifuge at room temperature using a tabletop centrifuge to separate supernatant and pellet. Separate supernatant by aspiration and retain both supernatant and pellet.

When a heating block is used, care must be taken that the transfer of heat to the tubes is adequate. See Basic Protocol 2 step 4 annotation for proper technique.

ALTERNATE PROTOCOL

Preparation and Analysis of Glycoconjugates

17.16.5

3. Dialyze supernatant overnight at 4°C against 10 vol water using 1000-MWCO tubing, then lyophilize the solution outside the tubing. Repeat the dialysis twice again and pool the recovered material.

When total volumes are small (100 µl to 1 ml), the dialysis tubing can be placed inside a test tube. In this case, it must be closed with knots instead of plastic clamps.

4. Treat the pellet obtained in step 2, resuspended in a similar volume of water, twice more at pH 2 with heating as described in step 2, centrifuging and dialyzing the supernatants each time as described in step 3 to recover the hydrolysis products.
5. Pool the lyophilized dialysates and purify the mixture of sialic acids by ion-exchange chromatography (see Basic Protocol 2, steps 9 to 14). The annotation to Basic Protocol 2, step 14 describes options for analysis.

STRONG ACID HYDROLYSIS FOR QUANTITATIVE RELEASE OF HEXOSES, PENTOSES, HEXOSAMINES, AND URONIC ACIDS FROM GLYCOCONJUGATES

This protocol describes several sets of conditions for the acid hydrolysis of monosaccharides from glycoconjugates. When no data is available from previous experiments regarding optimal conditions, it is recommended that one try more than one set of conditions to determine which ones are optimal. It is also important to prove the reproducibility of the method under the conditions chosen. The mixtures of free monosaccharides obtained by acid hydrolysis can be directly analyzed by high-pH anion-exchange chromatography with pulsed amperometric detection (HPAE-PAD) or by derivatization followed by GLC (see *UNIT 17.19A* for both techniques).

Materials

- Glycoconjugate-containing sample to be analyzed
- Internal standard (i.e., a monosaccharide that does not occur naturally in the sample)
- Standard mixture (see recipe)
- 2 M and 4 M trifluoroacetic acid prepared from concentrated TFA (HPLC/spectra grade sequanal quality, Pierce)
- 99% methanol (anhydrous; e.g., Aldrich)
- Heating block or oven
- Small glass culture tubes or 3.5-ml glass vials with Teflon-lined screw caps
- Nitrogen (N₂) or vacuum evaporation system: e.g., Speedvac (Savant) or shaker-evaporator (Baxter Scientific)
- Additional reagents and equipment for phenol–sulfuric acid assay for monosaccharides (*UNIT 17.9*) and compositional analysis of monosaccharides released from glycoproteins (*UNIT 17.19A*)

1. If sufficient material is available, estimate the total carbohydrate content of the sample to be analyzed by the phenol–sulfuric acid assay (*UNIT 17.9*).

Analysis can be done without having this information when sample is precious, as the analytical tools used for the compositional analysis of acid hydrolysates (i.e., HPAEC-PAD, GLC) are far more sensitive than the colorimetric assay.

2. Using N₂, a Speedvac system, or a lyophilizer, evaporate three aliquots of the sample to be analyzed (each containing 5 to 50 µg carbohydrate) to dryness in small glass tubes or 3.5-ml glass vials. If the planned compositional analysis will be done by GLC, add 1 to 10 µg of internal standard to the sample before evaporating it.

Rhamnitol and arabinitol are good choices as internal standards for analysis of animal glycoconjugates, and inositol for plant polysaccharides.

3. Prepare (as in step 2) three aliquots of the standard mixture appropriate for the monosaccharides to be determined and the analytical method to be used, and three blanks to detect possible contamination. For GLC analysis, also add the internal standard.

The time involved in HPLC or GPC analysis of each sample is quite long (see UNIT 17.19A); therefore, preparation of a mixture of the appropriate standards in equimolar amounts helps reduce the analysis time. On the other hand, when identification of one particular component is doubtful, coinjection of one aliquot of the sample with one aliquot of the suspected standard into the GLC or HPLC column gives a definitive answer on the presence of that particular monosaccharide. In such cases, processing each monosaccharide standard individually in parallel can be helpful.

An appropriate blank is a material that has been processed exactly as the sample was (e.g., a pool of fractions from a chromatography step that showed only background response to the method used for monitoring). Blanks are especially useful when very small amounts of material are processed, as in such cases the limit of sensitivity will be determined by the accumulated contaminants (e.g., from Sephadex columns or dirty glassware).

4. Dissolve the three evaporated aliquots of each sample, standard, and blank in 100 to 500 μ l of 2 M TFA. Flush with N_2 and cap the tubes.
5. Using a 100°C heating block or oven, heat one sample, one standard, and one blank 3 hr; another sample, standard, and blank 4 hr; and the remaining sample, standard, and blank 6 hr.

This time course will determine the best conditions for maximum recovery with minimum destruction. When insufficient material is available for a time-course experiment, use 3 hr of hydrolysis for glycoproteins, glycopeptides, or free oligosaccharides of the N- and/or O-linked type that contain hexosamines and neutral monosaccharides. Use 6 hr of hydrolysis when the sample is suspected to contain glycosyluronic acids (e.g., proteoglycans or glycosaminoglycan chains).

When a heating block is used, care must be taken that the transfer of heat to the tubes is adequate. See Basic Protocol 1 step 4 annotation for proper technique.

6. After heating, evaporate solution in each tube using a nitrogen or vacuum evaporation system. Wash residues twice with 99% methanol, then evaporate again.

Store the dry hydrolysates at -20°C until ready for compositional analysis.

7. Analyze the hydrolysate by HPAE-PAD or derivatize and analyze by GLC (see UNIT 17.19A).

8. Compare the recovery of each monosaccharide obtained using the different hydrolysis times and decide upon the most suitable hydrolysis time for the sample under study. Repeat the analysis using such conditions and check for reproducibility.

If quantitation remains uncertain, hydrolysis can be repeated with the addition of a known amount of an internal standard, even when HPLC is used for the analysis. Because the constituents will be known at this point, any noninterfering monosaccharide or alditol can be used as internal standard. The choice will depend on the method used for analysis. When the analysis is done by HPAE-PAD, monosaccharide alditols cannot be used as internal standards because they are not retained by the Carbo-Pak PA-1 column used for monosaccharide separation. In this case, 2-deoxyrhamnose or 2-deoxyglucose are appropriate as internal standards. Prepare an aqueous solution of the standard and add a known amount to the sample, evaporating them together before dissolving in the acid at step 4. The standard must be present in an amount comparable to that of the major constituents of the sample.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Sodium formate buffer, pH 5.5

Weigh 68 mg sodium formate, dissolve in water, then bring volume to 1 liter. Adjust to pH 5.5 by adding 1 M formic acid dropwise.

Standard mixture

For GLC of alditol acetates: Prepare an equimolar mixture of the following:

D-(+)-glucose (anhydrous, mixed anomers; Sigma)

D-(+)-galactose (crystalline; Sigma)

D-(+)-mannose (crystalline; Sigma)

D-(+)-xylose (99%; Sigma)

For HPAE-PAD: To the above mixture (without xylose), add equimolar amounts of:

N-acetyl-D-galactosamine (Sigma)

N-acetyl-D-glucosamine (Sigma)

D-glucuronolactone (Sigma; when uronic acid is expected)

If xylose is expected, include it in the mixture, but be careful to use the right conditions for HPAEC-PAD (UNIT 17.19A).

COMMENTARY

Background Information

Fucose release

Fucosyl residues are typically in nonreducing terminal positions and are therefore susceptible to acid hydrolysis under relatively mild conditions. However, specific sites of attachment can increase the stability of the glycosidic bond (e.g., a positively charged amino group produced by de-*N*-acetylation of an *N*-acetylhexosamine residue will lead to a stable glycosidic linkage at the 3 position). Thus, it is necessary to determine for each specific glycoconjugate the conditions required for complete liberation with minimal destruction. The parameters to be varied are the type of acid, concentration of acid, and time and temperature used for the hydrolysis. The set of conditions suggested in Basic Protocol 1 are the best starting point.

Most of the problems encountered when trying to determine the best hydrolysis conditions for releasing fucose residues from a given glycoconjugate have been reviewed by Gottschalk (1972). Typical conditions are 0.5 M hydrochloric acid at 100°C for 16 hr (Schrager and Oates, 1968), although 15 min at 100°C in 1 M HCl are enough to release fucose from orosomucoid (Gottschalk, 1972), and 0.6 N sulfuric acid at 100°C for 1 hr is required to release all the fucose from total serum proteins (Gyorky and Houck, 1965).

Sialic acid release

More than 25 different kinds of modified sialic acids have now been reported to be found in nature. Most arise from substitution of the parent molecule with a variety of different groups. These modifications have been shown to affect a wide spectrum of biological phenomena. Many studies of sialic acids have failed to recognize the complexity of this family of sugars, because conventional methods for analyzing glycoconjugates—e.g., methanolysis, hydrazinolysis, methylation analysis, and β -elimination—result in the destruction of *O*-substituted species, especially *O*-acetyl esters.

The classical method for releasing sialic acids from glycoconjugates (incubation with 0.1 N H₂SO₄ for 1 hr at 80°C) results in extensive destruction of *O*-acetyl groups (Schauer, 1978). In addition, the presence of *O*-acetyl groups makes the sialic acid molecule partially or completely resistant to release by all available bacterial and viral neuraminidases (Schauer, 1978, 1982; Schauer and Corfield, 1982). The use of milder conditions (incubation with 0.5 M formic acid for 1 hr at 80°C) allowed the release and identification of many previously undetected *O*-acetylated sialic acids (Schauer 1978, 1982). However, even under these conditions quantitative analysis is not possible as a result of significant destruction and incomplete release of *O*-acetylated species using formic acid (pH 2.1) for acid hydrolysis (Schauer, 1978; Varki and Kornfeld, 1980;

Varki and Diaz, 1983). Prolonged hydrolysis in 2 M acetic acid (pH 2.4 to 2.5) at 80°C was found to achieve maximal release of *O*-acetylated sialic acids with minimal loss of *O*-acetyl groups (Varki and Diaz, 1983). These latter conditions have been successfully used to release and purify labile substituted sialic acids from different biological sources (Manzi et al., 1990). Hydrolysis times vary for different glycoconjugates. When sialic acids are acetylated at the 4 position, complete hydrolysis is difficult to achieve, but once released, the acetyl group becomes very labile, producing a 4,7-anhydro species.

Further complexity arises from the migration of *O*-acetyl groups from the 7 or 8 positions to the thermodynamically more stable 9 position of the sialic acid exocyclic side chain. This migration occurs rapidly, with $t_{1/2}$ ranging from minutes to hours, depending on the pH and temperature (Kamerling and Vliegthart, 1989; Varki and Diaz, 1983). Migration is minimal between pH 3 and 5.

A recent review (Varki, 1992) covers the diversity in the sialic acids, including the different problems encountered during their analysis and the methods available to overcome these problems.

Strong acid hydrolysis with TFA

Hydrolysis of glycosidic linkages involving hexoses requires more vigorous conditions than the ones used for fucose or sialic acids. Typically, hydrochloric (1 or 2 M, 100°C, 1 to 6 hr), sulfuric (0.1 to 2 N, 100°C, 4 to 12 hr), or trifluoroacetic acid (2 M, 121°C, 1 to 2 hr) have been used for this purpose, under conditions that vary depending on the substrate. Provided that the most labile species—e.g., sialic acids—are quantitated separately, the most severe problem encountered when determining the monosaccharide composition is the incomplete release of 2-acetamido sugars and glycosyluronic acids. The presence of these sugars can often be predicted based on the origin of the glycoprotein under study. In the case of acetamido sugars, if *N*-deacetylation occurs first, the stability of the glycosidic linkage is increased. Therefore, the conditions must be such that hydrolysis of the glycosidic linkage is substantially faster than the de-*N*-acetylation reaction. The glycosidic linkage of glycosyluronic acids is particularly resistant to acid hydrolysis, and further inhibition of their complete release occurs when the adjacent sugar in the chain is an *N*-sulfated or *N*-acetylated hexosamine. This problem is routinely encoun-

tered in glycosaminoglycan chains, where quantitative release requires a previous reduction of the carboxylic acid. On the other hand, liberated glycosyluronic acids are very susceptible to degradation, particularly by decarboxylation. Therefore, analysis of glycosaminoglycan chains is better achieved using enzymes (see UNIT 17.19B).

When enough material is available, recovery and reproducibility can be assessed under several different sets of conditions. In many cases this is not possible, and incubation with 2 M TFA for 3 hr at 100°C is recommended under such circumstances.

A review of the different conditions used for the release of monosaccharides from glycoproteins, including a detailed analysis of the mechanisms of acid hydrolysis of glycosides, is provided by Gottschalk (1972). In most cases, hydrolysis with TFA will produce as good a recovery of fucose as hydrolysis with 0.5 M HCl, although in the former case other sugars are also released. Where the sample is incubated with 2 M TFA at 121°C, 25% of the fucose decomposes after 6 hr. However, because only 1 hr is required for complete release, this rate of decomposition is tolerable (Albersheim et al., 1967). Where the sample is heated at 100°C, 98% recovery of fucose is achieved even after 6 hr (Biermann, 1988). Usually, estimation of the content of hexosamines in glycoproteins has been based on HCl hydrolysis at different concentrations (ranging from 2 M to 6 M) at temperatures close to 100°C for varying periods of time (ranging from 1 to 24 hr; Gottschalk, 1972). Also, incubation with trifluoroacetic acid (0.5 M, 100°C, 19 hr; 4 M, 125°C, 1 hr; or 4 M, 100°C, 4 hr) has been shown to give good results (Keene et al., 1983; Neeser and Schweizer, 1984). The variety of methods clearly indicates that the effectiveness of the hydrolysis greatly depends on the glycoconjugate—e.g., the type of linkage, the type of aglycone (noncarbohydrate portion), and the presence of substituents such as *N*-acetyl groups. Mannosamine is less acid-stable than glucosamine and galactosamine (Ludowieg and Benmaman, 1967). Analysis of the rates of decomposition of monosaccharides in the presence of 2 M (10 mg/ml) TFA—by continuing hydrolysis of polysaccharides after most of the monosaccharides have been liberated—have indicated that after 6 hr at 121°C, >50% of the xylose and arabinose and >25% of the galactose, rhamnose, and fucose are decomposed (Albersheim et al., 1967). However, as most of the monosaccharides are liberated within 1 hr,

these rates of decomposition are tolerable. Hydrolysis of urinary glycoconjugates with 2 M TFA for up to 15 hr at 100°C indicated that the maximum yield of aldoses and uronic acids is obtained after 6 hr. The recovery of the individual monosaccharides added at the beginning of the treatment was >93% in all cases, including that of glucuronic acid (Honda et al., 1981). A comparison between the action of different acids on each type of carbohydrate-containing molecule was done by Biermann (1988). Conditions used for acid hydrolysis of glycoconjugates before GLC analysis have also been reviewed by Kamerling and Vliegthart (1989).

Critical Parameters

Fucose release. Use of high-quality acids and highly purified deionized water is recommended. In the case of glycoproteins, destruction arising from the interaction between liberated sugars and amino acids can be minimized by using a low concentration of glycoprotein to perform the hydrolysis (<1 mg/ml) and excluding oxygen (by displacing it with dry nitrogen or performing the hydrolysis in a tube sealed under vacuum).

Sialic acid release. All the parameters involved in the protocol (e.g., temperature, pH, and concentration) must be carefully controlled. Because pH values outside the range of 3 to 7 should be avoided, strongly basic anion-exchange resins (e.g., Dowex 1 or 2) should not be used. Samples must be fresh, and must be processed and analyzed immediately. It is also critical that purified samples be kept dry at -70° or -80°C while stored. However, even storage at these temperatures for extended periods of time can result in migration or loss of *O*-acetyl groups. It should be pointed out that optimal methods for the release and purification of the rare forms of sialic acids (e.g., *O*-methylated, *O*-sulfated, or multiply modified) have not been adequately worked out.

Strong acid hydrolysis with TFA. High-quality acids must be used and highly purified deionized water must be used to dilute the acid, because trace iron can destroy hexosamines. Degradation is also avoided by excluding oxygen (usually by flushing with nitrogen, although it is also possible to work under vacuum). Working at a low concentration of glycoconjugate (<1 mg/ml) reduces the destruction of sugars. A competing sugar not present in the glycoprotein can also be added to reduce destruction (ribose has been used for this purpose). It must be kept in mind that—

even when treating the standards in parallel—they may not reflect the decomposition suffered by the glycosidically bound monosaccharides in the sample, because in the latter case they spend less time as free glycoses. Therefore, a method that yields less decomposition is always preferred to a correction factor worked up on the basis of monosaccharide standards.

Anticipated Results

Fucose release. Basic Protocol 1 will cleave the glycosidic linkages of all terminal nonreducing fucosyl residues. Once free, the fucosyl residues will remain intact, giving a reasonable estimation of the amount of fucose in the glycoconjugate (UNIT 17.19). Complete defucosylation of a sample can be determined by analysis of the amount of fucose in the hydrolysate at different time points. However, the use of TFA (strong acid hydrolysis; Basic Protocol 3) permits an accurate estimation of fucose together with the rest of the sugars. Therefore, strong acid hydrolysis is recommended when an analysis of the total glycosyl composition is required. The most valuable use of Basic Protocol 1 is therefore the defucosylation of glycoconjugates for further analysis.

Sialic acid release. The conditions for release and purification of sialic acids used in these protocols ensure maximum release of most modified sialic acids (with the exemption of methylated or sulfated species), prevent migration of *O*-acetyl groups from the 7 position to the 9 position, and prevent de-*O*-acylation. Therefore, careful use of the suggested protocols will result in the most accurate possible quantitation of the different sialic acid species present in a glycoconjugate. Sialic acids obtained by these procedures can be analyzed by HPAEC-PAD (UNIT 17.19A) or other HPLC techniques with (UNIT 17.18) or without derivatization (UNIT 17.19A). Therefore, an accurate quantitation also depends on the careful use of the final method of analysis. Basic Protocol 2 can be used to obtain a mixture of Neu5Ac, Neu5Gc, and of some of the mono-, di-, and tri-*O*-acetylated derivatives of these sialic acids from commercially available standards such as bovine submaxillary mucin. A mixture of standards will be very useful when analyzing the presence of sialic acid modifications in a glycoconjugate.

Strong acid hydrolysis with TFA. Careful application of Basic Protocol 3 will result in hydrolysis of the glycosidic linkages of hexoses, hexosamines, and uronic acids in glycoconjugates with minimal destruction.

Time Considerations

Fucose release. Because an 8-hr reaction is involved, it is better to prepare the samples the previous day. All hydrolysis and recovery procedures can be completed during the second day. Any additional time involved depends on the method used for analysis.

Sialic acids. After the time course to determine the time required for complete hydrolysis, release and purification require 2 days. Analysis must then be done immediately.

Strong acid hydrolysis with TFA. Preparation, hydrolysis, and drying of the hydrolysate should take ≤ 8 hr. The time required for analysis (by HPLC or GLC) is indicated in UNIT 17.19A.

Enzymatic Release of Oligosaccharides from Glycolipids

UNIT 17.17A

USE OF ENDOGLYCOCERAMIDASE FOR SELECTIVE CLEAVAGE OF GLYCOLIPIDS

BASIC
PROTOCOL

Selective cleavage of the oligosaccharide moiety of glycolipids for further structural analysis can be achieved by means of endoglycoceramidase (EGCase), an enzyme specific for the linkages between oligosaccharide and ceramide residues in glycolipids. The method can be used for analysis of glycolipids present in macroscopic amounts or for glycolipids that have been radiolabeled in their carbohydrate moiety. A variety of different methods can be used for analysis of the released oligosaccharides.

Materials

Sample to be analyzed—neutral glycolipids (UNIT 17.2), gangliosides (UNIT 17.17B), or desialylated gangliosides (see UNIT 17.12)—in organic solvent

1 mg/ml disialoganglioside-G_{D1a} (Sigma) in 2:1 (v/v) chloroform/methanol

0.5% (w/v) sodium taurocholate in 0.05 M sodium acetate buffer, pH 6.0

Endoglycoceramidase (EGCase; from *Rhodococcus sp.*; for purification see Ito and Yamagata, 1989a)

Toluene

Methanol

60:40:9 (v/v/v) chloroform/methanol/0.2% (w/v; aqueous) calcium chloride

Orcinol/sulfuric acid reagent (see recipe)

2:1 (v/v) chloroform/methanol

Bath sonicator

Precoated high-performance thin-layer (HPTLC) silica gel 60 plates (10 × 10-cm; Merck)

Glass chromatography tank

140°C oven

Tabletop centrifuge

Digest sample with EGCase

1. Evaporate an aliquot of the sample to be analyzed to dryness in a glass vial. Simultaneously evaporate 10 µl of 1 mg/ml disialoganglioside-G_{D1a} in the same manner, as a positive control.

When analyzing complex mixtures of unknown composition, estimate the amount of sample to be aliquotted by carrying out this protocol with two or three different amounts of sample.

Evaporation can be done by simply leaving the glass vial containing the chloroform/methanol solution open to the atmosphere or by using a Speedvac evaporator.

2. Dissolve the evaporated residues in 50 µl 0.5% sodium taurocholate in 0.05 M sodium acetate buffer, pH 6.0 by brief sonication in a bath sonicator.

0.4% Triton X-100 can be used in place of sodium taurocholate. EGCase molecules aggregate in the absence of detergents.

3. Add 12 mU of EGCase to each sample. Place the vials containing the samples, with caps loosened, inside a closed container in which an open tube of toluene is also placed to create a toluene atmosphere. Begin incubating at 37°C.

Preparation and
Analysis of
Glycoconjugates

Supplement 32

- At intervals of 0, 1, 3, 6, 15, and 20 hr of incubation, take an aliquot of the reaction mixture with a volume corresponding to ≥ 1 nmol of each glycolipid. Dilute each aliquot with 9 vol methanol.

Determine optimal incubation time for cleavage

- Apply an aliquot of each diluted sample hydrolysate and G_{D1a} hydrolysate (1 to 2 nmol) along a line drawn 1 cm from the bottom of an HPTLC silica gel 60 plate.

Depending on how many points are used, multiple plates may be required. Five to seven samples can be spotted per plate.

The plates must be marked in advance with pencil lines 1 cm from the top and bottom of the plate. The bottom line should be further divided with pencil marks into 1-cm lanes with ~ 0.5 -cm spacings between lanes. The lanes will correspond to the different incubation times used in step 4.

- Air dry plate and place in a glass chromatography tank that has been equilibrated with 60:40:9 chloroform:methanol:0.02% aqueous calcium chloride.

The HPTLC is to separate the glycolipids. Released oligosaccharides can be analyzed by HPTLC on silica gel 60 plates using 2:1:1 (v/v/v) 1-butanol:glacial acetic acid:water as the developing solvent.

- Let the solvent ascend until it reaches the upper line, then take the plate out of the tank and allow to thoroughly air dry in a fume hood.

- Spray with orcinol-sulfuric acid reagent and heat at 140°C for 5 min.

Alternatively, if the carbohydrate moiety has been radiolabeled, the plate can be submitted to autoradiography.

- Note the lane in which complete release of oligosaccharides is indicated by the disappearance of the glycolipid bands that are present in the starting material.

If no lane indicating complete reaction is seen, longer incubation periods should be tried. The time points indicated to step 4 are for analysis of purified glycolipids for which some information is available. A time course up to 72 hr is suggested for unknown glycolipid structures. In these cases, add 36 mU of EGCase instead of 12 mU.

Analyze released oligosaccharides

- Set up reaction as described in steps 1 to 3, incubate for the time determined to be optimal for complete release of oligosaccharides, then stop the reaction by adding 2 vol of 2:1 chloroform:methanol.

- Shake the mixture of aqueous cleaved glycolipid and organic solvent, then centrifuge 10 min at 2000 rpm in a tabletop centrifuge. Remove the upper (aqueous) phase containing the oligosaccharides and lyophilize. Store at -20°C .

The remaining glycolipids and ceramides will partition into the lower (organic) phase.

The dried sample can be dissolved in water and submitted to a variety of different methods of oligosaccharide analysis. The method to be chosen will depend on the availability of instrumentation, the complexity of the sample, the amount of material available, and the questions to be answered. Possible methods for the analysis of the released oligosaccharides include: ion-exchange HPLC of anionic oligosaccharides (UNIT 17.21A) and sizing HPLC of neutral oligosaccharides (UNIT 17.21B). High-performance anion-exchange chromatography on pellicular-resin columns can also be used for both anionic and neutral oligosaccharides. Radiolabeled samples are monitored by liquid scintillation counting of collected fractions, and nonradiolabeled ones by pulsed amperometric detection (PAD).

In most cases, dilution of the reaction mixture before injection into an HPLC system will suffice. When desalting by gel-filtration chromatography (UNIT 10.9) is required prior to further analysis, the released oligosaccharides can be separated from remaining glycolipids and ceramides and at the same time desalted by passing the reaction mixture from step 10 (without adding organic solvent) through a Dowex 50 (hydrogen form) gel-filtration column and washing with water. Long-chain nonpolar molecules will be retained by hydrophobic interactions and cations will be exchanged. The oligosaccharides that are recovered should be lyophilized. Alternatively, gel-filtration chromatography may be performed on the upper phase (step 11) using an 0.6 × 20-cm Sephadex G-10 column, eluting with water. The elution may be monitored by spotting aliquots of each fraction on a piece of silica gel-coated TLC plate and staining the carbohydrates with orcinol-sulfuric acid reagent (i.e., by spraying the dried plate and heating 15 min at 110°C). All fractions containing carbohydrates are then pooled and lyophilized.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Orcinol/sulfuric acid reagent

Weigh 200 mg orcinol (5-methylresorcinol·H₂O, formula weight 142.15; Aldrich). Dissolve in 100 ml ice-cold 2 M sulfuric acid. Store in a glass container at 4°C; discard when solution turns brownish.

COMMENTARY

Background Information

Endoglycosylceramidase (EGCase) is an enzyme capable of hydrolyzing the linkage between the oligosaccharides and ceramides of acidic and neutral glycolipids to produce free, intact oligosaccharide and ceramide residues. The enzyme does not cleave the linkages between monosaccharides and ceramides (in cerebroside) or between oligosaccharides and diacylglycerol (in glycoglycerolipids). Commercially available EGCase is isolated from the culture supernatant of *Rhodococcus* sp. and has an apparent molecular weight >16 kDa as determined by gel-filtration chromatography on Sephadex G-100. This preparation contains three isozymes with molecular weights of 60,000 to 75 kDa as determined by SDS-PAGE.

One unit of enzyme is defined as the amount needed to catalyze the release of 1 μmol/min of reducing power (as glucose) from a substrate of mixed bovine brain gangliosides at 37°C, pH 6.0. The specific activity is not less than 15 mU/mg of protein.

Chemical treatments—e.g., ozonolysis and periodate oxidation—have been used to obtain free oligosaccharides from glycosphingolipids. However, these reactions cause disruption of the ceramide residues.

Ito and Yamagata (1986) reported a novel glycosphingolipid-specific endoglycosidase—endoglycosylceramidase—or “endoglyco-

ceramidase” for short. The enzyme, isolated from the culture supernatant of *Rhodococcus* sp. strain G-74-2, was capable of cleaving the linkage between oligosaccharides and ceramide, releasing both parts intact. Later, similar enzymes called ceramide-glycanases were found in leeches (Li et al., 1986) and earthworms (Li et al., 1987). The crude enzyme, however, could not be used to release oligosaccharides from living cells because contamination with hemolysin caused cell death.

A variety of methods for the analysis of the released oligosaccharides have been developed. Some of them include a derivatization step to incorporate a fluorescent or hydrophobic tag, followed by HPLC analysis of the products (Shimamura et al., 1988; Rasilo et al., 1989). Analysis of the released oligosaccharides by HPAE-PAD (see UNIT 17.19A) has also been reported (Ito et al., 1991), as well as the use of the enzyme in the structural characterization of metabolically radiolabeled gangliosides (Manzi et al., 1990).

In 1989, a mutant strain of *Rhodococcus* sp., M-750, was isolated. This organism was capable of producing three forms of endoglycosylceramidase, and two of these forms were purified (Ito and Yamagata, 1989a). The three isoenzymes were separated from each other and their substrate-specificity examined with various glycosphingolipids. EGCase I (with a pI of 5.3)

and EGCase II (with a pI of 4.5) hydrolyze the glucosyl-ceramide linkage of globo-, lacto-, and ganglio-type glycosphingolipids. EGCase I hydrolyzes globo-type glycosphingolipids much faster than EGCase II. Neither of these two isoenzymes hydrolyzes the galactosyl-ceramide linkage for which EGCase III is specific (Ito and Yamagata, 1989b). A new mutant, M-777, produced EGCases at levels 5-fold higher than M-750 (Ito et al., 1991).

In spite of extensive purification of the enzymes, effective EGCase cleavage of glycosphingolipids in vivo while maintaining viability of the cells still presents two problems. First, the activity of the enzymes is very low in the absence of detergents, and a detergent capable of stimulating activity without impairing cell viability has not been found. Second, the optimal pH is quite acidic, which is another factor that prevents the study of the biological functions of glycosphingolipids. Recently, Ito et al. (1991) reported finding two activator proteins in the culture supernatant of *Rhodococcus* sp. strain M-777. Activator protein II was purified and shown to stimulate the activity of EGCase II much more than that of EGCase I, but was nonspecific with respect to the glycolipid. Activator protein I seems to be specific for stimulating the activity of EGCase I. Following the addition of activator protein II, EGCase II hydrolyzed cell-surface glycosphingolipids quite efficiently at a neutral pH where almost no hydrolysis occurred with EGCase II alone (Ito et al., 1991). In the near future, the use of activator proteins might permit the study of the biological functions of glycosphingolipids in living cells using EGCase.

Critical Parameters

If the activity of EGCase towards disialoganglioside-G_{D1a} is defined as 100% at pH 5 to 6, only 50% of that activity is observed at pH 7, and 20% at pH 4. The enzyme is completely inactive at pH 3. Maximum stability of the enzyme is observed between pH 6 and 8.

The enzyme is inhibited by Cu²⁺, Ba²⁺, and Hg²⁺. It is stable in buffered solution for 6 months at 4°C. Excessive freeze-thawing should be avoided.

The commercially available enzyme does not contain sphingomyelinase, β-galactosidase, β-mannosidase, β-galactosaminidase, β-glucosidase, α-fucosidase, or sialidase activity. Trace amounts of β-glucosaminidase, or α-mannosidase, as well as protease activity, can

sometimes be detected—this is indicated in the data sheet provided by the manufacturer.

Sonication of the substrate prior to the addition of enzyme is recommended.

It is always necessary to determine empirically the time required for complete cleavage, as different glycolipids exhibit different rates of hydrolysis.

Anticipated Results

The use of this protocol, in combination with appropriate analysis of the released oligosaccharides, will allow the structural characterization of the types of carbohydrate chains that are linked to glycolipids in a given system. However, as mixtures of glycolipids may be complicated, the usefulness of this protocol can be driven one step forward by studying purified glycolipids. Where this is done, the released oligosaccharides can be submitted to acid hydrolysis for composition analysis (UNITS 17.19A & 17.19B).

Time Considerations

Up to 3 days of incubation with the enzyme may be required for complete release. The time required for analysis of the released oligosaccharides depends on the method used.

Endo- β -Galactosidases and Keratanase

INTRODUCTION

Endo- β -galactosidases were discovered during the search for a keratan sulfate-degrading enzyme in the culture filtrates of *Coccobacillus* sp. (Hirano and Meyer, 1971), *Pseudomonas* sp. (Nakasawa and Suzuki, 1975), and *Escherichia freundii* (Kitamikado et al., 1970a,b,c). Later studies on the *E. freundii* keratanase demonstrated that this enzyme is capable of hydrolyzing a wide range of glycoconjugates—including nonsulfated oligosaccharides isolated from milk as well as the carbohydrate moieties of glycoproteins and glycolipids—thus expanding the applicability of this enzyme as an endo- β -galactosidase to a variety of complex glycoconjugates (Fukuda and Matsumura, 1975, 1976). Endo- β -galactosidase produced by *Bacterioides fragilis* has similar properties to that from *E. freundii* (Scudder et al., 1983). On the other hand, keratanase isolated from *Pseudomonas* sp. is specific to the sulfated poly lactosamines, and thus only hydrolyzes keratan sulfates (Nakazawa and Suzuki, 1975; Fukuda, 1985; Nakasawa et al., 1984). An endo- β -galactosidase found in *Diplococcus pneumoniae* showed strict specificity toward blood-group A and B structures (Takasaki and Kobata, 1976). More recently, an endo- β -galactosidase specific to Gal α 1 \rightarrow 3Gal was found in the culture filtrate of *Clostridium perfringens* (Fushuku et al., 1987).

ENDO- β -GALACTOSIDASE FROM *E. FREUNDII*

Source

The *E. freundii* line designated also as *Citrobacter freundii* EGI (Paoletti et al., 1990) can be obtained from American Type Culture Collection (ATCC; APPENDIX 4). The endo- β -glycosidase enzyme can be purified from the culture filtrate of this organism by affinity chromatography using side chain-free mucins.

Properties

Estimates of the molecular weight of the endo- β -galactosidase from *E. freundii* range from 28 to 32 kDa, depending on the method employed. The enzyme is stable in a solution of pH 4.5 to ~5.5, but unstable below pH 4.0 or above pH 6.0. It is stabilized by addition of 450 μ g/ml BSA to the enzyme solution. The activity of this enzyme is optimal between pH 5.5 and

5.8, using a sodium acetate buffer. The isoelectric point is estimated to be pH 8.0 (Nakagawa et al., 1980).

Substrates and Specificity

E. freundii endo- β -galactosidase hydrolyzes high-molecular-weight substrates at the middle of the carbohydrate chain by random depolymerization (Fukuda and Matsumura, 1976).

Cleavage of keratan sulfates

E. freundii endo- β -galactosidase hydrolyzes the β -galactosidic bond of the keratan sulfates as shown in Figure 17.17.1A, but does not cleave the bond if the adjacent galactose residue is sulfated at the C-6 position, as indicated in Figure 17.17.1B. The sulfate group on GlcNAc is not a necessary factor for *E. freundii* endo- β -galactosidase, as a nonsulfated disaccharide is released from the keratan sulfate. Sulfation of the galactose residue at the C-6 position, however, hinders hydrolysis of the galactosidic bond by endo- β -galactosidase.

Cleavage of glycoproteins

The usefulness of the *E. freundii* endo- β -galactosidase has been shown in detection of poly lactosaminoglycans in glycoproteins. The endo- β -galactosidase was found to be active upon human erythrocyte band 3 carbohydrate (Fukuda et al., 1979), large glycopeptides from mouse embryonal carcinoma F9 cells (Muramatsu et al., 1979), and glycopeptides isolated from a GM1 gangliosidosis patient (Tsay et al., 1975)—all of which were found to contain keratan-like poly lactosaminoglycans with the aid of this enzyme. Poly lactosaminoglycans are present in various glycoproteins—including a glucose-transporter protein, lysosomal membrane proteins, precursor of Rh antigen, fibronectin from human placenta, lymphocyte-associated antigen 1 (LFA-1) α and β -chains, and laminin.

Endo- β -galactosidase from *E. freundii* can hydrolyze galactose as shown in Figure 17.17.2. The galactose at the branch point is also susceptible, although with a low efficiency (Fukuda et al., 1984).

The endo- β -galactosidase can hydrolyze fucosylated lactosaminoglycans as shown in Figure 17.17.3, but the galactosyl linkage attached to the fucosylated N-acetylglucosamine

Figure 17.17.2 Hydrolysis of galactose in glycoproteins by *E. freundii* endo- β -galactosidase.

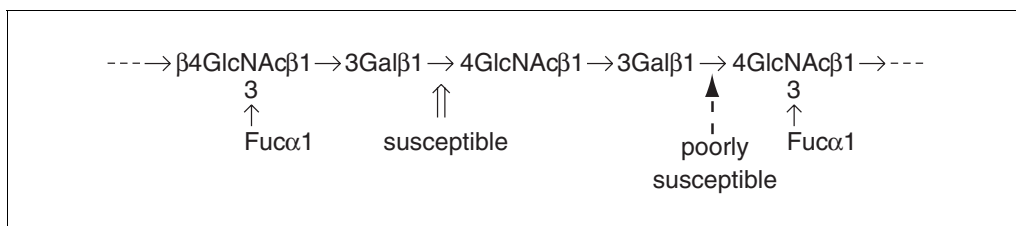

Figure 17.17.3 Hydrolysis of fucosylated lactosaminoglycans by *E. freundii* endo- β -galactosidase. The galactosyl residue attached to the fucosylated N-acetylglucosamine is poorly susceptible.

is poorly susceptible to the enzyme (Sponcer et al., 1984; Kannagi et al., 1982a).

Cleavage of glycolipids

The so-called lacto-series glycolipids ($R_3 \rightarrow \text{GlcNAc}\beta 1 \rightarrow 3\text{-Gal}\beta 1 \rightarrow 4\text{Glc} \rightarrow \text{Cer}$) are susceptible to endo- β -galactosidase (Fukuda et al., 1976). For example, endo- β -galactosidase hydrolyzes lacto-N-neotetraosylceramide, producing trisaccharide and glucosylceramide as shown in Figure 17.17.4A and lacto-N-neohexaosylceramide is hydrolyzed to produce two oligosaccharides—lacto-N-triaosylceramide and glucosylceramide—as shown in Figure 17.17.4B. Branched lacto-series glycolipids—e.g., lacto-iso-N-neooctaosylceramide—are hydrolyzed to a large

oligosaccharide and glucosylceramide as shown in Figure 17.17.4C.

Although the β -galactosidic linkage at the branch point in the erythrocyte polylectosaminoglycan-peptides is cleaved by endo- β -galactosidase, under practical conditions the hydrolysis of glycolipids at the branch point is too poor to be detected.

Hydrolysis of α_2 -glycolipid (Kannagi et al., 1982b) indicates that not only the $\text{GlcNAc}\beta 1 \rightarrow 3\text{Gal}\beta 1 \rightarrow$ structure, but also the $\text{GalNAc}\beta 1 \rightarrow 3\text{Gal}\beta 1 \rightarrow$ structure is susceptible to endo- β -galactosidase.

Cleavage of oligosaccharides

E. freundii endo- β -galactosidase can hydrolyze oligosaccharides isolated from human

Figure 17.17.4 Hydrolysis of glycolipids by *E. freundii* endo-β-galactosidase. **(A)** Enzyme hydrolyzes lacto-N-neotetraosylceramide producing trisaccharide and glucosylceramide. **(B)** Enzyme hydrolyzes lacto-N-neohexaosylceramide to produce lacto-N-triaosylceramide and glucosylceramide. **(C)** Enzyme hydrolyzes branched lacto-series glycolipid to produce large oligosaccharide and glucosylceramide.

milk (Fukuda, 1981; Nakagawa et al., 1980). Affinity of the enzyme for oligosaccharide substrates is weaker than that for polylactosaminoglycan, keratan sulfate, and glycolipid substrates. A high concentration of the enzyme is needed for an efficient enzymic hydrolysis of oligosaccharides.

Application of Endo-β-Galactosidase to Various glycoconjugates

Glycopeptides

To digest glycopeptides with endo-β-galactosidase, mix 10 to 100 μg of the glycopeptide—metabolically labeled (UNIT 17.4) or unlabeled—and 25 mU of endo-β-galactosidase with 200 μl of 0.2 M sodium acetate buffer, pH 5.0 (APPENDIX 2), then incubate at 37°C overnight. The oligosaccharides released by endo-β-galactosidase are usually analyzed by gel filtration (UNIT 10.9). In preparation for this, the digest of unlabeled glycopeptides is reduced with NaB[³H]₄ (see UNIT 17.5). The resulting

[³H]-labeled oligosaccharide alcohols are then applied to a gel-filtration column packed with Sephadex G-50 (Pharmacia Biotech) and/or a column packed with Bio-Gel P-4 (Bio-Rad).

Upon Bio-Gel P-4 gel filtration, the oligosaccharide components are eluted at the elution volumes of disaccharides, trisaccharides, and tetrasaccharides; larger (or sialylated) molecules are eluted in the void volume. The results obtained for erythrocyte band 3 showed that the oligosaccharide alcohols released are: GlcNAcβ1→3GalOH, Galβ1→4GlcNAcβ1→3GalOH, and Fucα1→2Galβ1→4GlcNAcβ1→3GalOH.

The oligosaccharide components eluted in the void volume from a Bio-Gel P-4 column are sialylated oligosaccharides—because after desialylation these components are often eluted at the elution volumes of trisaccharides or larger oligosaccharides. The structure of the smallest sialylated oligosaccharide component released from band 3 was: NeuNAcα2→3Galβ1→4GlcNAcβ1→3GalOH.

Because disaccharides should be produced from the internal moieties of poly lactosamine in which tri- and tetrasaccharides represent nonreducing terminals. Thus, in the absence of fucosylation or sialylation the ratio of disaccharides to tri- and tetrasaccharides indicates the length of the poly lactosamine repeats. These analyses, combined with methylation analyses of intact poly lactosamines have yielded substantial structural information on glycoproteins.

Glycolipids

To hydrolyze glycolipids with endo- β -galactosidase, take an aliquot corresponding to 10 μ g of glycolipid dissolved in 2:1 (v/v) chloroform/methanol and place in a small glass test tube or microcentrifuge tube. Dry the glycolipid sample under N_2 gas. To the dried sample, add 10 μ l of 0.2 M sodium acetate buffer, pH 5.8 (APPENDIX 2) containing 20 μ g sodium deoxytaurocholate, as well as 10 μ l of 0.25 mU/ μ l endo- β -galactosidase. Incubate 2 hr to overnight to achieve enzymatic hydrolysis. Sialylated glycolipid—e.g., sialylparagloboside and linear lacto-series glycolipids—can be hydrolyzed easily under these conditions; stronger conditions—e.g., 10 \times more enzyme—are required for hydrolysis of branched and/or highly fucosylated glycolipids.

Intact cells (Fukuda et al., 1979)

Endo- β -galactosidase can directly modify cell-surface glycoproteins and glycolipids. When human erythrocytes are treated with endo- β -galactosidase, Ii antigens and ABO blood-group antigens are abolished or decreased. In addition to these antigenic changes, poly lactosamines on band 3 and glycoproteins on band 4.5 are hydrolyzed, though O-linked oligosaccharides in glycoporphins remain unaffected. Glycolipids on the cell surface are also hydrolyzed by endo- β -galactosidase, but only lacto-series glycolipids with long carbohydrate chains are hydrolyzed by this treatment. The innermost galactosyl linkage of glycolipids, R \rightarrow Gal β 1 \rightarrow 4Glc \rightarrow Cer, is not susceptible to the enzyme treatment on the cell surface. Endo- β -galactosidase treatment of intact cells, combined with cell-surface labeling using galactose oxidase or galactosyltransferase, has been useful for identifying poly lactosamine-bearing glycoproteins.

To perform cell-surface labeling and endo- β -galactosidase digestion, the galactose and

N-acetyl galactosamine residues on the cell surface can be specifically labeled by the galactose oxidase/ $NaB[^3H]_4$ method (Gahmberg and Hakomori, 1973). Wash the erythrocytes three times with cold PBS (APPENDIX 2), then suspend $\sim 2 \times 10^7$ cells (or 200 μ l of packed cells) in 1 ml PBS pH 7.4. Add 10 μ l of 1 U/ml galactose oxidase (Sigma) in PBS, pH 7.4 and incubate 2 hr at room temperature. After incubation, add 2.5 mCi $NaB[^3H]_4$ in 50 μ l 0.01 N NaOH and incubate 30 min at room temperature. Finally, add ~ 0.5 mg nonradioactive $NaBH_4$ and wash 3 \times with cold PBS (pH 7.0), centrifuging between washes. Resuspend 0.1 ml of these surface-labeled cells (as packed cells) in PBS pH 7.0 to a final volume of 200 μ l. To this cell suspension, add 25 μ l of 1 U/ml endo- β -galactosidase, then incubate 2 hr at room temperature. Wash the cells with 3 ml cold PBS (pH 7.0) and centrifuge. The pelleted cells can be used for glycoprotein and glycolipid analysis, and the supernatant can be analyzed for released oligosaccharides. This procedure can be used not only for erythrocytes, but also for nucleated cells.

To analyze glycoproteins and glycolipids of surface-labeled cells, prepare erythrocyte membranes from the surface-labeled cells that have been treated with or without endo- β -galactosidase as described above. Membrane lysates from nucleated cells—e.g., lymphocytes and fibroblasts—can be prepared by vortexing the cells in an equal volume of cold PBS containing 0.5% NP-40 and 1 mM PMSF. The nuclei are then separated out by centrifugation, after which the supernatant containing the cell lysate may be dissolved in SDS sample buffer and subjected to SDS-polyacrylamide gel electrophoresis (UNIT 10.2), followed by fluorography (APPENDIX 3A) to detect radioactive protein components.

To extract glycolipids from erythrocyte membranes or intact cells, these are dissolved in 10 vol of 2:1 (v/v) chloroform/methanol and the extract fractionated by Folch partition (UNIT 17.3) into lower and upper phases. If necessary, upper-phase glycolipids can be further separated into neutral and acidic glycolipids by DEAE-Sephadex. Each glycolipid fraction is finally analyzed by thin-layer chromatography followed by fluorography. Oligosaccharides released from the cell surface by endo- β -galactosidase treatment can also be analyzed by gel-filtration chromatography on Sephadex G-50 and by paper chromatography.

ENDO-β-GALACTOSIDASE FROM BACTEROIDES FRAGILIS (Scudder et al., 1983)

Source

Endo-β-galactosidase from *B. fragilis* is commercially available from Genzyme (APPENDIX 4).

Properties

The properties and specificities of the *B. fragilis* endo-β-galactosidase are similar to those of the corresponding *E. freundii* enzyme. The enzyme can be stored at -20°C for long periods of time; storage at a protein concentration of 44 μg/ml at 4°C for 2 to 3 months did not affect the activity, but storage at a low concentration (<3 μg/ml) causes a significant loss of activity. In the presence of 0.2 mg/ml of albumin, the enzyme retains its activity over a wide range of pH.

Substrates and Specificity (Scudder et al., 1983, 1984, 1986)

B. fragilis endo-β-galactosidase hydrolyzes keratan sulfate and produces sulfated and non-sulfated oligosaccharides, which are identical to the digestion products of keratan sulfate with *E. freundii* endo-β-galactosidase. Hydrolysis of oligosaccharides by endo-β-galactosidases from *B. fragilis* and *E. freundii* shows that both enzymes hydrolyze the internal Galβ1→4Glc linkage of type 1 and type 2 oligosaccharides. The type 2 oligosaccharide lacto-N-neotetraose was hydrolyzed to a greater extent than its type 1 isomer, lacto-N-tetraose. *B. fragilis* endo-β-galactosidase hydrolyzes the linear but not the branched carbohydrate chain of lacto-series glycolipids. Because the *B. fragilis* endo-β-galactosidase is quite similar to that from *E. freundii*, this enzyme can be applied widely to the analysis of glycoconjugates, as described for the *E. freundii* enzyme.

ENDO-β-GALACTOSIDASE FROM FLAVOBACTERIUM KERATOLYTICUS (Kitamikado et al., 1981)

Endo-β-galactosidase from *F. keratolyticus* has been purified, and the specificity of this enzyme has been compared with that of the *E. freundii* enzyme. *F. keratolyticus* endo-β-galactosidase is similar to the *E. freundii* enzyme, except that the *F. keratolyticus* enzyme can hydrolyze oligosaccharide substrates more efficiently.

BLOOD-GROUP TYPE A and B-SPECIFIC

ENDO-β-GALACTOSIDASE FROM DIPLOCOCCUS PNEUMONIAE (Takasaki and Kobata, 1976)

Culture filtrate from *Diplococcus pneumoniae* (also called *Streptococcus pneumoniae*) is known as a rich source of endo- and exoglycosidases including β-galactosidase, β-N-acetylglucosaminidase, endo-α-N-acetylglucosaminidase, endo-N-acetylglucosaminidase (endo-D), endo-β-galactosidase DII, and blood group A and B-specific endo-β-galactosidase. The last enzyme hydrolyzes the structure shown in Figure 17.17.5. It hydrolyzes the blood-group A determinant faster than the B determinant, and hydrolyzes the oligosaccharides with A and B determinants that are composed of type 2 chains, but not those composed of type 1 chains.

ENDO-β-GALACTOSIDASE DII FROM DIPLOCOCCUS PNEUMONIAE (Fukuda, 1985)

An endo-β-galactosidase that hydrolyzes the internal β-galactosidic linkages of the structure shown in Figure 17.17.6 was found in the culture supernatant of *D. pneumoniae*. This enzyme was named endo-β-galactosidase DII to differentiate it from the previously isolated blood-group type A and B-specific endo-β-

Figure 17.17.5 Structure hydrolyzed by blood-group AB-specific endo-β-glycosylase from *D. pneumoniae*.

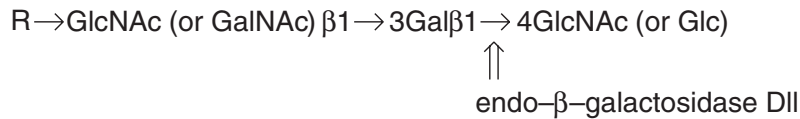

Figure 17.17.6 Structure hydrolyzed by endo- β -galactosidase DII from *D. pneumoniae*. R = H, Gal β 1 \rightarrow 4, or NeuNAc α 2 \rightarrow 3/6Gal β 1 \rightarrow 4.

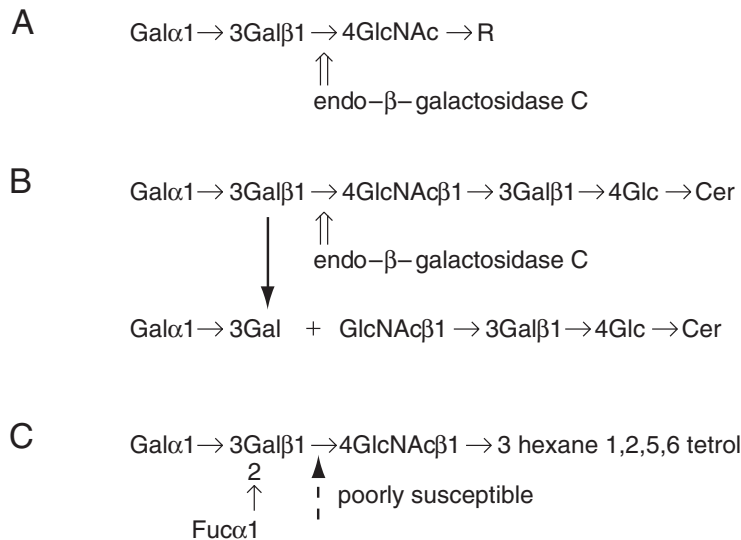

Figure 17.17.7 Hydrolysis by endo- β -glycosidase C from *C. perfringens*. **(A)** Enzyme hydrolyzes β -galactosidic linkages of glycoproteins and glycolipids. **(B)** Enzyme hydrolyzes the glycolipid pentaglycosylceramide. **(C)** Enzyme does not hydrolyze blood-group B oligosaccharide.

galactosidase from the same bacterium. The specificity of endo- β -galactosidase DII is similar to that of *E. freundii* endo- β -galactosidase, as both recognize the N-acetylglucosaminyl structure and hydrolyze internal β -galactosyl linkages. However, endo- β -galactosidase DII differs from the *E. freundii* enzyme in that it does not degrade keratan sulfate. Endo- β -galactosidase DII hydrolyzes glycolipids and polyglucosaminoglycans endoglycosidically, but from the nonreducing-terminal end.

ENDO- β -GALACTOSIDASE C FROM CLOSTRIDIUM PERFRINGENS (Fushuku et al., 1987)

Endo- β -galactosidase C hydrolyzes β -galactosidic linkages of glycoproteins and glycolipids that have the terminal structure Gal α 1 \rightarrow 3Gal β 1 \rightarrow 4GlcNAc as shown in Figure 17.17.7A. This terminal Gal α 1 \rightarrow 3Gal β 1 \rightarrow structure is present in mice, rabbits, cattle, and new world monkeys, but not in humans, apes, or old world monkeys.

The carbohydrate moiety of a glycoprotein that has a Gal α 1 \rightarrow 3Gal β 1 \rightarrow 4GlcNAc \rightarrow terminal structure can be efficiently hydrolyzed by endo- β -galactosidase C, which releases the disaccharide Gal α 1 \rightarrow 3Gal. Glycolipids having this terminal structure can also be hydrolyzed. For example, pentaglycosylceramide isolated from rabbit erythrocyte membranes is hydrolyzed as shown in Figure 17.17.7B.

The enzyme, however, does not hydrolyze blood-group B oligosaccharide (as shown in Figure 17.17.7C) although it hydrolyzes Gal α 1 \rightarrow 3Gal β 1 \rightarrow 4GlcNAc β 1 \rightarrow 3 hexane 1,2,5,6 tetrol. Endo- β -galactosidase C does not hydrolyze polyglucosaminoglycans from human erythrocytes of blood-group B. Thus, the enzyme is different from the endo- β -galactosidase from *D. pneumoniae*, which acts on blood group A and B antigens, as well as the endo- β -galactosidases from *E. freundii*, *B. fragilis*, and *F. keratolyticus*, which act on polyglucosaminoglycans. In addition, endo- β -

galactosidase C does not hydrolyze keratan sulfate.

KERATANASE FROM *PSEUDOMONAS* SP. (Nakazawa and Suzuki, 1975)

Source

Keratanase (or keratan sulfate-specific endo- β -galactosidase) has been purified from *Pseudomonas* sp. cell extract and is commercially available from Miles (APPENDIX 4).

Properties

The purified enzyme has been stored in ice. The pH optimum is between 7.2 and 7.4 using corneal keratan sulfate as substrate. At a 1 mM concentration, Ca^{2+} , Mg^{2+} , and Mn^{2+} have no effect on the enzymatic activity. Acetate and maleate elicit a slight increase in activity (~15%) at concentrations of 0.05 M.

Substrates and Specificity

Keratanase from *Pseudomonas* sp. hydrolyzes keratan sulfate but not chondroitin sulfates, hyaluronic acid, dermatan sulfate, or heparin. In contrast to *E. freundii* endo- β -galactosidase, this enzyme does not hydrolyze lacto-N-tetraose, lacto-series glycolipids, or erythrocyte polylectosaminoglycans—thus *Pseudomonas* endo- β -galactosidase is specific for keratan sulfate. Two sulfated oligosaccharides—

6-sulfo-GlcNAc β 1 \rightarrow 3Gal and
6-sulfo-GlcNAc β 1 \rightarrow 3-6-sulfo-GlcNAc β 1 \rightarrow
4-6-sulfo-GlcNAc β 1 \rightarrow 3Gal—

have been identified in the digestion products from keratan sulfates produced by this enzyme. However, the nonsulfated disaccharide GlcNAc β 1 \rightarrow 3Gal is not produced.

Applications

This enzyme has been quite useful in distinguishing keratan sulfates or sulfated polylectosaminoglycans from nonsulfated polylectosaminoglycans (Nakazawa et al., 1984).

ENDO- β -GALACTOSIDASE SPECIFIC TO THE REGION LINKING CHONDROITIN SULFATE AND THE CORE PROTEIN (Takagaki et al., 1990a,b)

Endo- β -galactosidase that degrades the linkage between a chondroitin sulfate and core protein has been reported in rabbit liver and in the midgut gland of the mollusk *Patinopecten* sp. Chondroitin sulfate-containing proteogly-

cans were digested with endo- β -xylosidase from the midgut gland of *Patinopecten* sp., and the released chondroitin sulfate (with an R-Gal β 1 \rightarrow 3Gal β 1 \rightarrow 3Gal β 1 \rightarrow 4Xyl terminus) was conjugated with pyridylamine (PA) by reductive amination. This chondroitin sulfate-PA was incubated with a crude enzyme solution from the midgut gland of *Patinopecten* sp. HPLC analysis of the PA-oligosaccharide product identified Gal β 1 \rightarrow 4Xyl-PA, suggesting strongly that an endo- β -galactosidase had specifically hydrolyzed the Gal β 1 \rightarrow 3Gal linkage in the linkage region of chondroitin sulfate.

ANALYSIS OF SACCHARIDES RELEASED FROM GLYCOCONJUGATES

Many of the more specific and sensitive methods for analyzing the structure of oligosaccharides require that the oligosaccharides be first released from the glycoconjugate to which they are attached and, if necessary, purified away from the protein moiety. The units presented in this section describe various ways in which such released oligosaccharides can be analyzed. It must be recognized that no matter how good such a method is, it is highly dependent upon the quality of the preceding steps—i.e., the specific and quantitative release of the oligosaccharide from the glycoconjugate and the use of an appropriate purification scheme that does not result in selective losses. The methods presented in this section include those designed for the analysis of monosaccharides (*UNIT 17.18*) and those designed for the study of oligosaccharides (or glycopeptides; *UNITS 17.19-17.23*). The first group primarily provide monosaccharide compositional information and are a good starting point for the analysis of a previously unexplored glycoconjugate. Methods in the latter group range from simple techniques for determining basic properties of an oligosaccharide, to complex and sophisticated methodologies requiring the use of expensive instruments.

There are of course many other well-established techniques and approaches to the structural analysis of oligosaccharides, some of which require specialized instrumentation (e.g., mass spectrometry and nuclear magnetic resonance). The choice of techniques for inclusion in this section was based partly on the criteria of ease of use and broad general utility to the average molecular biologist.

Analysis of Monosaccharides

UNIT 17.18

This unit presents methods for assaying sialic acids, reducing sugars, and hexosamines. The BCA assay (Basic Protocol 1) detects free reducing termini in sugars released from glycoconjugates by appropriate treatments. Assays employing Ehrlich reagent (DMAB) detect hexosamines and *N*-acetylhexosamines (Basic Protocol 2 and Alternate Protocol); Basic Protocol 2 also includes a method for hydrolyzing the glycosidic linkages of the hexosamines and a method for re-*N*-acetylation is described in Support Protocol 1). The TBA (Basic Protocol 3) and DMB assays (Basic Protocol 4) can be used to quantitate and fractionate free forms of many types of sialic acids; techniques for liberating the sialic acids from the parent glycoconjugates are provided in Support Protocols 2 and 3. (Another alternative, the ferric orcinol method presented in *UNIT 17.9*, can measure both free and glycosidically bound sialic acids irrespective of modifications, but with much reduced sensitivity.)

Note that the acid hydrolysis conditions used to release sialic acids are much milder than those used for other monosaccharides—indeed, sialic acids are destroyed under the harsher conditions. Therefore, a sialic acid-containing molecule needs to be subjected to at least two separate analyses—one for sialic acids and one for the other monosaccharides.

BCA ASSAY FOR REDUCING SUGARS WITH SPECTROPHOTOMETRIC DETECTION

BASIC PROTOCOL 1

This protocol presents the most sensitive method developed to date to measure free reducing termini in sugars. This type of assay is useful for determining the total amount of oligosaccharides released from N-linked or O-linked glycoconjugates by enzymatic treatment (*UNIT 17.13A*) or from glycolipids by endoglycoceramidase (*UNIT 17.17A*). It may also be used to determine the total sugars present after acid hydrolysis.

Preparation and Analysis of Glycoconjugates

17.18.1

Materials

Sample in water or aqueous buffer
Standard: e.g., glucosamine hydrochloride or *N*-acetyl-D-glucosamine (both available from Sigma)
Bovine serum albumin (BSA)
BCA reagent (reagent C; see recipe)
16 × 115-mm Pyrex test tubes
Clean glass marbles
Heating block, 80°C
Spectrophotometer and 1.0-ml glass cuvettes

1. In 16 × 115-mm Pyrex test tubes, prepare duplicates containing aliquots of sample and of 2 to 25 nmol of an appropriate standard in 300 µl water. Also prepare a blank consisting of 300 µl of water or the buffer in which sample is dissolved, and a control containing BSA at a concentration equal to the maximum protein concentration expected in the samples.

Avoid borate ions in the buffer; but if these cannot be avoided, make sure to adjust the pH to 10.6 to avoid interference.

*The expected reducing sugar for the type of sample under analysis should be used as standard. *N*-acetylglucosamine should be used for oligosaccharides released from *N*-linked glycoproteins; glucose for oligosaccharides released from gangliosides.*

2. Add 700 µl BCA reagent to each tube, vortex, and cover with glass marbles to prevent evaporation. Heat 30 min at 80°C.
3. Allow tubes to cool to room temperature. Transfer solutions to 1.0-ml glass cuvettes and measure the absorbance at 560 nm, adjusting against the values obtained for the blank.
4. Prepare a standard curve of absorbance vs. nmol reducing sugar.
5. Determine the amount of reducing sugar in each sample by reference to the standard curve.

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

BCA reagent

Reagent A: Dissolve 1.5 g disodium 2,2'-bicinchoninate (4,4'-dicarboxy-2,2'-biquinoline; FW 388.3; Sigma) in 1 liter water. Add 71.6 g anhydrous sodium carbonate (ACS reagent grade, FW 105.99; Sigma) while stirring. Dilute to 1.15 liters with water. Store in a dark bottle at room temperature (stable several months).

Reagent B: Dissolve 3.5 g aspartic acid (FW 133.1; Sigma) and 5.0 g anhydrous sodium carbonate in 100 ml water, shaking to dissolve (this produces foam). In a separate container, dissolve 1.09 g copper sulfate (CuSO₄·5 H₂O, FW 249.6; ACS reagent grade) in 40 ml water. Mix the two solutions and dilute to 150 ml with water (a temporary fluffy blue precipitate may appear). Store at 4°C (stable several months).

Reagent C (BCA reagent): Mix 23 ml reagent A and 1 ml reagent B with 6 ml of 100% ethanol. The solution will have an intense blue color and strong fluorescence. Store in a brown bottle up to 2 weeks at 4°C (discard earlier if purple background color increases). Let stand 2 hr before use.

Commentary

Background Information

Most assays proposed for reduction of sugars make use of inorganic oxidants that accept electrons from sugar aldehyde groups. Aldoses are converted to aldonic acids (and higher oxidation products) and either the metal ions directly formed, metal oxides, or the complexation products of the latter with chromogenic chelators are quantitated. The appropriate oxidation/reduction potential for this reaction depends on the pH and complexation constants.

The BCA reagent forms colored complexes with copper(I); it is possible to couple this reaction to the reduction from copper(II) to copper(I) produced by reducing sugars in alkaline solution.

The most commonly used reduction assay for sugars is the one developed by Park and Johnson (1949) as a modification of the colorimetric method of Folin and Malmros (1929). This method, based on the production of Prussian blue following the reduction of ferricyanide ions in alkaline solution, has a detection limit of ~1 µg (5 nmol) reducing sugar.

Mopper and Gindler (1973) later proposed a new colorimetric reagent for automatic sugar chromatography that was sensitive to ~10⁻¹⁰ mol of sugar in the ethanol/water mobile phase. The dye is based on the formation of a deep-blue complex with Cu(I) ions and 2,2'-bichinchoninic acid in alkaline solution. The reaction is first order over a wide range. However, the sensitivity of the reaction is lower and the linearity range is reduced in water solution. Moreover, when borate ions are present, the Mopper-Gindler reagent produces only a faint color. Sinner and Puls (1978) achieved increased color formation by adjusting the reagent/borate buffer mixture, when used, to the optimal pH of the reaction (10.6), and increased the linear detection range by doubling the BCA concentration. Using these conditions, 55 pmol can be detected in the effluent from an HPLC column with an on-line UV spectrophotometer. McFeeters (1980) adapted the method to manual sugar determinations using ethylene glycol instead of ethanol to increase color formation. The conditions used for on-line detection can also be applied to manual analysis provided special care is taken to compensate for the volatility of ethanol.

Waffenschmidt and Jaenicke (1987) have suggested that for the manual spectrophotomet-

ric quantitation of sugar samples, the sensitivity of the reaction could be improved by replacing the aspartic acid in the BCA reagent with serine.

Critical Parameters

Using manual spectrophotometry, reliable detection is achieved with <3 nmol of mono-, oligo-, or polysaccharides. Buffering salts, sulfuric acid, sodium hydroxide, hydrochloric acid, and acetic acid do not interfere. It is also possible to work in the presence of borate ions if the pH is adjusted. The expected reducing sugar for the type of sample under analysis is used as a standard. However, linear responses may not be obtained with increasing size of the oligosaccharide (Doner and Irwin, 1992). Proteins cause a low level of interference of ~50:1 (w/w) protein/sugar.

Anticipated Results

With this protocol it is possible to detect with confidence 3 nmol of reducing sugar (mono-, oligo- or polysaccharide) in aqueous solution.

Time Considerations

The assay can be completed in ~1 hr.

ASSAYS FOR FREE HEXOSAMINES WITH SPECTROPHOTOMETRIC DETECTION

Free hexosamines can be quantitated spectrophotometrically by a series of procedures derived from the Elson-Morgan and Morgan-Elson reactions that can be used for both hexosamines and N-acetylated hexosamines. These assays require a hydrolysis step (see Basic Protocol 2) to cleave the glycosidic linkages of the hexosamines. This hydrolysis also produces de-N-acetylation. Thus, a re-N-acetylation step is required (see Support Protocol 1) for the Morgan-Elson assay.

Acetylacetone/DMAB (Elson-Morgan) Assay for Free Hexosamines

Materials

Hexosamine-containing sample ($\geq 6 \mu\text{g}$ hexosamine) in aqueous solution
1 mM hexosamine standard stock solution(s): *N*-acetylglucosamine and/or
N-acetylgalactosamine (see recipe)
4 M HCl (diluted from ACS reagent-grade concentrated HCl)
Acetylacetone reagent (see recipe)
95% ethanol
Ehrlich reagent (DMAB)/HCl (see recipe)
13 \times 100-mm Pyrex test tubes with Teflon-lined screw caps
Nitrogen or vacuum evaporation system (Speedvac or shaker-evaporator)
Heating block or oven
Boiling water bath
Spectrophotometer and 1.0-ml glass cuvettes

Liberate hexosamines from glycosidic linkages

1. Dry triplicate aliquots of the sample (containing $\geq 6 \mu\text{g}$ hexosamine) in 13 \times 100-mm Pyrex test tubes with Teflon-lined screw caps.
2. From hexosamine standard stock solution(s), prepare triplicate standards containing 10, 20, 30, 40, 50, and 60 μg *N*-acetylglucosamine and/or *N*-acetylgalactosamine in water. Prepare a blank containing the same total volume of water.
3. Dissolve samples, standards, and blank in 4 M HCl (0.4 ml/mg dry sample). Flush with nitrogen and cap tubes. Heat 4 hr at 100°C.

Because the stability of this type of linkage depends on the structure of the glycoconjugate, optimal conditions for hydrolysis should be determined for each particular case (see UNIT 17.16). When using HCl, concentrations from 2 to 6 M and hydrolysis times from 2 to 10 hr should be tried.

4. Evaporate the HCl in a vacuum evaporation system or under nitrogen. Place the tubes overnight in a desiccator containing sodium hydroxide pellets under vacuum.

Quantitate hexosamines by condensation with alkaline acetylacetone and DMAB

5. Dissolve the hydrolysates in 250 μl water.
6. Add 500 μl acetylacetone reagent to each sample, standard, and blank. Vortex well and cap. Heat 10 min in a boiling water bath.
7. Cool to room temperature. Add 2.5 ml of 95% ethanol and vortex. Incubate 5 min at $75 \pm 2^\circ\text{C}$.
8. Add 500 μl DMAB/HCl and heat 30 min at $75 \pm 2^\circ\text{C}$.
9. Cool tubes to room temperature and add 2.5 ml of 95% ethanol. Let stand 30 min.

- Carefully transfer the solutions to 1.0-ml glass cuvettes and measure the absorbance at 520 nm, adjusting against the values obtained for the blank.
- Prepare a standard curve of absorbance vs. nmol hexosamine using the average value for each concentration.
- Determine the amount of hexosamine in the sample by reference to the standard curve.

Acidic DMAB (Morgan-Elson) Assay for Free *N*-Acetylhexosamines

**ALTERNATE
PROTOCOL**

Additional Materials (also see *Basic Protocol 2*)

20 mM potassium tetraborate
Ehrlich reagent (DMAB)/HCl/acetic acid (see recipe)

- Liberate hexosamines from their glycosidic linkages (see *Basic Protocol 2*, steps 1 to 4). Re-*N*-acetylate the samples (see *Support Protocol 1*).
- Dissolve each sample in 250 μ l water.
- Add 50 μ l of 20 mM potassium tetraborate to each sample, standard, and blank. Vortex well and cap. Heat 3 min in a boiling water bath.
- Cool rapidly to room temperature in a water bath.
- Add 1.5 ml DMAB/HCl/acetic acid, washing down any condensate that has formed, and vortex. Incubate 20 min at 37°C.
- Cool to room temperature. Carefully transfer the solutions to 1.0-ml glass cuvettes and measure the absorbance at 585 nm, adjusting against the values obtained for the blank.
- Prepare a standard curve of absorbance vs. nmol of hexosamine using the average value for each concentration.
- Determine the amount of hexosamine in the sample by reference to the standard curve.

RE-N-ACETYLATION OF FREE HEXOSAMINES

**SUPPORT
PROTOCOL 1**

Hexosamines that have been released from their glycosidic linkages are re-*N*-acetylated prior to detection using potassium tetraborate and DMAB/HCl/acetic acid (see *Alternate Protocol*).

Additional Materials (also see *Basic Protocol 2*)

1.5% (v/v) acetic anhydride (99%, Aldrich) in acetone (HPLC grade, Fisher)
Aqueous sample containing hexosamines liberated from glycosidic linkages by acid hydrolysis, and glucosamine and galactosamine standards treated in the same fashion (see *Basic Protocol 2*, step 2)

- Add 100 μ l of 1.5% acetic anhydride in acetone to 800 μ l of the aqueous solution of the samples containing the liberated hexosamines obtained by acid hydrolysis.
- Repeat the procedure for aqueous solutions of standard glucosamine and galactosamine hydrochlorides.
- Incubate samples and standards 5 min at room temperature.
- Dry under vacuum or with a nitrogen stream.

**Preparation and
Analysis of
Glycoconjugates**

17.18.5

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acetylacetone reagent

Prepare 48 ml of 0.625 M sodium carbonate (FW 106; anhydrous, ACS reagent grade) in water. Add 2 ml acetylacetone (2,4-pentanedione, FW 100.1; Sigma). Prepare just prior to use.

Ehrlich reagent (DMAB)/HCl/acetic acid

Add 1.5 ml water to 11 ml concentrated HCl. Add 87.5 ml glacial acetic acid (FW 60.05; 99.99%; Aldrich). Dissolve 10 g *p*-dimethylaminobenzaldehyde (DMAB)—4-(*N,N*-dimethylamino)benzaldehyde, DMAB; crystalline, ACS reagent grade, FW 149.2—in the HCl/acetic acid mixture. Store in a dark bottle at room temperature (stable several weeks). Dilute 10 ml of mixture to 100 ml with glacial acetic acid immediately before using.

Ehrlich reagent (DMAB)/HCl

Weigh 1.6 g *p*-dimethylaminobenzaldehyde (DMAB)—4-(*N,N*-dimethylamino)benzaldehyde, DMAB; crystalline, ACS reagent grade, FW 149.2. Dissolve in 30 ml concentrated HCl. Store in a dark bottle at room temperature (stable several weeks).

Hexosamine standard stock solutions, 1 mM

Glucosamine: Dissolve 9 mg D-glucosamine hydrochloride (2-deoxy-D-glucose hydrochloride, FW 179.2) or 11 mg of *N*-acetyl-D-glucosamine (2-acetamido-2-deoxy-D-glucose, FW 221.2) in water. Dilute to 50 ml with more water. Store in aliquots at -20°C and thaw as needed.

Galactosamine: Dissolve 9 g *N*-acetyl-D-galactosamine hydrochloride (2-deoxy-D-galactose hydrochloride, FW 179.2) or 11 g *N*-acetyl-D-galactosamine (2-acetamido-2-deoxy-D-galactose, FW 221.2) in water. Dilute to 50 ml with more water. Store in aliquots at -20°C and thaw as needed.

Hexosamines may be obtained from Sigma.

Commentary

Background Information

The hexosamines glucosamine and galactosamine are the only amino sugars detected to date as structural components of glycoproteins and glycolipids. They generally occur in *N*-acetylated form. Provided they are quantitatively released from their glycosidic linkages, hexosamines can be quantitated colorimetrically. The primary problem, however, is achieving this quantitative liberation, because amino sugars are extremely stable under strongly acidic conditions (see UNIT 17.16).

Most methods reported for colorimetric quantitation of glucosamine and galactosamine, *N*-acetylated or not, are based on the procedures described by Elson and Morgan (1933) and Morgan and Elson (1934).

The basis of the Morgan-Elson reaction for quantitating *N*-acetylglucosamine (2-acetami-

do-2-deoxy-D-glucose) and *N*-acetylgalactosamine (2-acetamido-2-deoxy-D-galactose) is the red color produced by various *N*-acetylhexosamine derivatives on treatment with acidic Ehrlich reagent (*p*-dimethylaminobenzaldehyde, or DMAB) following pretreatment with alkali. Detection of free amino sugars using this reaction can be achieved by including a re-*N*-acetylation step in the procedure (Roseman and Ludowieg, 1954; Levvy and McAllan, 1959). A more sensitive method was developed based on the observation that the presence of borate buffer increases the intensity of color in the reaction (Reissig et al., 1955). Different structures have been proposed for the chromogens formed during the alkaline treatment of *N*-acetylhexosamines in the Morgan-Elson reaction (Foster and Horton, 1959).

The Elson-Morgan reaction for quantitating glucosamine (2-amino-2-deoxy-D-glucose) and galactosamine (2-amino-2-deoxy-D-galactose) involves the production of a red color upon successive treatment with alkaline acetylacetone (2,4-pentanedione) and the Ehrlich reagent. Both hexosamines produce similar color intensities (Rondle and Morgan, 1955). Several red compounds with different ultraviolet absorption maxima are produced in the Elson-Morgan reaction. The proportion of these products depends on the conditions used for the reactions with acetylacetone and the Ehrlich reagent.

Different methods for quantitating both hexosamines individually (when both are present), based on their different reactivities and the differential effects of borate ions in the reactions, have also been developed (Roseman and Daffner, 1956; Tracey, 1955; Ludowieg and Benmaman, 1967).

The protocols described here are those suggested by Chaplin (1986)—i.e., direct reaction with Ehrlich reagent (Alternate Protocol)—and by Montreuil (1986)—i.e., condensation with acetylacetone/Ehrlich reagent (Basic Protocol 2).

Critical Parameters

The presence of neutral sugars and amino acids interferes with the Elson-Morgan assay (Basic Protocol 2), because these react to produce orange chromophores. Therefore, when working with crude hydrolysis mixtures, interfering compounds should be removed before the assay is performed. The reactivity of all 2-amino-2-deoxy sugars in this assay is equivalent. Very careful control of the reaction conditions is required to obtain reproducible results, however, as different chromophores may play the significant role and some chromophores are volatile (e.g., 2-methylpyrrole). An *O*-methyl substitution at position 4 or 6 has little effect in the reaction, but 6-*O*-phosphate and 3-*O*-methyl both cause a shift in the absorption maximum, and the latter also increases the color intensity.

In the Morgan-Elson reaction (Alternate Protocol), furanosidic intermediates are produced in the course of chromogen formation. Therefore, some alkali-stable substituents (e.g., 4-*O*-methyl groups) can prevent color production, while other groups that are easily eliminated (e.g., 3-*O*-acetyl groups) can cause increased chromogen formation. *N*-acetylgalactosamine yields only 23% of the color produced by *N*-acetylglucosamine. The presence of bo-

rate buffer increases the intensity of color in the reaction. With borate, the interference of hexoses and amino acids is less pronounced. The use of different alkaline buffers and heating times during prochromogen formation produces differences in color yield between the different 2-acetamido sugars.

When the Alternate Protocol is used, the absorption curve of hexosamines shows a maximum at 520 nm but the extinction coefficients for glucosamine and galactosamine are different. Sialic acids react to produce a blue coloration, and muramic acids and *N*-acetylhexosamines interfere. Sodium tetraborate and sodium chloride decrease the intensity of the coloration.

Anticipated Results

Any of the protocols described here will give a fair estimation of the total content of hexosamines in a given glycoconjugate, provided hexosamine release is complete.

Time Considerations

The most time-consuming step of this procedure is hydrolysis of the hexosamines, particularly when conditions for complete release need to be determined. The colorimetric reactions take 1 hr (Alternate Protocol) or 2 hr (Basic Protocol 2), respectively. If re-*N*-acetylation is required, an additional hour will be necessary.

THIOBARBITURIC ACID ASSAY FOR SIALIC ACIDS WITH SPECTROPHOTOMETRIC OR HPLC DETECTION

Unconjugated sialic acids can be measured by oxidation with periodate followed by reaction with the chromogen 2'-thiobarbituric acid (TBA) to form a salmon-pink compound. This chromophore can be detected either by conventional spectrophotometry, with a sensitivity of 1 to 10 nmol, or by HPLC, with a sensitivity of 2 to 10 pmol. The latter approach requires more equipment, but provides substantially improved sensitivity and eliminates interference by some compounds. The most common types of sialic acid, *N*-acetyl- and *N*-glycolylneuraminic acid (Neu5Ac and Neu5Gc, respectively), can be accurately quantitated by this assay. Modified (e.g., *O*-acetylated) sialic acids give variably reduced color response. Glycosidically bound molecules must be released by treatment with base (see Support Protocol 2) followed by mild acid (see Support Protocol 3) or sialidase treatment (*UNIT 17.12*) before detection.

Materials

- Sialic acid-containing sample in solution
- Periodate reagent (see recipe)
- 1 mM *N*-acetylneuraminic acid (Neu5Ac; store at -20°C ; stable indefinitely)
- 1 mM 2-deoxyribose (optional; store at -20°C ; stable indefinitely)
- Arsenite reagent (see recipe)
- TBA reagent (see recipe)
- Cyclohexanone (for spectrophotometric detection)
- HPLC elution buffer (see recipe; for HPLC detection)
- Heating block, 100°C
- For spectrophotometric detection:
 - New 12 \times 75-mm glass tubes
 - Clean glass marbles
 - Tabletop centrifuge
 - Spectrophotometer and 1.0-ml glass cuvettes
- For HPLC detection:
 - 0.4 \times 25-cm C_{18} reversed-phase HPLC column
 - Equipment for HPLC (*UNIT 10.2*)
 - HPLC UV detector with flow detector cell of volume $<20\ \mu\text{l}$, and integrating chart recorder if available

Prepare sample, standards, and controls

1. Prepare two identical 50- μl samples of free or released sialic acid in sample buffer. Add 25 μl periodate reagent to the sample without touching the sides of the tube. Vortex briefly at low speed to mix.

Free sialic acid samples may be derived from biochemical samples (e.g., purified proteins, total serum glycoproteins, or lipid extracts) either by sialidase digestion (UNIT 17.12) or by acid treatment (see Support Protocol 2 or UNIT 17.16).

Use new 12 × 75-mm glass tubes if later detection will be by spectrophotometric assay or 1.5-ml polypropylene microcentrifuge tubes for later HPLC assay.

2. Prepare a series of dilutions of Neu5Ac in the same buffer as that in which the sample is dissolved. Use a range of 1, 4, 10, and 15 nmol for the spectrophotometric assay and 2, 5, 20, 100, and 500 pmol for the HPLC assay. Also prepare two blank samples containing the same total quantity of buffer only. Treat standards and blanks with periodate as described in step 1.

Optionally, samples with 5 to 10 nmol 2-deoxyribose may also be prepared to be used as standards for interfering compounds in the sample.

Oxidize and react with TBA

3. Incubate all tubes 20 min at room temperature.
4. Slowly add 250 μ l arsenite reagent along the rim of each tube so it flows down the sides. Watch for a brown color to begin to develop in the sample and standard tubes (up to 2 min), then vortex vigorously.

The brown color results from the reduction of the periodate, which forms iodine. If any periodate remains unquenched, the TBA chromophore will not be produced. Occasionally the brown color will not appear (Troubleshooting).

5. Incubate tubes 5 min at room temperature.

At this point the tubes can be stored overnight at 4°C if desired.

6. Add 1 ml TBA reagent to each tube, mix well, and heat 15 min at 100°C. Cover each glass tube with a clean glass marble to minimize evaporation, or pierce microcentrifuge tube caps with a needle after closing. A pink color will develop in samples containing >0.5 nmol sialic acid. Chill 2 to 3 min on ice and keep on ice until chromophore detection is performed (beginning at step 7a or 7b).

Volumes of sample, periodate, and arsenite can be changed as long as the proportions remain the same. However, the volume of TBA can be decreased independently if necessary, to accommodate a small tube size (e.g., microcentrifuge tube).

Detect chromophore by spectrophotometric measurement

- 7a. Add 1 ml cyclohexanone to each tube. Vortex well to extract the pink chromophore into the upper (cyclohexanone) layer, then centrifuge 5 min at 500 to 2000 \times *g* (e.g., 1500 rpm in a tabletop centrifuge), room temperature, to separate the phases.

Depending on the size of the cuvettes, the volume of cyclohexanone can be reduced to improve sensitivity.

- 8a. Transfer an appropriate volume of the cyclohexanone layer (0.3 to 0.8 ml, depending on cuvette size) to a 1.0-ml glass cuvette. Read its absorbance at both 549 nm and 532 nm, adjusting against the values obtained for the blank.

The chromophore generated from sialic acids has an absorption maximum of 549 nm. Interfering substances, including 2-deoxyribose and peroxidation products of fatty acids, produce a chromophore with an absorption maximum of 532 nm.

- 9a. Calculate the ratios of A_{549}/A_{532} for the sialic acid standards and the sample. If the ratios match, this indicates that there is no interference. If the ratio is lower for the sample than the standard, perform the calculation indicated in steps 10a to 12a to compensate for interference.

- 10a. Calculate the value of $(0.9 \times A_{549} - 0.3 \times A_{532})$ for samples and standards.
- 11a. Plot a standard curve with these values and determine amount of sialic acid in the samples.
- 12a. Apply the calculations to the 2-deoxyribose sample to assure validity (this value should be close to zero after correction).

These correction coefficients are based on the original publications of Warren (1959) and Aminoff (1959) and generally work for most spectrophotometers. However, variations in slit width between instruments may decrease the correction coefficient accuracy. If unacceptable variance is found, correction coefficients should be determined directly as described in those original publications. The correction becomes less accurate if A_{532} is $>0.7 \times A_{549}$, and the result is practically meaningless if A_{532} is $>1.5 \times A_{549}$.

Detect chromophore by HPLC measurement

- 7b. Equilibrate an 0.4×25 -cm C_{18} reversed-phase HPLC column in HPLC elution buffer running at 0.7 to 1.0 ml/min. Connect column to a UV detector set at 549 nm. Connect the UV detector to an integrating data module, if available.

Faster flow rates, within the pressure limits of the column, will reduce the time required and will not adversely affect sensitivity. Columns 10 to 15 cm long may also be utilized.

All HPLC buffers must be filtered and degassed. A flow detector cell with a volume of $<20 \mu\text{l}$ is essential for maximal sensitivity.

- 8b. Keep the tubes on ice. Immediately prior to performing HPLC, microcentrifuge all tubes 2 to 4 min at $>5,000 \times g$, 4°C , to remove any precipitated reagents.

Keeping the samples chilled maximizes the precipitation of unused TBA, reducing the risk that it will precipitate in the HPLC apparatus.

- 9b. Inject aliquots of the derivatized Neu5Ac standards (and 2-deoxyribose standard, if included) and collect data using UV detector with flow recorder.

Chromophores resulting from these two sugars will elute at 5 to 10 min and 10 to 20 min, respectively, depending on the particular column and the methanol concentration in the elution buffer.

The concentration of methanol in the HPLC elution buffer should result in elution of the TBA chromophore at 6 to 10 min. If the chromophore elutes too early on the particular column in use, decrease the methanol concentration; likewise, increase methanol concentration if the peak elutes too late.

- 10b. Quantitate the signal from each standard, and blank by integration and construct a standard curve.

If a data module capable of integration is not available, the signal can be quantitated by measuring the peak height from a chart recorder.

- 11b. Inject 10 to $400 \mu\text{l}$ of each sample and collect data as in step 10b. Calculate the amount of sialic acid present based on the standard curve.

The amount of sample injected should be based on the amount of sialic acid believed to be present. Quantitation is not affected by the volume injected. Total volumes of sample and reagents can be decreased proportionately to further improve sensitivity by increasing the amount of chromophore present in the injected volume.

When setting up the column for the first time, inject sample of buffer blank or (derivatized) Neu5Ac (100 to 500 pmol) to verify elution times.

At the end of each day wash the column thoroughly with 50% acetonitrile or 50% methanol.

DE-O-ACETYLATION OF SIALIC ACIDS

O-acetylated sialic acids are detected with reduced sensitivity by the TBA assay. Furthermore, O-acetylation may reduce the release of sialic acids from glycoconjugates by either acid hydrolysis (see Support Protocol 3) or some sialidases (*UNIT 17.12*). Because sialic acids from some biological source may be as much as 50% to 100% O-acetylated, de-O-acetylation with base treatment is necessary for accurate quantitation. This fact can be useful, as the amount of color yield in the TBA assay before and after base treatment can be used to recognize the presence of O-acetylated sialic acids. Alternatively, specific O-acetylated sialic acid species can be identified by the DMB assay (see Basic Protocol 4).

Materials

Sialic acid-containing sample in solution
0.2 M NaOH (store at room temperature)
0.9 M H₂SO₄ (for acid release) or 0.2 M acetic acid (for enzymatic release)

1. Mix 20 μ l sialic acid-containing sample with 40 μ l of 0.1 M NaOH and incubate 30 min at 37°C.
- 2a. *For acid release:* Add 4.5 μ l of 0.9 M H₂SO₄ to bring to a final concentration of 0.1 M H₂SO₄ (in excess of Na₂SO₄) and proceed directly to BHT treatment (see Support Protocol 3, steps 2 to 4).

If the sample is free of potential lipid contaminants, the BHT step may be omitted and the sample utilized directly in the TBA or DMB assay.

- 2b. *For enzymatic release:* Neutralize with 20 μ l of 0.2 M acetic acid (check pH on a blank sample to verify it is between 5 and 7). Proceed to sialidase treatment (*UNIT 17.12*).

ACID RELEASE OF DE-O-ACETYLATED SIALIC ACIDS

Acid treatment (0.1 M H₂SO₄) can be used as an alternative to sialidase digestion (*UNIT 17.12*) to release glycosidically bound sialic acid molecules for subsequent quantitation by the TBA assay. O-acetylation is incompletely and variably destroyed by this type of acid treatment. On the other hand, O-acetylation can itself hinder the release of sialic acids. Thus, it is best to eliminate all O-acetyl esters prior to acid hydrolysis by base release (see Support Protocol 2). Alternatively, to preserve O-acetylation (for study with the DMB assay; see Basic Protocol 4), sialic acid may be released by mild acid treatment as described in *UNIT 17.16*.

Materials

Sialic acid-containing sample in solution, preferably de-O-acetylated (see Support Protocol 2)
0.2 M H₂SO₄
1% (w/v) BHT in ethanol (see recipe)
Clean glass marbles
Heating block, 80°C

1. Mix 25 μ l sample with 25 μ l of 0.2 M H₂SO₄ in the bottom of a clean glass tube.

If the sample has been de-O-acetylated in 40 μ l of 0.1 M NaOH and 4.5 μ l of 0.9 M H₂SO₄ added (in Support Protocol 2), this will result in a final excess acid concentration of 0.1 M and the same final volume.

2. Add 0.5 μ l of 1% BHT in ethanol to sample.
BHT prevents interference caused by peroxidation of hydroxylated fatty acids.
3. Cover the tube with a clean glass marble to minimize evaporation and heat 1 hr at 80°C.
4. Cool sample on ice. Proceed with TBA assay (see Basic Protocol 3, starting at step 1) without further adjustment.

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Arsenite reagent

Dissolve 10.0 g sodium arsenite and 7.1 g sodium sulfate in 70 ml of 0.1 M sulfuric acid. Add additional acid to bring volume to 100 ml. Store indefinitely at room temperature.

The final sodium arsenite concentration is 10% (w/v).

Butylated hydroxytoluene (BHT) in ethanol

Dissolve 100 mg BHT (2,6-di-*tert*-butyl-4-hydroxyanisole, FW 220.4; Sigma) in 10 ml of 100% ethanol. Store tightly capped at room temperature indefinitely.

HPLC elution buffer

Prepare a 2:3:5 (v/v/v) mixture of water/HPLC-grade methanol/0.2% (v/v) ortho-phosphoric acid (85%, ACS reagent grade). Filter mixture and degas.

Periodate reagent

128 mg sodium *meta*-periodate (Sigma; 0.2 M final)

1.3 ml H₂O

1.7 ml phosphoric acid (*ortho*-phosphoric acid, 85%, ACS reagent grade)

Mix well to dissolve

Store indefinitely at 4°C in a dark, foil-covered bottle

TBA reagent

Dissolve 14.2 g sodium sulfate in 170 ml water. Add 1.2 g 2-thiobarbituric acid (4,6-dihydroxypyrimidine-2-thiol, 98%; Sigma). Complete the dissolution of the TBA by adding 1 M NaOH dropwise to ~pH 9, then dilute with water to 200 ml. Store at room temperature.

The solution is stable almost indefinitely—even when a yellow precipitate appears, the reagent can still be used if care is taken to avoid the particulate material.

If HPLC detection is used, sodium sulfate may be omitted from both the TBA and arsenite solutions, as its function is to “salt out” the TBA chromophore into the cyclohexanone layer.

Commentary

Background Information

The original assay for sialic acids described independently by Warren (1959) and Aminoff (1959) is based upon the formation of an adduct between the periodate oxidation product of free unsubstituted sialic acids and 2'-thiobarbituric acid (TBA). The procedure has been modified

over the years (Schauer, 1978; Varki and Kornfeld 1980; Powell and Hart, 1986) to maximize its sensitivity and specificity and to minimize interference. The most useful modifications have been the following:

(1) Prior de-O-acetylation to eliminate the interference of *O*-acetyl esters with the perio-

date oxidation of sialic acid. An increase in color yield after de-O-acetylation indicates the presence of O-acetylation.

(2) An increase in the acid concentration in the arsenite reagent. This seems to avoid subsequent reaction failure by ensuring complete destruction of the periodate.

(3) Addition of BHT (butylated hydroxytoluene) during acid or enzyme release of sialic acids. This minimizes lipid peroxidation and formation of interfering malonaldehyde (Critical Parameters).

(4) Use of reversed-phase HPLC to remove interfering chromophores and improve sensitivity.

Critical Parameters

Complete oxidation of sialic acids in the presence of high concentrations of phosphoric acid and periodate yields β -formyl pyruvic acid. One molecule of this compound condenses with two molecules of TBA (under elevated temperature) to produce the brightly colored TBA adduct (Paerels & Schut, 1965). *O*-acetyl esters on the hydroxyl groups of sialic acids can cause varying degrees of interference, ranging from none (4-*O*-acetylation) or 50% (9-*O*-acetylation) to >90% (7-*O*-acetylation, multiple *O*-acetylations). Prior de-*O*-acetylation prevents this interference in the color yield. Less common substitutions (e.g., *O*-methyl groups) can also cause varying degrees of lower reactivity in comparison to Neu5Ac. For unknown reasons, the color yield also varies according to the substitution at the 5 position, in the approximate ratio of 1:0.8:2.0 for Neu5Ac, Neu5Gc, and 2-keto-3-deoxyoctonate (KDO—as well as, presumably, 2-keto-3-deoxynonosonic acid, KDN) respectively. For working purposes, Neu5Ac is initially used as a standard. Once the approximate amount of sialic acids in the sample is known, more detailed analysis of the types present can be performed (see Basic Protocol 4).

Compounds which, under the conditions of strong acid and periodate, yield β -formylpyruvic acid will yield a salmon-pink TBA chromophore of λ_{\max} 549 nm. These compounds include Neu5Ac, Neu5Gc, KDO, KDN, and the 3-keto-2-deoxyaldulosonic acids. Under these conditions other compounds yield malonaldehyde which, following condensation with TBA, yields an orange-yellow chromophore of λ_{\max} 532 nm. These compounds include 2-deoxyribose and the oxidation products of unsaturated lipids. Spontaneous peroxidation of lipids to malonaldehyde frequently occurs during sam-

ple handling and is accelerated by heat, light, acid pH, and some cations (lipids are frequently encountered, as sialic acids are often associated with membranes). Spontaneous peroxidation can be reduced or prevented by adding antioxidants such as BHT prior to storage or hydrolysis of samples. The presence of malonaldehyde-yielding substances can be detected and corrected for by measuring A_{549} and A_{532} (see Basic Protocol 1). Moreover, the two different chromophores arising from β -formylpyruvic acid and malonaldehyde are easily resolved by HPLC.

Troubleshooting

Failure of brown color to develop after addition of arsenite reagent may be caused by overly rapid addition of the arsenite or inadequate acid in the sample. This latter indicates that the periodate has not been fully consumed and will interfere with formation of the TBA chromophore. Alternatively, even if the brown color is seen, traces of periodate remaining on the walls of the reaction vessel (and therefore not exposed to the arsenite) may still also interfere. Certain buffers (particularly formate, which is frequently used during sialic acid purification) interfere when present in large quantities, giving a bright yellow color instead of the expected salmon pink. The predicted elution times of the chromophores from the C_{18} column are based on experience with several different columns from different suppliers. If trouble is encountered in detecting elution of the chromophores (from sialic acid or 2-deoxyribose), inject 10 to 50 ml of a visibly pink standard solution (e.g., 5 nmol). Two peaks should be seen eluting after the breakthrough peak (V_0), corresponding to the TBA adducts formed from β -formylpyruvic acid (eluting first) and malonaldehyde (eluting second). An even later-eluting reagent peak may also be seen, at an elution time 2 to 3 times that of the TBA chromophore, depending on the injected volume. If these peaks are not seen, or elute later than the indicated times, increase the concentration of methanol and allow the column to equilibrate at least 30 min between changes in methanol concentration.

Anticipated Results

For both the spectrophotometric and HPLC assays, the standard curve for A_{592} vs. nmol sialic acid should be linear over the suggested concentration ranges. Significant deviation from linearity indicates either improper dilution of the sialic acid standard or improper

concentration of one of the reagents. If modifications are made in the outlined protocol, the ratios of sample/periodate/arsenite must be kept constant, as these are optimized for concentrations of periodate, phosphoric acid, and arsenite. An excessive amount of any reagent can be as detrimental as an insufficient amount.

Time Considerations

Preparation of the standard curve and samples should take <3 hr. Determining the absorbance of each sample by HPLC will take ~15 to 20 min. Setup time for HPLC is indicated in *UNIT 10.12*.

BASIC PROTOCOL 4

DMB ASSAY FOR SIALIC ACIDS WITH HPLC DETECTION

The method of choice for characterizing the individual components of a sialic acid mixture is the preparation of fluorescent derivatives. Mixtures of free sialic acids obtained using the protocols described in *UNIT 17.16* or *UNIT 17.12* can be reacted directly with 1,2-diamino-4,5-methylenedioxybenzene dihydrochloride (DMB) without the need for further purification. DMB derivatives of sialic acids are analyzed by HPLC on a reversed-phase column and detected fluorometrically.

Materials

N-acetylneuraminic acid (Neu5Ac, MW 309.3; Boehringer Mannheim)

Standard mixture: sialic acids prepared from bovine submaxillary mucin (BSM) using the procedure in *UNIT 17.16*, or mixture of 100 pmol each Neu5Ac and *N*-glycolylneuraminic acid (Neu5Gc, MW 325.3; Sigma)

Sample containing mixture of free sialic acids in solution (5 to 1000 pmol; *UNIT 17.16* or *UNIT 17.12*)

DMB reagent (see recipe)

Acetonitrile (HPLC grade)

50% methanol (HPLC grade) in Milli-Q-purified water

Milli-Q-purified water: deionized water passed through a five-stage Milli-Q Plus system (Millipore)

Helium (for HPLC apparatus)

Heating block, 50°C

HPLC apparatus (preferably ternary system) including pump and fluorescent detector (*UNIT 10.12*)

TSK gel ODS-120T column (250 mm × 4.6 mm i.d., 5 μm particle size; TosoHass)

Guard cartridge TSK gel ODS-120T (1.5 × 3.2 mm)

Filtering unit with 0.45-μm Nylon 66 membranes (Alltech)

Prepare fluorescent derivatives of sialic acids

1. Transfer sample containing 5 to 1000 pmol free sialic acids to a 1.5-ml microcentrifuge tube and dry in a Speedvac. Prepare 1 nmol of each standard (Neu5Ac and standard mixture) in the same fashion.
2. Dissolve the samples in 1 to 5 μ l water.
3. Add 30 μ l DMB reagent and wrap each tube in aluminum foil. Heat 2.5 hr in a heating block at 50°C.
4. Remove and place on ice.

Analysis should be done as soon as possible, but the DMB derivatives can be kept overnight at 4°C.

Analyze the fluorescent derivatives by HPLC with fluorometric detection

5. Turn on the fluorescent detector. Set emission wavelength to 448 nm, excitation wavelength to 373 nm, high voltage to 900, range to 500, and response time to 0.5 sec.
6. Fill the three HPLC bottles with (respectively) acetonitrile, 50% methanol, and filtered Milli-Q-purified water. Degas for 15 min and filter through 0.45- μ m membranes.
7. Run each solvent through the attached lines of the HPLC apparatus to eliminate any bubbles.
8. Set the pump control unit for an isocratic elution with a ratio of 9:7:84 (v/v/v) acetonitrile/methanol/water.

Because 50% methanol is used (to avoid the production of bubbles that occurs when mixing water and pure methanol), 14% of this solvent needs to be run to obtain 7% methanol (i.e., run 9 parts acetonitrile, 14 parts methanol/water mix, and 77 parts water). When a ternary HPLC system is not available, the eluant can be prepared ahead in the ratio stated above.

9. Begin running the solvent at 0.3 ml/min, then connect the TSK gel column to the Guard cartridge. Increase the flow 0.1 ml/min at a time, waiting for stable backpressure between steps, until 0.9 ml/min flow is attained. Wait until a stable baseline is obtained.

The following settings are adequate for most integrators: attenuation, 512; peak threshold, 10000.

10. Inject 100 pmol DMB-derivatized Neu5Ac standard. Check the sensitivity and adjust the integrator settings as required (the way this step is performed will depend on the particular integrator used). Repeat the run if necessary.
11. Inject DMB-derivatized standard mixture (100 pmol each Neu5Ac and Neu5Gc, or mixture containing O-substituted standards prepared from BSM, if available).
12. Inject the derivatized samples. Adjust the integrator settings as necessary, and repeat to obtain all peaks in scale. Calculate the retention time of each peak relative to Neu5Ac and compare with those listed in Table 17.18.1.

Keep the volume of DMB reaction mixture injected as low as possible to maintain column performance. In other words, it is better to use lower attenuation in the integrator and inject a smaller volume of reagent into the HPLC column. When the total amount of sialic acids in the sample is not known, first inject 10% of the total reaction mixture with a low attenuation setting, then if necessary inject more or change the settings.

Table 17.18.1 Relative Elution Times of DMB-Derivatized Sialic Acids from TSK-ODS Column

Sialic acid	t_{Neu5Ac} (min)
Neu5Ac	1.00
Neu5Gc	0.84
Neu5-7Ac ₂	1.06
Neu5-9Ac ₂	1.57
Neu4-5Ac ₂	1.68
Neu5-7(8)-9Ac ₃	1.90
Neu5-7-8-9Ac ₄	1.98
Neu5Gc9Ac	0.88
Neu4Ac5Gc	1.53

13. Determine the units of area per picomole for Neu5Ac and/or Neu5Gc. Assuming equal detector responses, calculate the number of picomoles represented by each peak produced by the samples.

This system can be used to analyze radioactive samples by routing the column effluent to a radioisotope flow detector or fraction collector. The appropriate ratio of scintillation fluid needs to be checked because of the quenching effect of acetonitrile.

14. Verify the presence of the O-acetylated species (see Table 17.18.1 for relative retention times) by collecting each peak, lyophilizing, subjecting to de-O-acetylation (see Support Protocol 2), and reanalyzing. Alternatively, another aliquot of the starting material can be submitted to de-O-acetylation prior to derivatization. In this case, all peaks corresponding to O-acetylated species will collapse into the peak of their parent molecule (Neu5Ac or Neu5Gc).
15. At the end of the day, wash the column with 50% methanol for 30 min at a flow of 0.5 ml/min.

When resolution becomes poor, the column can be cleaned by running it in reverse flow at 0.5 ml/min with a gradient from 10% to 100% acetonitrile in 0.05% trifluoroacetic acid over 1 hr. The column must then be extensively washed with water at 0.5 ml/min, turned around, and reequilibrated with 50% methanol.

Reagents and Solutions

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

DMB reagent

1.6 g 1,2-diamino-4,5-methylenedioxybenzene dihydrochloride (DMB, FW 225.1; Sigma)

80.4 μ l glacial acetic acid (HPLC grade; 1.4 M final)

52.8 μ l 2-mercaptoethanol (FW 78.13; Bio-Rad)

72 μ l 0.25 M sodium hydrosulfite

Store in a container covered with aluminum foil 1 week at 4°C

DMB reagent is light sensitive.

The 0.25 M sodium hydrosulfite solution is made by dissolving the compound (FW 174.1; ~80% pure, Sigma) in water at 43.5 mg/ml.

Commentary

Background Information

Sialic acids released by hydrolysis in 2 M acetic acid or by enzymatic treatment are converted with 1,2-diamino-4,5-methylenedioxybenzene (DMB, a fluorogenic reagent for α -keto acids) to highly fluorescent derivatives (see Fig. 17.18.1) without the occurrence of *O*-acetyl migration and de-*O*-acetylation.

The derivatives are separated using a reversed-phase TSK ODS-120T column eluted isocratically with 9:7:84 (v/v/v) acetonitrile/methanol/water at room temperature in ~25 min. Fluorescence of the eluate is monitored at an excitation wavelength of 373 nm and an emission wavelength of 448 nm. The average limits of detection are 1 to 2 pmol at a signal-to-noise ratio of 3.

Fluorogenic reagents may be used for detection of α -keto acids in very dilute solutions because of their quantitative conversion into the corresponding substituted quinoxalines

(Spiker and Towne, 1962; Hara et al., 1985a). Because sialic acids are α -keto acids, Hara et al. (1985b) tried several of these reagents and found that 1,2-diamino-4,5-dimethoxybenzene reacts with Neu5Ac and Neu5Gc under conditions different than those for other α -keto acids and forms fluorescent compounds. They developed a method for detecting small amounts of Neu5Ac and Neu5Gc in serum and urine using HPLC (Hara et al., 1986) and further extended the method to the analysis of glycoproteins and glycolipids (Hara et al., 1987a). Screening different diamino benzenes as fluorogenic reagents revealed that 1,2-diamino-4,5-methylenedioxybenzene (DMB) is the best reagent for sensitive and rapid detection of α -keto acids (Hara et al., 1987b).

The DMB method could not be applied to *O*-acetylated sialic acids because of de-*O*-acetylation and *O*-acetyl migration in the sulfuric acid used in the reaction. However, *O*-acety-

Figure 17.18.1 Reaction of sialic acids with 1,2-diamino-4,5-methylenedioxybenzene (DMB) to form fluorescent derivatives.

lated sialic acids react with DMB in acetic acid at lower temperatures to form fluorescent derivatives, completely avoiding those reactions (Hara et al., 1989). More recently, the value of this technique has been confirmed and extended to the analysis of several additional sialic acid molecules (Manzi et al., 1990).

Critical Parameters

The reaction of sialic acids with DMB is highly specific under controlled conditions (other α -keto acids that may be present in biological samples give very weak responses and/or very delayed retention times under the conditions recommended for the analysis). Most known naturally occurring substituted sialic acids can be derivatized and separated (see Fig. 17.18.2). Exceptions are the 2,3-dehydro sialic acids and glycosides that do not have an α -keto group available for the reaction. The presence of *O*-acetyl esters can be confirmed by repeating the analysis after base treatment (see Support Protocol 2).

Reliable detection and quantitation is possible with 2.5 pmol of any sialic acid. To maintain column performance it is advisable to keep the injection volume of DMB reaction mixture as low as possible. Evidence obtained using ra-

dioactively labeled sialic acids indicates that different degree of derivatization probably occur with molecules with different substitutions. Therefore, it is possible to accurately quantitate a given peak only when a corresponding standard is available, and quantitation of substituted species by comparison with Neu5Ac is only approximate.

Anticipated Results

This protocol will give a qualitative and semiquantitative composition analysis of sialic acids in a mixture release from glycoconjugates using picomole amounts (Critical Parameters has a more detailed discussion).

Time Considerations

When several samples need to be analyzed, because the DMB reaction takes 2.5 hr it is best to do it at the end of the day and keep the derivatized samples at 4°C overnight before analysis. The total time required for each HPLC run is ~30 min. It is advisable to run standards at the beginning and the end of each day to compare relative retention times and area/pmol. A total of 10 to 12 runs can be done in one 8-hr day.

Figure 17.18.2 HPLC profile (fluorescence vs. time) of the DMB derivatives of total sialic acids released from BSM (bovine submaxillary mucin) with 2 M acetic acid and purified according to the protocol described in UNIT 17.16.

Total Compositional Analysis by High-Performance Liquid Chromatography or Gas-Liquid Chromatography

UNIT 17.19A

Once the presence of carbohydrate in a glycoprotein has been confirmed, the next step is to determine the precise molar ratio of its monosaccharide constituents using protocols in this unit and in the accompanying *UNIT 17.19B* (which presents the compositional analysis of labeled monosaccharides from glycosaminoglycans). This information helps to predict the type of oligosaccharide present and to determine the approach to detailed structural characterization. In some cases, it can also provide the first clues to the presence of a new type of sugar chain. The analysis involves two major phases. First, the release of the individual monosaccharides is achieved by methanolysis (Support Protocol 1), total acid hydrolysis (*UNIT 17.16*), or enzymatic release of sialic acids (*UNIT 17.12*). The second phase involves analysis by fractionation, characterization, and quantitation of the mixtures of monosaccharides by high-performance liquid chromatography using anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD; Basic Protocols 1, 2, and 3) and other HPLC systems (e.g., Alternate Protocol 1) or by gas-liquid chromatography with flame ionization detection (GLC-FID; Basic Protocol 4). The identity of the individual monosaccharides is determined by comparison with known standards processed and analyzed in the same way. Use of these protocols requires availability of instrumentation and understanding of setup maintenance and use.

STRATEGIC PLANNING

The flow chart in Figure 17.19.1 illustrates the alternative pathways and sequence of steps involved in compositional analysis. The protocols presented in this unit describe alternative approaches for the analysis of monosaccharide mixtures obtained by total acid hydrolysis (*UNIT 17.16*) or methanolysis (Support Protocol 1). The following considerations may help the investigator to plan the approach most appropriate for the starting material and intended results.

The choice of protocol to be used to release the individual monosaccharides from the starting glycoconjugate sample depends upon the nature of the material to be analyzed as well as the analysis method to be used. In general, glycoconjugates may be cleaved to their constituent monosaccharides by acid hydrolysis (*UNIT 17.16*) or methanolysis (Support Protocol 1). For the analysis of the constituents of neutral glycoconjugates, total acid hydrolysis of the sample is recommended. Glycoconjugates that may contain hexosamines or uronic acid can be broken down either by acid hydrolysis or methanolysis, and sialic acid residues can be released either enzymatically (as described in *UNIT 17.12*) or by hydrolysis in the presence of mild acid (*UNIT 17.16*). Note that the harsher acid conditions used to release the other monosaccharides cause destruction of sialic acids. For most glycoconjugates, the use of methanolysis to cleave glycosidic linkages is quite effective and generally results in less destruction of the monosaccharides than does acid hydrolysis (see Commentary for a more explicit discussion).

Frequently, the availability of instrumentation determines the choice between comparable options. For most HPLC approaches, such as those described in Basic Protocols 1, 2, and 3, the mixtures of monosaccharides released by acid hydrolysis is directly analysed without further treatment. Mixtures of monosaccharides, released by acid hydrolysis or by methanolysis, being subjected to analysis by GLC-FID (Basic Protocol 4), however, require an initial derivatization step (or series of steps) to convert the mixture to volatile

compounds. These volatile derivatives can be produced from monosaccharide mixtures using one of the two alternative methods described in the support protocols. In the first derivatization approach, monosaccharide mixtures obtained from acid hydrolysis undergo reduction and peracetylation to produce volatile alditol acetates (Support Protocol 2). In the second approach, the products of methanolysis are converted to volatile trimethylsilyl derivatives (Support Protocol 3). In both cases, the resulting volatile compounds are then analyzed by GLC-FID.

Many different methods have been developed for each strategy, each with its own advantages and disadvantages (a more complete discussion and comparison of alternatives is presented in the Commentary). This unit presents reliable methods that have been proven to be widely applicable.

COMPOSITIONAL ANALYSIS OF FREE MONOSACCHARIDES BY HPAEC-PAD

The mixtures of monosaccharides obtained by acid hydrolysis (*UNIT 17.16*) of a glycoconjugate can be directly analyzed by high-performance liquid chromatography using ion-exchange pellicular resin columns with pulsed amperometric detection (HPAEC-PAD). Figure 17.19.2 provides a schema of a HPAEC-PAD system equipped with a reservoir for postcolumn addition of base. The following protocol (for separating mixtures of neutral monosaccharides and hexoamines) refers to this basic system but may also be adapted for use with newer instruments such as the Dionex DX-300 or DX-500, in which the arrangement of components is somewhat different. In the DX-500, for example, vacuum rather than helium sparging is used to degas the eluants, and because the PAD detector is more sensitive, postcolumn addition of base is not needed. Furthermore, the system can be completely controlled from a computer so that a procedure, including the elution conditions and the detection and integration parameters, can be created and stored as a method file. This method can later be called up and used. Consult the manufacturers' instructions for details of the use of these newer systems. The basic principles of operation and detection and the columns used for separation are the same.

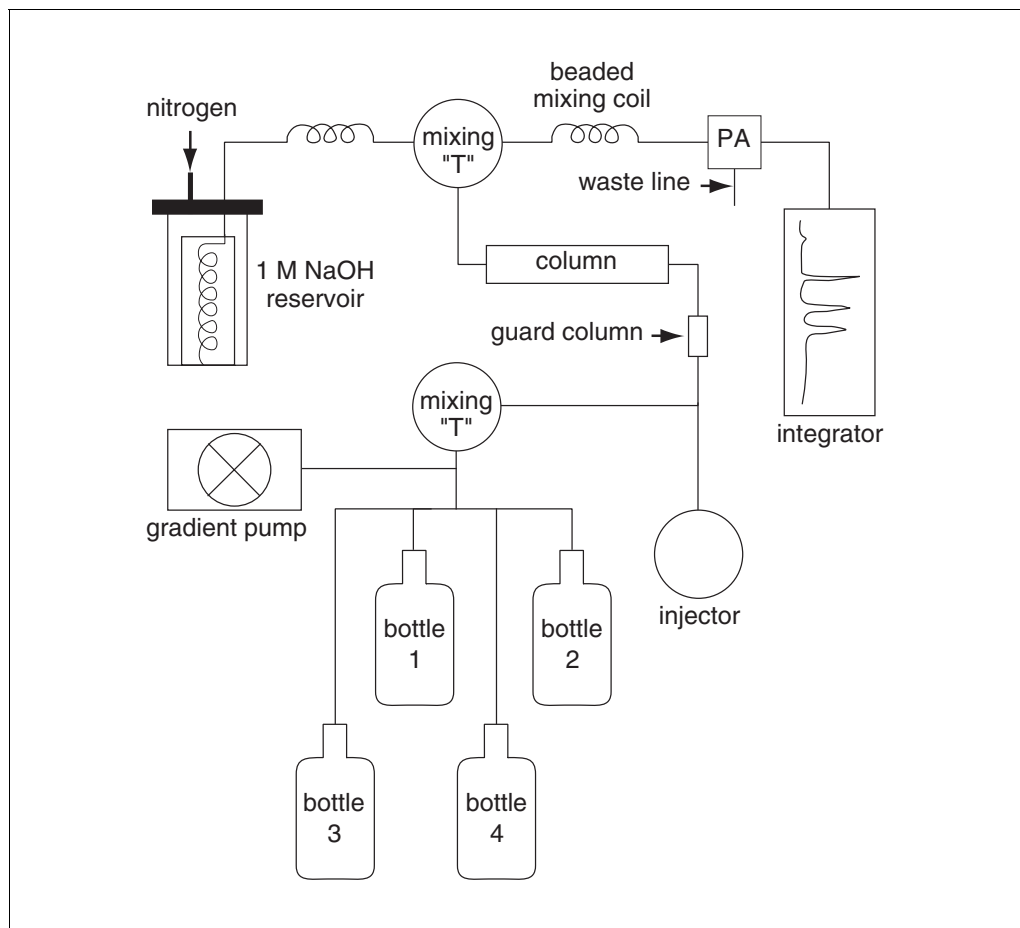

Figure 17.19.2 Schema of a high-performance anion-exchange chromatography system with pulsed-amperometric detector and post-column delivery system.

Analysis of Mixtures of Neutral Monosaccharides and Hexosamines

Materials

Milli-Q-purified water: water deionized by passage through a five-stage Milli-Q Plus system (Millipore)

Certified 50% (19.3 M) sodium hydroxide containing <0.1% sodium carbonate (Fisher)

Nitrogen

Monosaccharide standard mixture (see Support Protocol 4)

Monosaccharide sample prepared by acid hydrolysis (UNIT 17.16: Basic Protocol 3, Basic Protocol 1 when analyzing only fucose)

Filtering unit with 0.45- μ m Nylon 66 membranes (Alltech)

High-pH anion-exchange chromatography system with pulsed amperometric detector consisting of gradient pump, eluant degassing module, and PAD cell equipped with thin gasket (Dionex)

CarboPac PA-1 column (250 \times 4 mm; Dionex)

CarboPac PA Guard column (3 \times 25 mm; Dionex)

Prepare the HPAEC-PAD system

1. Filter 6 liters Milli-Q-purified water through a 0.45- μ m membrane. Transfer 2 liters to bottle 1, 1997 ml to bottle 2, and 1980 ml to bottle 3. Connect to helium sparge line and degas 15 min.

Always rinse the bottles before using them and make sure the lines are equipped with polyethylene inlet frit filters. If 4-liter bottles are available, double the volumes of liquid in the bottles.

2. Prepare 25 mM and 200 mM sodium hydroxide solutions by adding (using disposable plastic pipets) 2.6 and 20.8 ml of 50% sodium hydroxide solution to bottles 2 and 3, respectively. Avoid bubbling air when adding. Degas for another 15 min.

IMPORTANT NOTE: *It is critical that the sodium hydroxide solution be free of carbonate. Do not use sodium hydroxide pellets, as these are usually coated with a film of sodium carbonate produced by absorption of CO₂ from the air; instead, use only 50% (19.3 M) NaOH solution that is free of carbonate. Take the solution from the middle of the bottle. Any CO₂ absorbed will precipitate in 50% NaOH.*

Keep all eluants under helium or vacuum (depending on the instrument used) at all times. Discard any remaining eluants after ~2 weeks and prepare fresh ones. Do not store the Milli-Q-purified water to be used with this system in plastic containers. Rather, use freshly processed water taken directly from the Milli-Q purification system. Do not use plastic tubing extensions out of the Milli-Q system because these can become contaminated with microorganisms.

3. Run solvent from each bottle individually through the attached lines to remove any bubbles.
4. Connect the 4 \times 250-mm CarboPac PA-1 column to the 3 \times 25-mm CarboPac PA Guard column.
5. Set the pump control unit (or computer, if using a computerized system) to deliver a flow rate of 1.0 ml/min with an appropriate elution regimen (see Table 17.19A.1 for examples).

When both Xyl and Man are present in the sample, a very diluted eluent is used to achieve resolution. This considerably increases the time of analysis. Thus, when Xyl is not expected, an isocratic elution using 16 mM NaOH is preferred. These conditions are appropriate for the analysis of N- and O-linked oligosaccharides, and considerably shorter. However, it is important to keep in mind that Xyl and Man will coelute if both are present.

Table 17.19A.1 Sample HPAEC Elution Regimens for Compositional Analysis of Neutral Monosaccharides and Hexosamines^a

Time (min)	%			Comments
	Water	25 mM NaOH	200 mM NaOH	
Separation of Fuc, GalNH₂, GlcNH₂, Gal, Glc, Xyl, and Man				
Initial	92	8	0	
0.0	92	8	0	2 mM isocratic
40.0	92	8	0	
42.0	0	0	100	200 mM regeneration
47.0	0	0	100	End of regeneration
49.0	92	8	0	Reequilibration at initial conditions
90.0	92	8	0	
Separation of Fuc, GalNH₂, GlcNH₂, Gal, Glc, and Man				
Initial	92	0	8	
0.0	92	0	8	16 mM isocratic
22.0	92	0	8	
23.0	0	0	100	200 mM regeneration
33.0	0	0	100	End of regeneration
34.0	92	0	8	Reequilibration at initial conditions
50.0	92	0	8	

^aThe regeneration step between runs ensures reproducibility. When eluting with very diluted solutions such as those used in the first regimen above, at least 30 min of equilibration at the initial conditions is required to achieve good reproducibility between runs.

Figure 17.19.3 HPAEC-PAD profile of a mixture of monosaccharide standards containing Fuc, GalNH₂, GlcNH₂, Gal, Glc, and Man. The standards (10 nmol each) were hydrolyzed with 2 M trifluoroacetic acid (TFA) for 4 hr at 100°C, dried, and dissolved in 1.0 ml water. A 100- μ l aliquot (containing 1 nmol of each monosaccharide) was injected on the column and eluted isocratically using 16 mM NaOH.

Figure 17.19.3 shows a typical chromatogram of the mixture of standards used for compositional analysis of N- and O-linked oligosaccharides. Note that glucose is included, not because it is present in these oligosaccharides but because it is a very common contaminant.

6. Start the system and wait until a stable backpressure is attained (usual working pressures are between 1200 and 1500 psi and the maximum allowable pressure is 2000 psi).
7. Enter the settings for the PAD detector (or PED detector working in PAD mode) as indicated in Table 17.19A.2. When using a PADII detector, set the response time to 1 sec, the applied potential range to 1, and the output range to 300 nA. When using

Table 17.19A.2 PAD Detector Settings for Detection of Neutral Monosaccharides and Hexosamines

Time (sec)	Potential (V)	Integration
0.00	0.05	
0.20	0.05	Begin
0.40	0.05	End
0.41	0.75	
0.60	0.75	
0.61	-0.15	
1.00	-0.15	

an ED40 detector in a DX300 or DX500 instrument, select the carbohydrate waveform.

In the DX300 and DX500 systems, each method includes elution conditions, detector settings, and integration parameters. These can be manually selected from the control panels or entered using the software provided by the manufacturer. In both cases, when a method is loaded, the pump starts and the detector is turned on.

Perform postcolumn addition of base (when using a PADI or early versions of the PADI detector only)

8. Pressurize the postcolumn reservoir to deliver 0.3 to 0.4 ml/min of 1 M NaOH solution (helium pressure should be ~32 psi, resulting in a 360 mM sodium hydroxide concentration at the electrode). Check the amount delivered by measuring the total flow out of the PAD cell with a small graduated cylinder.

A regular piston pump cannot be used because this produces a wavy baseline due to pulsation.

When using newer versions of the PADI cell, this step (designed to improve the sensitivity of detection with the older models) is unnecessary. In this case proceed directly to step 10.

9. Make sure that there are no bubbles inside the reference electrode. Wait 15 min for the detector to stabilize, then press the Auto Offset control.

Check the baseline

10. Check the detector baseline using an integrator or the software provided by the manufacturer, and do not proceed until it is stable. Offset as necessary. When using an integrator, the appropriate settings are attenuation, 1024 and peak threshold, 10,000.

Analyze the standards

11. Dissolve dried acid hydrolyzed (UNIT 17.16) monosaccharide standard mixture in 100 to 1000 μ l water. Inject 10 to 100 μ l of mixture onto column.

Use 100 μ l when the mixture contains 2.5 nmol of each monosaccharide and 1000 μ l when the mixture contains 10 nmol of each monosaccharide. Sufficient quantities of the standard mixture should be hydrolyzed to allow for several injections if necessary.

The standard mixture should contain 250 pmol to 1 nmol each of Fuc, GalNH₂, GlcNH₂, Gal, Glc, Xyl, and Man; 250 pmol to 1 nmol each of Fuc, GalNH₂, GlcNH₂, Gal, Glc, and Man; or 250 pmol to 1 nmol Fuc (when only analyzing fucose). The

amount of each monosaccharide standard injected depends on the sensitivity of the particular detector and needs to be determined empirically in each case. The amount of standard mixture injected will depend on the amount of sample available. When the sample is limited, it is necessary to work at high sensitivity, and in this case will be more difficult to obtain a good baseline; also, the amount of standards injected should be adjusted to be in the same range for improved quantitation.

Always prepare standards with extreme care (see Support Protocol 3), as their quality will determine the accuracy of sample quantitation. Always use standards that have been hydrolyzed under the same conditions as the samples. This will correct for the different rates of hydrolysis and different recoveries of the different monosaccharides.

12. Check the resolution between monosaccharides (resolution of Gal/GlcN and Xyl/Man are usually critical, and inversion of the relative order of the components in these pairs may be observed). If resolution is poor, change the concentration of base (when retention times are too short, less base is required).

When using very dilute eluants (e.g., 2 mM NaOH), the concentration required for complete resolution may change when new 25 mM NaOH solution is prepared. This optimum concentration is also different for different columns. Therefore, when a new solution is prepared or a new column is used, always check the resolution obtained for the standard mixture. When using higher concentrations of NaOH as eluant, this sort of variation is not observed.

Analyze the samples

13. When good resolution of the standards is achieved, inject the samples.
14. When using PADI or PADII detectors, it may be necessary (depending on the response obtained for the samples) to change the working range to 100 nA or 1 μ A. Wait until a good baseline is obtained, then inject another sample.

When using newer detectors, these adjustments are made automatically.

15. Quantitate the standard run and use these data (area per nmol or pmol of each monosaccharide) to calculate the amount in nmol or pmol of each component in the sample.

It is advisable to average the results from at least three runs of standards to obtain more accurate response factors for each monosaccharide and improve the accuracy of the determination. This can be easily accomplished when using the software provided by the manufacturer by doing an average calibration and using those parameters to analyze the sample runs.

Maintain the system running at maximum performance

16. If resolution is lost and retention times become too short, wash the column for 30 min with 1 M sodium hydroxide. Wash extensively with water, then return to the working eluant. Wait for the baseline to stabilize under running conditions and check the performance of the column by injecting 10 μ l standard mixture. If performance is not recovered, wash the column with 1 M HCl for 30 min at 1.0 ml/min. Wash extensively with water, then with 1 M NaOH for 30 min at the same flow rate. Wash extensively with water, reequilibrate with the working eluant, and check again.

Prepare high-concentration eluants used for regeneration in separate bottles, or wash the bottles extensively after they have been used to hold these solutions. Also, remember to wash the lines that have carried concentrated solutions before connecting them to the column for regular analysis.

**Analysis of Mixtures of Neutral Monosaccharides, Hexosamines,
and Uronic Acids**

The use of a sodium acetate/sodium hydroxide gradient allows the elution of anionic saccharides, such as uronic acids, that would otherwise be retained by the column.

Additional Materials (also see *Basic Protocol 1*)

Sodium acetate ($\text{CH}_3\text{CO}_2\text{Na}\cdot 3\text{H}_2\text{O}$, FW 136.08; ACS certified grade)

1. Filter 8 liters Milli-Q-purified water through 0.45- μm membrane. Transfer 2 liters to bottle 1. Connect to helium sparge line and degas 15 min.
2. Prepare the following solutions in bottles 2, 3, and 4:

Bottle 2 (200 mM sodium hydroxide): Transfer 1980 ml filtered Milli-Q-purified water to bottle and degas for 15 min. Using a disposable plastic pipet, add 20.8 ml of 50% sodium hydroxide, then continue degassing for 15 min.

Bottle 3 (1 M sodium acetate): Weigh 272 g sodium acetate and dissolve in filter through 0.45- μm membrane, Milli-Q-purified water, then dilute to 2000 ml in a graduated cylinder. Filter through a 0.45- μm membrane. Transfer to bottle, and degas for 15 min.

Bottle 4 (1 M sodium hydroxide): Transfer 1896 ml filtered Milli-Q-purified water to bottle 4 and degas for 15 min. Add 104 ml of 50% sodium hydroxide measured in a plastic cylinder, and continue degassing for 15 min.

3. Run solvent from each bottle individually through the attached lines to remove any bubbles.
4. Connect 4 \times 250-mm CarboPac PA-1 column to the 3 \times 25-mm CarboPac PA Guard column.
5. Set the pump control unit or computer to deliver a flow rate of 1.0 ml/min with an appropriate elution regimen (see Table 17.19A.3 for an example).

A typical resulting chromatogram is shown in Fig. 17.19.4.

Figure 17.19.4 HPAEC-PAD profile of a mixture of monosaccharide standards containing Fuc, GalNH₂, GlcNH₂, Gal, Glc, Man, Neu5Ac, GalUA, and GlcUA. The standards (20 nmol of each neutral and amino sugar and 50 nmol of each hexouronic acid) were hydrolyzed with 2 M trifluoroacetic acid (TFA) for 6 hr at 100°C and dried; 20 nmol Neu5Ac was then added and the mixture dissolved in 1.0 ml water. A 100- μl aliquot (containing 2 nmol of each neutral monosaccharide, hexosamine, and Neu5Ac, and 5 nmol of each glycosyluronic acid) was injected on the column and eluted using the gradient described in Table 17.19A.3.

^aThis gradient separates Fuc, GalNH₂, GlcNH₂, Gal, Glc, Man, GalUA, and GlcUA. A typical chromatogram is shown in Figure 17.19.4.

^bNext injection follows reset (at 130 min).

6. Analyze the standards and samples (see Basic Protocol 1, steps 12 to 15).

The standard mixture should contain 250 pmol to 1 nmol of each neutral monosaccharide and hexosamine and of the appropriate glycosyluronic acid. As in Basic Protocol 2, inject 10 to 100 μ l of this mixture on the column.

Analysis of Mixtures of Sialic Acids

Sialic acids can be separated using the same anion-exchange pellicular resin column without base in the eluant; this permits analysis of O-acetylated species. HPAEC-PAD can be used when ≥ 0.5 nmol are available. Therefore, it is possible to determine the molar ratios of individual sialic acids in mixtures that have been released from glycoconjugates and purified using the protocols described in *UNITS 17.12 & 17.16*. This procedure can also be used for preparative purposes using a larger chromatography column.

Additional Materials (also see *Basic Protocol 2*)

Glacial acetic acid (17.4 M)

N-acetylneuraminic acid (Neu5Ac, MW 309.3; Boehringer Mannheim)

N-glycolylneuraminic acid (Neu5Gc, MW 325.3; Sigma)

Standard mixture: sialic acids prepared from bovine submaxillary mucin (BSM) using the procedures in *UNIT 17.16* (Basic Protocol 2 or Alternate Protocol) or *UNIT 17.12*, or equimolar mixture of Neu5Gc and Neu5Ac processed as for the sample

BASIC PROTOCOL 3

Preparation and Analysis of Glycoconjugates

17.19.9

Prepare the HPAEC-PAD system

1. Filter 2 liters Milli-Q-purified water through 0.45- μ m membrane. Transfer 1 liter to bottle 1, connect to helium sparge line, and degas 15 min.
2. Prepare 1 M sodium hydroxide solution (see Basic Protocol 1, step 2).
3. Weigh 0.68 g sodium acetate and dissolve in Milli-Q-purified water, diluting the solution to 1 liter final. Filter the resulting 5 mM sodium acetate buffer, transfer to bottle 2, connect to helium sparge line, and degas for 15 min.
4. Prepare 1 liter of 5 mM acetic acid using filtered Milli-Q-purified water and glacial acetic acid. Transfer to bottle 3 and degas for 15 min.
5. Run each solvent through the attached lines to remove any bubbles.
6. Connect the 4 \times 250 mM CarboPac PA-1 column with the 3 \times 25-mm CarboPac PA Guard column.
7. Set the pump control unit or computer to deliver a flow rate of 1.0 ml/min with an appropriate two-step elution regimen (see Table 17.19A.4 for an example).

For preparative purposes, a 9 \times 250-mm column at a flow rate of 5 ml/min should be used.

8. Start the system and wait until a stable back pressure is attained (usual working pressures are between 950 and 1400 psi and the maximum allowable pressure is 2000 psi).
9. Perform postcolumn addition of base (if using PADI or earlier PADII system) and determine detector baseline (see Basic Protocol 1, steps 8 to 11).

Analyze the standards

10. Inject 10 μ l of a water solution containing 5 nmol Neu5Ac, working in the 300 nA range.

If the samples to be analyzed have been submitted to acid hydrolysis for the release of sialic acids, use a Neu5Ac standard treated in the same manner for quantitation.

Neu5Gc	1.17	1.5
Neu5-7Ac ₂	0.74	0.36
Neu5-9Ac ₂	0.95	0.35
Neu4-5Ac ₂	0.76	0.39
Neu5-7(8)-9Ac ₃	0.74	0.23
Neu5-7-8-9Ac ₄	0.62	— ^b
Neu5Gc9Ac	1.06	0.49
Neu4Ac5Gc	0.86	0.54

^aUsing condition B.

^bElutes close to the salt peak.

- Change the range to 100 nA, wait until a good baseline is obtained again, and inject 500 pmol of Neu5Ac in the same volume.

When using a newer version of the PADII detector, these adjustments will be done automatically.

- If a standard mixture containing several sialic acids (obtained from BSM) is available, inject 10 μl containing 500 pmol of each and check the resolution. If this is not available, an equimolar mixture of Neu5Ac and Neu5Gc can be used.

The total running time is under 30 min.

Analyze the samples

- When good resolution and adequate retention times are achieved, inject the sialic acid samples. Compare the relative retention times with those listed in Table 17.19A.5.

It is advisable to average the results from at least three runs of standards to obtain more accurate response factors for each monosaccharide and improve the accuracy of the determination. This can be easily accomplished when using the software provided by the manufacturer by doing an average calibration and using those parameters to analyze the sample runs.

- Characterization of individual peaks can be achieved by repeating the analysis after saponification of *O*-acetyl groups (see UNIT 17.18).
- Determine the response obtained for standard Neu5Ac (area per pmol) and calculate the molar ratio of sialic acids in the mixture considering the following response factors:

<i>Sialic acid</i>	<i>Response factor</i>
Neu5Ac	1.00
Neu5Gc	1.15
Neu5-9Ac ₂	0.46
Neu5-7(8)-9Ac ₃	0.45

Detector responses for other sialic acids have not been determined, but lower response factors for more highly substituted species should be expected.

COMPOSITIONAL ANALYSIS OF FREE SIALIC ACIDS BY AMINE- ADSORPTION ION-SUPPRESSION HPLC WITH UV DETECTION

As an alternative to Basic Protocol 3, mixtures of free sialic acids can be analyzed by amine-adsorption ion-suppression HPLC with UV detection. The choice depends on the instrumentation available and the level of sensitivity required for a particular sample.

This system can be used to analyze radioactive samples if the column effluent is routed to a flow detector or fraction collector. When a flow detector is used, the appropriate ratio of scintillation fluid to be used has to be checked because of the quenching effect of acetonitrile. When fractions are collected and 72% acetonitrile is used, it is necessary to dry them, redissolve them in water, and then measure their radioactivity in a β -counter after addition of scintillation cocktail. When 64% acetonitrile is used, the addition of 1 vol water followed by 10 vol scintillation cocktail yields good sensitivity.

Materials

- Monobasic sodium phosphate (anhydrous, MW 120.0; reagent grade, Sigma)
- Milli-Q-purified water: water deionized by passage through five-stage Milli-Q Plus system (Millipore)
- Acetonitrile (HPLC grade, Fisher)
- N*-acetylneuraminic acid (Neu5Ac, MW 309.3; Boehringer Mannheim)
- N*-glycolylneuraminic acid (Neu5Gc, MW 325.3; Sigma)
- Standard mixture: sialic acids from bovine submaxillary mucin (BSM) prepared using procedures in *UNIT 17.16* or *UNIT 17.12*, or equimolar mixture of Neu5Ac and Neu5Gc processed as for the sample
- Sialic acid sample prepared by acid hydrolysis (*UNIT 17.16*, Basic Protocol 2 or Alternate Protocol) or enzymatic release (*UNIT 17.12*)

- HPLC apparatus with pump and UV detector
- Filtering unit with 0.45- μ m Nylon 66 membranes (Alltech)
- Micropak AX-5 (300 mm \times 7.8 mm i.d., particle size 9 μ m; Varian)
- Micropak AX-5 Guard column (4 cm \times 4 mm)

- Additional reagents and equipment for de-O-acetylation (*UNIT 17.18*)

Prepare the HPLC system

1. Turn on the UV detector and set the wavelength to 200 nm.
2. Prepare 1 liter of 0.25 M monobasic sodium phosphate (30 g/liter) in Milli-Q-purified water and filter through 0.45- μ m membrane.
3. Fill the bottles in the HPLC system with (1) acetonitrile, (2) Milli-Q-purified water filtered through 0.45- μ m membrane, and (3) filtered 0.25 M monobasic sodium phosphate from step 2. Degas 15 min by helium sparging.
4. Run each solvent through the attached lines to eliminate any bubbles.

CAUTION: Do not allow direct mixing of stock acetonitrile and sodium phosphate, as this will cause precipitation of salts in the lines.

5. Set the pump control unit to deliver a flow rate of 1 ml/min with an appropriate isocratic elution regimen as indicated in Table 17.19A.6.
6. Start running the solvent, then connect the 300 \times 7.8-mm Micropak AX-5 column to the 4 cm \times 4 mm Guard column.
7. Wait until the back pressure stabilizes and check the baseline. Wait until a stable baseline is obtained.

Table 17.19A.6 Amine Absorption/Ion Suppression HPLC Elution Regimen for Compositional Analysis of Sialic Acids

Conditions ^a	Flow (ml/min)	%		
		1	2	3
A	1	64	26	10
B	1	72	18	10

^aCondition A is used when only separation of Neu5Ac and Neu5Gc is required. Condition B is used when a mixture containing substituted species will be analyzed.

Analyze the standards

8. Inject 10 μ l of a solution of Neu5Ac in water (10 nmol Neu5Ac total). Check the sensitivity and adjust the integrator settings as required (a good signal-to-noise ratio is normally obtained using attenuation range 8). Repeat if necessary.

It is possible to work in attenuation range 4 to detect 5 nmol of Neu5Ac, but the background is considerably higher.

9. Inject 10 μ l of a mixture of Neu5Ac and Neu5Gc standards containing 10 nmol of each monosaccharide. If using condition B, use a mixture containing substituted sialic acid standards instead obtained from BSM (if available). Check for resolution and adjust the elution conditions if required.

CAUTION: *Remember that sodium phosphate will start precipitating at >72% acetonitrile. Condition B constitutes the maximum compatible percentages of acetonitrile and phosphate.*

Analyze the samples

10. Inject the sialic acid samples. Adjust the integrator settings as required and repeat if necessary.
11. Determine the percentage of each component, assuming equal detector responses.
12. Confirm the presence of O-acetylated species by subjecting the sample to de-O-acetylation (UNIT 17.18), then repeating the analysis. Compare the relative retention times to those listed in Table 17.19A.1.

Maintain the system running with maximum performance

13. Wash the column 30 min with water. Run 100% acetonitrile for 10 min. Disconnect the column.

CAUTION: *Never stop the flow if the lines contain phosphate, as they may become clogged. Also wash the filter and the line coming from the reservoir after using any salt.*

14. If resolution is lost and retention times become reduced, clean the column by running 0.5 M phosphoric acid for at least 1 hr at 1 ml/min flow, then washing extensively with water before changing to the working buffer.

More complete regeneration of the column can be achieved by injecting three 1-ml volumes of 3-aminopropyltriethoxysilane while running the column in 100% acetonitrile, washing extensively with the same solvent, with water, and then with 0.5 M phosphate before use. The performance of the column should be fully recovered after this treatment; however, the retention times may not be identical.

COMPOSITIONAL ANALYSIS BY GLC-FID

This protocol describes the quantitative analysis of derivatized methyl glycosides and alditols through the use of a gas-liquid chromatograph with a flame-ionization detector (see Fig. 17.19.5). With this apparatus, it is quite straightforward to determine the molar ratio of the monosaccharide components of a given glycoconjugate. This analysis can be performed after complete acid hydrolysis (*UNIT 17.16*) and conversion of the free monosaccharides to volatile peracetylated alditols (see Support Protocol 2). It is also possible to cleave the glycosidic linkages with methanol/HCl to produce methyl glycosides, which are converted into volatile trimethylsilylethers (see Support Protocol 3) for further GLC analysis. The last method is preferred when hexosamines or uronic acid are expected to be found in the sample.

Materials

- Monosaccharide standard mixture (see Support Protocol 3) prepared in the same manner as the sample
- Monosaccharide sample prepared by acid hydrolysis (*UNIT 17.16*, Basic Protocol 3) followed by derivatization by peracetylation (see Support Protocol 2) and/or by methanolysis (Support Protocol 1) followed by derivatization by pertrimethylsilylation (see Support Protocol 3)
- Internal standard prepared in the same manner as the sample
- 0.25 mm × 30 m 5% DB-5 fused silica capillary column (J&W Scientific)
- Gas chromatograph with dual-flame ionization detector
- Helium (research grade)
- Hydrogen and air lines (for FID detector only)

Gas-liquid chromatograph with flame-ionization detector (GLC-FID)

1. Connect the capillary column to the gas chromatograph and begin running the carrier gas at a flow rate of 1.5 ml/min. Set the makeup gas flow rate of 35 ml/min and the split ratio to 10:1.

When <25 μg of total carbohydrates are processed, a splitless injection is required.

Figure 17.19.5 Schema of a gas-liquid chromatograph with flame-ionization detector.

Several other types of stationary phases can be used for the analysis of acetylated alditols: e.g., CP-Sil 5 WCOT, SP-1000, Silar 10C, OV-1, SE-54, 5% DB-5, DB-1, Carbowax 20M, SE-30, OV-101, and OV-275. In the less polar stationary phases, amino sugar alditols can also be analyzed. Other stationary phases used for the analysis of trimethylsilylated glycosides and methyl glycoside methyl esters include CP-Sil 5 WCOT, 5% DB-5, DB-1, SE-30, and OV-101. Appropriate conditions vary from one to another. Typical chromatograms and relative retention times can be found in Kammerling and Vliegthart (1989) and references therein.

2. Set the GLC oven temperature to 50°C, the injector-port temperature to 150°C, and the FID detector temperature to 250°C, and wait for stabilization.
3. Open the air and hydrogen lines and adjust the flows. Ignite the detector. Check the background.
4. Set up an appropriate temperature program:
 - a. *Alditol acetates*: Start at 50°C and keep at 50°C for 2 min; then go from 50°C to 150°C at 20°C/min (5 min); then go from 150°C to 250°C at 4°C/min (25.0 min); then keep at 4°C for 5 min. (Total running time is 37 min.)
 - b. *Trimethylsilylethers of methyl glycosides*: Start at 50°C and keep at 50°C for 3 min; then go from 50°C to 170°C at 20°C/min (6 min); then go from 170°C to 250°C at 6°C/min (13.3 min); then keep at 250°C for 2.7 min. (Total running time is 25 min.)
5. Inject 1 µl of the mixture of derivatized standards (see Support Protocol 2 and Support Protocol 3). Adjust the settings of the integrator and repeat as necessary to obtain all the peaks on scale.
6. Determine the retention times of each peak relative to the internal standard.
7. Inject the standards (containing internal standard) one at a time to assign the peaks and determine the response factors. In the case of TMS derivatives, also determine the contribution of each peak to the total (%), and select the peak of each monosaccharide to be used for quantitation:

$$R = \frac{\text{nmol internal standard} \times \text{area monosaccharide}}{\text{nmol monosaccharide} \times \text{area internal standard}}$$
8. Inject 1 µl of sample (containing internal standard). Repeat as needed to obtain a good profile.
9. Tentatively assign the peaks by comparison of the relative retention times with those of the standards. If a discrepancy arises, repeat analysis, coinjecting the sample with the individual standard. The questioned peak should appear separated from the standard if it is not the same compound.
10. Determine the molar percentage of individual components by reference to the internal standard:

$$\text{nmol sugar}/\mu\text{g sample} = \frac{\text{area of monosaccharide peak} \times \text{nmoles internal standard}}{\text{area of internal standard peak} \times R \times \mu\text{g of sample}}$$

**QUANTITATIVE RELEASE OF NEUTRAL MONOSACCHARIDES,
HEXOSAMINES, AND URONIC ACIDS BY METHANOLYSIS**

Glycoconjugate samples are hydrolyzed by heating in the presence of methanolic HCl, followed by treatment with pyridine and acetic anhydride.

Materials

- Glycoconjugate sample containing 5 to 50 µg total sugar
- Internal monosaccharide standard: monosaccharide that does not occur naturally in the sample (e.g., monosaccharide alditol that yields only one peak upon gas chromatography, see *UNIT 17.16*; see Support Protocol 4 for monosaccharide preparation)
- Monosaccharide standards: monosaccharides expected to be found in the sample (see Support Protocol 4 for preparation)
- Phosphorus pentoxide (Fisher)
- Acetyl chloride (FW 78.50, 98% pure; Aldrich)
- Methanol (anhydrous, 99% pure, Aldrich; store in desiccator)
- Pyridine (anhydrous silylation grade, Pierce; store in desiccator)
- Acetic anhydride
- 1.5-ml glass Reacti-Vials (Pierce) with Teflon-lined screw caps, either new (rinsed with water, then with ethanol, and dried) *or* acid-cleaned (see recipe)
- Heating block or oven
- Nitrogen or vacuum evaporation system (Speedvac or shaker-evaporator)

1. Combine the glycoconjugate sample and 1 to 10 µg internal monosaccharide standard in a 1.5-ml precleaned or acid-cleaned Reacti-Vial. Lyophilize mixture.
2. Prepare a set of standards consisting of separate solutions containing 50 nmol of each monosaccharide that is expected to be found in the sample, each one also containing 5 nmol of the same internal standard used for the sample. Also prepare a mixture of all the expected monosaccharides plus internal standard. Treat all standards in parallel with the sample.
3. Dry the lyophilized sample and standards overnight in a vacuum desiccator over phosphorus pentoxide.
4. Prepare methanolic HCl (either reagent A or reagent B) by adding acetyl chloride to anhydrous methanol in the following proportions:

	Acetyl chloride	Anhydrous methanol	Final concentration of HCl in methanol
Reagent A	3.50 vol	100 vol	0.50 M
Reagent B	7.00	100 vol	1.00 M

CAUTION: *Add the acetyl chloride carefully, as the resulting reaction is highly exothermic.*

Methanolic HCl reagent A is used except when glycosyluronic acids are present; in such cases reagent B is preferred. Alternatively, an initial acid hydrolysis may be performed using 200 µl of 2 M trifluoroacetic acid (TFA) for 1 hr at 121°C. TFA should then be evaporated under a nitrogen stream or in Speedvac system and samples washed twice with methanol, then evaporated again. This procedure ensures complete recovery of hexosamines but destroys sialic acids. Afterwards, proceed to step 4, and use reagent A.

Prepare a large enough volume of methanolic HCl to minimize pipetting errors, but only in the range required for the experiment, as it cannot be stored.

- Dissolve dried sample and standards (from step 3) in 200 μ l methanolic HCl (reagent A or B), then cap the vials.
- Heat 16 hr at 65°C if using reagent A or 24 hr at 85°C if using reagent B. Check the screw caps for tightness after the first 15 min of heating, then vortex and continue heating.

This procedure yields methyl glycosides of each monosaccharide residue in the glycoconjugate. Hexosamines will be de-N-acetylated.

- Evaporate sample and standards using a stream of nitrogen at room temperature or a Speedvac system.
- Add 100 μ l anhydrous pyridine and vortex to resuspend the residue. Add 100 μ l acetic anhydride, vortex 1 min, and evaporate to dryness under a stream of nitrogen.

This treatment produces re-N-acetylation of hexosamines. Some O-acetyl groups may be incorporated.

- Dissolve the residue in 200 μ l of 0.5 M methanolic HCl, then heat 1 hr at 65°C.

This treatment assures the cleavage of any O-acetyl groups incorporated in step 8.

- Evaporate under a stream of nitrogen, then dry further overnight in a vacuum desiccator over phosphorus pentoxide.

PREPARATION OF VOLATILE DERIVATIVES OF FREE GLYCOSES

Volatile derivatives of free glycoses are prepared by first reducing the free sugars to alditols with sodium borohydride, then peracetylation with acetic anhydride. The resulting alditol acetates can be analyzed immediately by GLC-FID (see Basic Protocol 2).

Materials

- 10 mg/ml sodium borohydride in 1 M ammonium hydroxide (ACS reagent grade)
- Monosaccharide sample prepared by acid hydrolysis (UNIT 17.16, Basic Protocol 3, or Basic Protocol 1 when analyzing only fucose)
- Neutral sugar standard mixture (see Support Protocol 4) submitted to acid hydrolysis (UNIT 17.16, Basic Protocol 3)
- Sodium borohydride (FW 37.8; store in desiccator)
- Glacial acetic acid (FW 60.05; 99.99% pure)
- 1% acetic acid in methanol (anhydrous, 99% pure)
- Acetic anhydride (99% pure)
- Toluene
- Chloroform (anhydrous, 99% pure)
- Acetone (99.9% pure, HPLC grade)
- Phosphorous pentoxide (as desiccant)
- 3.5-ml glass vials with Teflon-lined screw caps
- Nitrogen evaporation unit (Reacti-Vap Evaporator, Reacti-Therm Heating Module, and Reacti-Block B-1 or S-1, Pierce)
- Heating block or oven, 100°C
- Tabletop centrifuge
- Reacti-Vials (Pierce) or other glass test tubes

Reduce mixtures of free glycoses to alditols

- Add 250 μ l of 1 M ammonium hydroxide/10 mg/ml sodium borohydride to the monosaccharide sample and the neutral sugar standard mixture in 3.5-ml glass vials with Teflon-lined screw caps. Let stand 10 min, then check for persistence of

SUPPORT PROTOCOL 2

Preparation and Analysis of Glycoconjugates

17.19.17

microbubbles in the reaction mixture. If these cannot be seen, add a few micrograms of solid sodium borohydride.

It is important that no residue of acid from the hydrolysis be present or the hydride will be rapidly destroyed. If excessive bubbling occurs when adding the borohydride, add methanol and evaporate two or three times, then repeat the reduction.

3. Incubate 2 hr at room temperature.

This reaction can also be run overnight.

4. Add glacial acetic acid dropwise until no further bubbling is observed.

Care must be taken to avoid losing sample with the bubbling, as the reaction is violent. This problem may be circumvented by using a 20% (v/v) solution of acetic acid in methanol instead of glacial acetic acid.

5. Add 250 μ l of 1% acetic acid in methanol to each tube. Evaporate to dryness using a nitrogen evaporation unit or under vacuum using a Speedvac system with the heating element set at 40°C. Repeat four more times.

This treatment removes volatile methyl borate, producing sodium acetate. Complete removal of borate is indicated by colorless crystals, as compared with white powder previously present. When a nitrogen evaporation unit is employed, care must be taken not to blow away the solid residue, particularly in the final steps.

6. Dry sample and standards in a vacuum dessicator overnight over phosphorus pentoxide.

Peracetylate the alditols

7. Add 200 μ l acetic anhydride, vortex, and cap the tubes.

8. Heat 3 hr at 100°C, mixing after the first 15 min of heating to make sure that the solid residue is suspended. Let cool to room temperature.

9. Add 200 μ l toluene. Evaporate to dryness at 40°C using a shaker-evaporator or Speedvac or under nitrogen. Add toluene as needed to dry completely.

Toluene helps to eliminate the reagents by forming an azeotrope.

Clean reaction mixtures by extraction

10. Add 0.5 ml water and 0.5 ml chloroform to each tube, cap, and vortex well. Centrifuge briefly at low speed to clearly separate the two phases.

Salts will be extracted into the water layer, leaving the peracetylated alditols in the organic layer.

11. Remove the upper (water) layer with a Pasteur pipet. Wash the organic layer with water two more times.

12. Transfer the chloroform layer to a clean tube or Reacti-Vial and dry under nitrogen at room temperature or in a Speedvac system.

13. Dissolve in 5 to 50 μ l acetone, depending on the amount of starting material, and use 1 μ l for GLC-FID analysis (Basic Protocol 2).

PREPARATION OF VOLATILE DERIVATIVES OF METHYL GLYCOSIDES

SUPPORT
PROTOCOL 3

Volatile derivatives of methyl glycosides (trimethylsilylethers of neutral sugars and hexosamines and methyl esters of uronic acids) are prepared from the dried methyl glycosides (see Support Protocol 1) using a commercial silylation reagent. The silylated samples must then be analyzed immediately by GLC-FID (see Basic Protocol 2).

Materials

Dried methanolized samples and standards (see Support Protocol 1, step 10)
Tri-Sil Reagent [2:1:10 (v/v/v) hexamethyldisilazane/trimethylchlorosilane/
pyridine; Pierce]
96% hexane (HPLC grade)
Nitrogen stream
Tabletop centrifuge
Reacti-Vials (Pierce)

1. Suspend each dried sample and standard in 100 μ l Tri-Sil and cap vial. Incubate 30 min at room temperature.

Samples and all required standards must be processed in parallel.

2. Evaporate the silylating reagent under a stream of dry nitrogen.

Nitrogen can be dried by including a drying tube in the line.

3. Add 0.5 ml hexane, dissolve the derivatives, and centrifuge briefly at low speed to separate insoluble salts.
4. Transfer supernatant to a clean Reacti-Vial and evaporate under dry nitrogen stream as in step 2.
5. Dissolve the residue 5 to 50 μ l hexane, depending on the amount of starting material. Use 1 μ l of solution for GLC analysis.

PREPARATION OF MONOSACCHARIDE STANDARD SOLUTIONS

SUPPORT
PROTOCOL 4

Proper preparation and storage of monosaccharide standard solutions is critical to achieve good quantitation in a compositional analysis (Hardy and Townsend, 1994).

Materials

NaOH pellets
Monosaccharide standards
Milli-Q-purified water: water deionized by passage through a Milli-Q Plus system
(Millipore)
Vacuum desiccator
Glass vials
100-ml volumetric flasks

1. Prepare a vacuum desiccator containing a plastic beaker with NaOH pellets.
2. Tare a group of glass vials (twice the number of standards to be used). Weight ~500 mg of each monosaccharide standard in separate vials and cover each vial with aluminum foil or a loosely placed clean cap. Cover the extra vials in the same manner and place all the vials in the desiccator.
3. Put the desiccator under continuous vacuum for 1 day.

Preparation and
Analysis of
Glycoconjugates

17.19.19

4. Weigh the vials and return them to the desiccator for another day under vacuum. Continue to do this every day until the change in weight from one day to the next is <1%.

This is normally achieved in 3 to 4 days.

5. Transfer a sample (e.g., 15 mg) of each standard to one of the empty, desiccated tared vials and determine the exact weight of the monosaccharides.
6. Add Milli-Q-purified water to each vial to give a 100 mM solution. Mix well to dissolve.
7. Prepare a dilution of each of these primary standard solutions by transferring 100 μ l of each solution to a 100-ml volumetric flask (100 pmol/ μ l). Dilute to 100 ml with Milli-Q-purified water and mix.
8. Divide each standard into 1-ml aliquots and store these at -20°C until needed.
9. Prepare a mixture of all the required monosaccharides by transferring 100 μ l of each primary standard solution to a 100-ml volumetric flask (100 pmol/ μ l). Bring up to 100 ml with Milli-Q-purified water and mix.
10. Divide the standard mixture into 1-ml aliquots and store these at -20°C until needed.
11. When required, defrost one aliquot of each desired standard solution and use them within 1 or 2 days. Do not refreeze the standards.

Standards prepared in this manner can be used directly for HPAEC or HPLC analysis or lyophilized and used for GLC analysis.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Acid-cleaned glass vials

Heat 1.5-ml glass vials (e.g., Reacti-Vials, Pierce) with Teflon-lined screw caps at 50°C for at least 3 hr each time in concentrated nitric acid and then in 6 M HCl. Rinse thoroughly with water, then with ethanol, and dry in an oven. When $<5\mu\text{g}$ of total carbohydrates is analyzed, it is recommended to silanize the glass vials by incubating them 15 min at room temperature with a 2% solution of dichlorodimethylsilane in toluene, decanting the solution, rinsing successively with methanol and hot distilled water, and allowing the vials to dry.

New vials should be at least rinsed with water, then with ethanol, and dried.

COMMENTARY

Background Information

High-performance anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) and gas-liquid chromatography with gas-liquid chromatography with mass spectroscopic detection (GLC-MS) are the methods most widely used today for compositional analysis of the carbohydrate moieties of glycoproteins. Both methods are able to detect all the possible known monosaccharides. With the HPAEC-PAD system it is possible to analyze qualitatively and quantitatively a mixture of free monosaccharides containing as little as

50 pmol of each individual component. With GLC methods, the use of internal standards helps improve quantitation because the injection of reproducible proportions of the sample into the column is not easy.

HPAEC-PAD and other HPLC techniques

Different high-performance liquid chromatography (HPLC) systems have been used for the analysis of free glycoses obtained by acid hydrolysis, but sensitivity and resolution between individual monosaccharides were traditionally poor. The technique became popular

for analyzing glycoproteins and other glycoconjugates available in limited amounts from biological sources only after pellicular resin anion-exchange columns and the pulse-amperometric detector were developed. Neutral saccharides are analyzed at high pH (12 to 14), at which they are partially or completely ionized. Separation is achieved by adjusting the eluant pH. Anionic saccharides can be separated using sodium acetate/sodium hydroxide gradients. Therefore, with appropriate adjustment of the elution conditions, this system permits not only the compositional analysis of free monosaccharide mixtures but also the analysis of oligo- and polysaccharides (Lee, 1990).

Pulsed amperometric detection (PAD) utilizes a repeating sequence of three potentials applied for specific durations. The resulting total current is the sum of (1) the carbohydrate oxidation current, (2) the current due to the charging of the electrode surface, and (3) the current caused by the oxidation of the gold electrode. The current is only measured during the first applied potential and has been shown to be linear over $>4^{1/2}$ orders of magnitude. Recently, the parameters used for these three steps were optimized (LaCourse and Johnson, 1991). Molecules with similar size and structure are reported to have similar response factors. On the other hand, substituents on hydroxyl groups are expected to affect the sensitivity of detection. The detector works only at high pH. Thus, when base-labile species that are separated without the use of base in the eluant are analyzed, it is necessary to add alkali to the effluent before it enters the PAD cell.

Isocratic elution with sodium hydroxide (2 to 16 mM; the optimal concentration varies from column to column) allows for the separation of neutral sugars and hexosamines. Different sodium acetate gradients have been employed for the analysis of acidic monosaccharides and of mixtures of these and other sugars. The system is also useful for sialic acids, with a limit of detection of ~ 200 pmol (Manzi et al., 1990). Oligo- and polysaccharides can also be analyzed with this system using appropriate conditions (Hardy and Townsend, 1988; 1989). Although monosaccharide alditols are not retained by this column (they will come out in the void volume), oligosaccharide alditols can be analyzed (Reddy and Bush, 1991). Maintenance of a stable column temperature is critical to obtaining reproducible results; failure to do so can cause lack of separation of critical pairs of monosaccharides (Van Riel and Olieman, 1991).

Because only 1% of the sample is oxidized in the electrode, the system can be used preparatively without the need for a bypass. When analyzing base-labile sialic acids, this method cannot be used, because the postcolumn addition of base required for detection will cause saponification of the *O*-acetyl esters. However, the pellicular resin column can be used for fractionation and the eluate routed to a fraction collector. After the fractions are monitored by the TBA assay (UNIT 17.18), they can be pooled and desalted. This method has proved to be the best HPLC technique available for preparative fractionation of mixtures of sialic acids containing labile substituents (Manzi et al., 1990).

Another useful system for the analysis of free sialic acids is amine adsorption-ion suppression HPLC. This is based upon hydrogen bonding between the hydroxyl groups of saccharides and the amine moieties of the stationary phase (Mellis and Baenziger, 1981; Bergh et al., 1981). To fractionate anionic molecules, phosphate is added to the mobile phase to suppress the ionic effects while retaining hydrogen bonding (Mellis and Baenziger, 1983). Good separation of sialic acids is obtained in isocratic mode with a mixture of acetonitrile/water/0.25 M monobasic sodium phosphate at 1 ml/min (Diaz and Varki, 1985). It is necessary to maintain a minimum concentration of 10% phosphate buffer with a maximum working percentage of acetonitrile of 72% (above this the phosphate starts to precipitate). A 64:26:10 (v/v/v) ratio of acetonitrile/water/0.25 M sodium phosphate can be used to separate Neu5Ac and Neu5Gc. For *O*-acetylated sialic acids, however, it is necessary to increase the percentage of acetonitrile to a ratio of 72:18:10 (v/v/v) so as to increase the retention times of the sialic acids (Manzi et al., 1990). Chromatography is monitored by absorption at 200 nm, which requires extremely high-purity samples and reagents. The same analytical column can be used for preparative purposes (up to 400 nmol of sialic acids with a good resolution of the peaks). Recovery of sialic acids is $\sim 65\%$, but some loss and migration of *O*-acetyl groups occur.

GLC-FID

To analyze mixtures of glycoses or methylglycosides by gas-liquid chromatography, it is necessary to prepare volatile derivatives. Alditol acetates are the most widely used derivatives for monosaccharides obtained by acid hydrolysis, whereas trimethylsilylethers of methyl glycosides or methyl glycoside methyl esters are

the preferred derivatives for methanolysis products. These are the derivatives of choice for any glycoconjugate-derived sugar because of the amount of information that can be obtained from them (e.g., retention times in different columns). Other volatile compounds, such as aldononitrile acetates and trifluoroacetylated alditols, have also been successfully employed (as reviewed by Kammerling and Vliegenthart, 1989).

Acetylestere of alditols

When only neutral sugars need to be analyzed, the most common derivatization method is the conversion of the free monosaccharides into their alditol acetates. Each monosaccharide produces a single derivative, giving a simple chromatogram that can be easily interpreted and quantitated. The total analysis time is also shorter because all required standards can be processed as a mixture, requiring only one GLC run.

The procedure involves the reduction of the glycoses to alditols with sodium borohydride; elimination of the excess of hydride with acid; elimination of the boric acid produced as trimethylborate by coevaporation with acidified methanol; and peracetylation of all free hydroxyl groups. Different protocols to achieve this last step have been developed (Kammerling and Vliegenthart, 1989; Albersheim et al., 1967; York et al., 1985). It is possible to simply use the sodium acetate produced in the reaction as the catalyst, and achieve complete acetylation by heating with acetic anhydride. Because leftover borate could inhibit the acetylation, some protocols add pyridine to drive the reaction to completion.

Cleavage of glycosidic linkages by methanolysis

Cleavage of all glycosidic linkages by methanolysis is very effective and causes less destruction of the monosaccharides than acid hydrolysis. Monosaccharides are converted to their methyl glycosides and glycosyluronic acids to their methyl esters methyl glycosides. The *N*-acetyl group of amino sugars are completely cleaved by extensive methanolysis, and it is advisable to incorporate a re-*N*-acetylation step to avoid the production of additional peaks in the chromatogram. A drawback to the reacylation step is that some *O*-acetylation occurs (in some primary hydroxyl groups), but a short additional treatment with methanolic HCl eliminates these groups (Rickert and Sweeley,

1978). Because of anomerization, each monosaccharide produces several methylglycosides (α and β anomers of the pyranosidic and furanosidic forms), which yields a characteristic pattern of peaks in the GLC run. When the sample contains several monosaccharides, however, the pattern is quite complex, with some peaks superimposed, and this makes quantitation difficult. Nevertheless, by processing each of the individual monosaccharides that are expected in parallel, running each one separately under the same conditions, and determining the contribution of each peak to the total, an accurate quantitation can still be achieved.

Different conditions have been used for methanolysis of carbohydrates in glycoproteins using methanolic HCl, including 0.5 M for 16 hr at 65°C (Reinhold, 1972) and 0.75 M for 3 hr at 80°C (Wong et al., 1980). Conditions for the simultaneous release of neutral monosaccharides, acetamido sugars, uronic acids, octulosonic acids, and sialic acids (2 M TFA for 12 hr at 100°C under vacuum) have been reported (Clarke et al., 1991). Nevertheless, the cleavage of the uronic acid glycosidic linkage may be incomplete in some cases, and several glycosyluronic acids produce a certain percentage of 3,6-lactones. The glycosidic linkages of sialic acids are cleaved with good yield, but a significant proportion of the released molecules are destroyed. Although special conditions that minimize this destruction have been developed (Schauer, 1978), *N*-acyl groups and most *O*-acetyl esters are eliminated. Thus, release of intact sialic acids requires much milder acid hydrolysis of a separate aliquot of the sample.

Volatile derivatives of methyl glycosides

The content of neutral sugars, amino sugars, and glycosyluronic acids can be simultaneously determined by this method. Different reagents and procedures have been used to silylate mixtures of methyl glycosides (Kammerling and Vliegenthart, 1989). The most widely used procedure uses 5:1:5 (v/v/v) pyridine/hexamethyldisilazane/trimethylchlorosilane and an incubation that can range from 15 min at room temperature to 20 min at 80°C.

Sialic acids have also been analyzed as trimethylsilyl esters trimethylsilyl ethers or methyl esters trimethylsilyl ethers. Although conditions have been worked out for preparing these two types of derivatives while preserving labile natural substituents such as *O*-acyl groups (Schauer and Corfield, 1982), the derivatization of sialic acids is frequently in-

complete. Further problems are encountered during the subsequent chromatographic separation because the high temperatures required to elute these molecules result in partial destruction of the labile substituents. Therefore, this approach to sialic acid analysis has been replaced by HPLC methods with or without derivatization (see *UNIT 17.18*).

Qualitative and quantitative analysis

Analysis of volatile monosaccharide derivatives is achieved by gas-liquid chromatography. A combined adsorption/partition mechanism takes place between the volatile derivatives and the particular stationary phase that is a liquid at working temperatures. Through the large number of theoretical plates available in the length of the fused-silica capillary columns, the individual components of the mixtures under analysis are separated according to their particular structural characteristics. The mobile phase (helium) carries the molecules throughout the column and to the detector, where the ionization of the flame changes upon their passage, producing an electrical output. This signal is amplified and registered.

Initial characterization of individual peaks is done by comparison with standards run in the same conditions. The retention times of each standard relative to the component used as internal standard in the sample are calculated and compared with the relative retention times of each peak in the chromatogram of the sample. Typical elution profiles as well as relative retention times in the different columns under different conditions can be found in the literature (Kammerling and Vliegthart, 1989, and references therein).

A known amount of an internal standard (a monosaccharide or alditol that does not occur naturally) is added to each glycoconjugate at the beginning of its processing. Losses during the preparation of the sample for GLC will be proportionally the same for each component of the sample and for the internal standard. Thus, the ratio of analyte to internal standard will remain the same, even though the absolute amounts of both may be lower at the end. Quantitative analysis is performed by determining the detector responses for individual monosaccharides relative to the internal standard (known amounts are injected and the areas determined).

Critical Parameters

HPAEC-PAD and other HPLC techniques

When HPAEC-PAD is used for analysis of sialic acids, the sialic acids (which have a pK_a of ~ 2.0) bind to the resin at neutral pH, and it is necessary to use an anion to elute them. Samples are loaded in water to ensure binding and submitted to a pH gradient elution with dilute sodium acetate and acetic acid. This permits the separation of different *O*-acetylated sialic acid species, whose binding to the resin is relatively weaker with higher numbers of substituents. The relative detector responses vary significantly with the presence of different numbers of free hydroxyl groups. The response observed for Neu5Gc is 15% higher than that for Neu5Ac, which bears one fewer hydroxyl group. In contrast, the responses of the detector for Neu5-9Ac₂ and Neu5-7(8)-9Ac₃ are only 46% and 45% of the response for Neu5Ac, respectively. However, because of the possibility of partial de-*O*-acetylation between the point of addition of postcolumn alkali and the PAD detector, the detector response factors may vary somewhat in different laboratories. For preparative purposes, a maximum of 2 μ mol of total sialic acids can be injected without overloading the 9 mm \times 25 cm semipreparative column. After removal by Dowex 50 (H⁺) chromatography of the small amount of acetate required for separation using the HPAEC column, an excellent recovery (>90%) of acetylated species is possible.

When gradients that end in high concentrations of acetate (>100 mM) are used, the slow reequilibration of the column with low concentrations of hydroxide and acetate results in lower retention times and impaired separation. Resolution of some pairs of monosaccharides (e.g., Gal-GlcN and Xyl-Man) during the first isocratic step is extremely sensitive to minor changes in solvent composition. Therefore, extended equilibration periods between runs are necessary to obtain reproducible results. A shorter delay between runs, resulting in a column that is not fully equilibrated but that still achieves adequate separation for a set of monosaccharides, can produce repeatable results if an automatic sample injector with constant intervals between injections is employed.

When using amine adsorption-ion suppression chromatography, the relative proportion of solvents can be varied according to the kind of sialic acids to be separated. Because the eluant is monitored by UV absorbance at 200 nm, residual amounts of purification reagents pro-

Table 17.19A.7 Molecular Weights of Monosaccharides Found in Glycoproteins and Their Volatile Derivatives^a

Monosaccharide	Molecular weight of:				
	Aldoses	Alditols	Acetylated alditols	Methyl glycosides and methyl ester methyl glycosides	TMS ethers of methyl glycosides and methyl ester methyl glycosides
Hexoses	180	182	434	194	482
Pentoses	150	152	362	164	380
Deoxyhexoses	164	166	376	178	394
Hexosamines	179	181	431	193	481
<i>N</i> -acetylhexosamines	221	223	473	235	523
Hexosyluronic acids	194	NA	NA	222	438

^aNA, not applicable.

duce an absorption peak close to the void volume. The lower limit of reliable detection is 2 nmol, and the detector responses are equal for all sialic acids. For preparative purposes, the eluant is monitored by UV and the peaks collected directly on ice, diluted 10-fold with cold water, and purified by ion-exchange chromatography on Dowex 3-X4A (formate; see *UNIT 17.16*) at 4°C. The column is washed with 10 vol of 10 mM formic acid and eluted with 7 vol of 1 M formic acid, and sialic acids are recovered by lyophilization.

GLC with FID detection

When the assignment of some peaks in gas-liquid chromatography (a GLC) run remains uncertain, coinjection with the suspected monosaccharide allows confirmation.

When analyzing trimethylsilylated methyl glycosides, the sample is quantitated by choosing one nonsuperimposed peak for each monosaccharide and considering how much of the compound this area represents. Absolute molar content of monosaccharide in the sample can be calculated when a known amount of an internal standard was added to the sample before processing.

Because the linkage between *N*-acetylglucosamine and asparagine is barely cleaved by methanolysis, this fact has to be considered when quantitation is required. Dehydration of monosaccharides can also occur to a small extent.

Anticipated Results

When analyzing a neutral glycoconjugate (one that does not contain hexosamines, uronic acids, or sialic acids), total acid hydrolysis followed by HPAEC-PAD or reduction/peracetylation and GLC-FID will indicate the relative composition or absolute composition (when an

internal standard is added) of individual monosaccharides. When fucose is present, mild acid hydrolysis conditions can be tried to assure minimal destruction.

When hexosamines or uronic acids are present, acid hydrolysis followed by HPAEC-PAD or methanolysis followed by re-*N*-acetylation/pertrimethylsilylation and GLC-FID can be used. Optimal conditions for maximum release (for both types of sugars) and minimal destruction (for uronic acids) must be employed for both approaches.

When sialic acids are present, HPAEC-PAD or amine adsorption-ion suppression HPLC with UV detection can be employed for compositional analysis of the different species after mild acid hydrolysis or enzymatic release. Alternatively, released sialic acids can be derivatized with DMB and submitted to HPLC (see *UNIT 17.18*).

In some cases it is necessary to use more than one protocol to obtain the complete compositional analysis of sugars.

Analysis of monosaccharides using one of the HPLC-PAD methods described in Basic Protocols 1, 2, or 3 results in the successful separation of the mixture into constituent monosaccharides. Figure 17.19.3 and Figure 17.19.4. illustrate separation profiles obtained from a mixture of monosaccharids subjected to HPAC-PAD.

As mentioned before, a characteristic pattern is obtained for each monosaccharide in the case of trimethylsilylated methyl glycosides. By doing individual runs of each monosaccharide and including an internal standard, it is possible to calculate the percentage of the total monosaccharide that each peak represents. Generally a minimum of 100 ng of each component is required for confident detection. Mo-

lecular weights of the monosaccharides found in glycoproteins, their alditols and methyl glycosides, and their volatile derivatives used in the protocols included in this section are listed in Table 17.19A.7.

Time Considerations

The total time of analysis for each particular method depends on how many runs of HPLC or GLC are required per sample. This depends in turn on the complexity of the sample, as sometimes coinjection with known standards may be required.

Composition of Labeled Monosaccharides from Glycosaminoglycans

BASIC PROTOCOL

Proteoglycans can be labeled metabolically with [³H]glucosamine (UNIT 17.4) to incorporate label into glucosamine and galactosamine. After isolation of proteoglycans (UNIT 17.2), glycosaminoglycans can be released from the proteoglycans by β-elimination (UNIT 17.15) and the distribution of labeled glucosamine and galactosamine in the isolated glycosaminoglycans can be determined. The glycosaminoglycans are hydrolyzed in acid until all the N-acetyl groups and N- and O-sulfates are removed. This procedure yields oligosaccharides in which some but not all of the uronic acid and amino sugar glycosidic bonds have been hydrolyzed. This partially hydrolyzed product is then treated with nitrous acid at pH 4 (UNIT 17.22A) to obtain a deaminative cleavage of the remaining amino sugar glycosidic bonds in which the reducing terminal of each of the resulting products is an anhydro-D-mannose (from D-GlcN) or an anhydro-D-talose (from D-GalN). The final depolymerization mixture, which contains disaccharides (uronosyl-anhydro sugars), free uronic acids, and free anhydro sugars, is reduced with NaBH₄ to convert the anhydromannose and androtalose residues to anhydromannitol and anhydrotalitol residues, respectively. The mixtures are then separated by paper chromatography and the amount of each labeled component is quantified by scintillation counting.

This procedure can also be used to determine the composition of glycosaminoglycans that have not been labeled metabolically. Samples of unlabeled glycosaminoglycans can be depolymerized in the same manner and the hydrolysis/deamination mixture can be reduced with NaB³H₄ to give stoichiometric ³H labeling of each reducing sugar component of the mixture.

The protocol has been described under the assumption that the user has a working knowledge of the chromatographic procedures required and of the use of radioisotopes in quantitative procedures.

Materials

Glycosaminoglycan sample (optionally, metabolically labeled with [³H]glucosamine; UNIT 17.4)
 20 μCi/ml [¹⁴C]glucose solution (>40 mCi/mmol; optional internal standard)
 3 M and 0.5 M H₂SO₄
 White mineral oil
 5.5 M NaNO₂
 1 M Na₂CO₃
 0.25 M NaBH₄ or 0.25 M ~500 mCi/mmol NaB³H₄, in 0.25 M NaOH
 0.1 M and 1 M NaOH
 Paper chromatography System 1 and System 2 (see recipes)
 Scintillation cocktail (see recipe)
 6 × 150-mm test tubes
 Sand baths: heating elements (Pierce) filled with sand, 99° and 50°C
 Hamilton syringe
 Whatman no. 3 chromatography paper (grade 3 Chr)
 Whatman cellulose phosphate chromatography paper (grade P 81)
 Paper chromatography jars for descending chromatography
 Scintillation counter suitable for dual-label counting

Hydrolyze glycosaminoglycans with acid

1. Dissolve glycosaminoglycan sample in water and dialyze exhaustively against water to remove salts.

If glycosaminoglycan sample is already radiolabeled (UNIT 17.4), its specific activity must be sufficient to permit detection following the procedure. If unlabeled glycosaminoglycans are to be analyzed after labeling by NaB^3H_4 reduction, a glycosaminoglycan concentration of 1 to 10 mg/ml is desirable. More specifically, the glycosaminoglycan sample should yield 0.1 to 1000 μmol of each mono- or disaccharide to be assayed. This amount of material will incorporate $>10^4$ cpm into each product after reduction with NaB^3H_4 with a specific activity of ~ 500 mCi/mmol.

2. Transfer 40 μl of dissolved sample to a 6 \times 150–mm test tube, add 20 μl of 20 $\mu\text{Ci/ml}$ [^{14}C]glucose, and mix.

The [^{14}C]glucose is an optional addition that provides an internal standard. It can be replaced with 20 μl water if desired. The [^{14}C]glucose introduced should give $\sim 50,000$ cpm/ μl glycosaminoglycan solution and should have a specific activity high enough (>40 mCi/mmol) so that the amount of ^3H incorporated upon reduction with NaB^3H_4 will not be significant.

3. Add 12 μl of 3 M H_2SO_4 to the sample, cover the meniscus with a layer of white mineral oil to prevent evaporation of water (which would concentrate the acid during hydrolysis), and heat the mixture 6 hr at 99°C in a sand bath.

The sample should not be heated at a temperature that would cause the water (acid) to boil during the hydrolysis. Boiling will disrupt the mineral oil layer and allow water to evaporate, concentrating the acid.

Cleave with nitrous acid

4. Cool the hydrolysate. Remove 8 μl with a Hamilton syringe and place in a 6 \times 150–mm test tube, then add 20 μl of 5.5 M NaNO_2 (a large excess) to the sample. Allow deamination reaction to proceed 10 min at room temperature.

If a [^{14}C]glucose internal standard is used, the volume of sample taken should be reflected by the amount of ^{14}C in the aliquot, but the same ratio of sample to NaNO_2 solution must be used in order to bring the pH to 4 (the NaNO_2 neutralizes the acid). The sample pH, which may be measured with pH paper, should be ~ 4 during the deamination reaction.

Reduce with sodium borohydride

5. Add 8 μl of 1 M Na_2CO_3 (pH ~ 8.5) followed by 5 μl of 0.25 M NaBH_4 or NaB^3H_4 .

Unlabeled NaBH_4 is used if the sample has previously been metabolically radiolabeled, and NaB^3H_4 is used if the sample has not been labeled.

CAUTION: *All NaB^3H_4 manipulations (steps 5 to 9) must be carried out in a well-ventilated fume hood.*

6. Cork the reaction tube and heat 30 min at 50°C in a sand bath to reduce the aldehyde groups formed in the deamination reaction.
7. Cool the reduced sample to room temperature. Working in the fume hood, add sufficient 0.5 M H_2SO_4 (~ 20 μl) to the sample to reduce the pH to <3 (this destroys excess NaBH_4 or NaB^3H_4).
8. After ~ 30 min, dry the sample in a stream of air. Redissolve sample in water and dry again to remove residual H_2 or $^3\text{H}_2$ gas.
9. Dissolve the sample in 50 μl water and add 1 M NaOH until the solution become slightly alkaline (pH 8 to 10), as observed with pH paper.

Spot samples and separate by chromatography

10. Mark sheets of Whatman no. 3 and Whatman cellulose phosphate chromatography paper with pencil lines $\frac{1}{2}$ in. apart, then cut the sheets perpendicularly to the lines to create strips $1 \times \sim 22$ in. (2.5×57 cm).
11. Spot 5- to 10- μ l aliquots of each reduced sample from step 8 onto two strips of Whatman no. 3 paper and one strip of cellulose phosphate paper. Place the aliquots in the middle of the sixth $\frac{1}{2}$ -in. segment from one end of each strip; this end is the wick. Allow the spots to dry.

IMPORTANT NOTE: *No more than 5 to 10 μ l of the original hydrolysate should be analyzed on a chromatogram, because excess salt in the sample may interfere with the resolution of the components of the mixture. The borate remaining in the sample after the destruction of the NaBH_4 has no effect on the migration of the products.*

12. Fold the wick ends so that they will fit properly into a descending paper chromatography trough. Place the two Whatman no. 3 strips in chromatography jar containing paper chromatography System 1 reagent and allow them to develop for 15 and 40 hr, respectively. Place the cellulose phosphate strip in a jar containing paper chromatography System 2 reagent and allow it to develop for 10 to 12 hr.

Determine radioactivity by scintillation counting

13. Remove developed strips from solvents after the appropriate times have elapsed. Allow the strips to dry, then cut strips into $\frac{1}{2}$ -in. segments along the pencil markings made in step 10. Place the segments in separate scintillation vials.
14. Add scintillation cocktail to each scintillation vial to cover the paper segment. Determine the radioactivity of each segment by counting in a scintillation counter under optimal conditions for dual-label counting.
15. Plot the data for each strip as cpm vs. segment number.

Analyze data

16. If a [^{14}C]glucitol internal standard was used, compare the migration position of each peak with that of the standard to identify the ^3H -labeled peaks (see Table 17.19B.1).

^3H is counted with an efficiency of $\sim 5\%$. ^3H peaks that overlap with the [^{14}C]glucose peak must be corrected for the ^{14}C spillover into the ^3H channel.

Table 17.19B.1 shows the R_{glucitol} values (the distance that each reduced component on the chromatogram migrates relative to the distance that the [^{14}C]glucitol internal standard migrates) for the expected hydrolysis products in the two chromatography systems. The 15-hr run in System 1 gives a value for the fast-moving anhydromannose and anhydrotalose formed from glucosamine and galactosamine, respectively. The 40-hr run in System 1 separates unhydrolyzed disaccharides, while the [^{14}C]glucitol peak migrates to the end of the strip. Separation of glucuronic and iduronic acids, which migrate together in System 1, is obtained on the System 2 chromatogram.

17. Sum the ^3H cpm in each peak and normalize the result to the same number of [^{14}C]glucitol cpm (the value for the ^{14}C cpm used for the normalization may be chosen arbitrarily, but it must be the same for each paper strip used for the glycosaminoglycan sample being analyzed).
18. Calculate the percentage of each monosaccharide in the hydrolysate as [(total cpm for the monosaccharide in question)/(total cpm in all components)] $\times 100$. Calculate the relative amounts of each monosaccharide component from Table 17.19B.2.

Table 17.19B.1 R_{glucitol} Values for [³H]Alditols^a

Product ^b	Chromatography system	
	System 1	System 2
Gal _R (KS)	1.0	—
<i>Deamination products</i>		
AMan _R (GlcN)	2.0	—
ATal _R (GalN)	2.0	—
<i>Uronic acids</i>		
GlcA _R (Hep, HS, DS)	0.95	0.55
IdoA _R (Hep, HS, DS)	0.95	0.33
<i>Disaccharides</i>		
αIdoA1-4AMan _R (Hep and HS)	0.70	1.15
βGlcA1-4AMan _R (Hep and HS)	0.50	1.00
αIdoA1-3ATal _R (DS)	0.64	0.64
βGlcA1-3ATal _R (CS and DS)	0.45	0.48
βGlcA1-3AMan _R (HA)	—	1.00

^aAll values are for aldehyde-reduced sugars, as indicated by the subscript R. Abbreviations: AMan, anhydro-D-mannose; ATal, anhydro-D-talose; CS, chondroitin sulfate; DS, dermatan sulfate; Gal, D-galactose; GlcA, D-glucuronic acid; GlcN, D-glucosamine; Hep, heparin, HS; heparan sulfate; IdoA, L-iduronic acid; KS, keratan sulfate.

^bThe glycosaminoglycan from which each product is derived is given in parentheses. Standards for AMan_R and ATal_R can be obtained by treating GlcN and GalN, respectively, with nitrous acid at pH 4 and reducing the products with NaB³H₄ (Shively and Conrad, 1970). Standards for IdoA and disaccharides must be obtained by hydrolysis and nitrous acid deamination of heparin, chondroitin sulfate, dermatan sulfate or hyaluronic acid followed by NaB³H₄ reduction of the products (Conrad, 1980).

Table 17.19B.2 Cpm Equivalentents for Monosaccharides^a

Amount of monosaccharide	Sum of total normalized ³ H cpm in:
GlcA _R	GlcA _R + βGlcA1-4AMan _R + βGlcA1-3ATal _R + βGlcA1-3AMan _R
IdoA _R	IdoA _R + αIdoA1-4AMan _R + αIdoA1-3ATal _R
AMan _R	AMan _R + βGlcA1-4AMan _R + βGlcA1-3AMan _R
ATal _R	ATal _R + βGlcA1-3ATal _R + αIdoA1-3ATal _R

^aThe subscript R refers to the aldehyde-reduced form of each mono- or disaccharide. See Table 17.19.8 for abbreviations.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Paper chromatography System 1

18:3:1:4 (v/v/v/v) ethyl acetate/glacial acetic acid/88% formic acid/water.

System 1 is used with Whatman no. 3 chromatography paper.

Paper chromatography System 2

3:2:1 (v/v/v) ethyl acetate/pyridine/0.005 M boric acid.

System 2 is used with cellulose phosphate chromatography paper.

Scintillation cocktail

4 g diphenyloxazole in 1 liter toluene.

COMMENTARY

Background Information

With the exception of keratan sulfate, which contains alternating D-galactose and N-acetyl-D-glucosamine residues, all glycosaminoglycans are sequences of disaccharide units containing a uronic acid (D-glucuronic acid and/or L-iduronic acid) and an amino sugar (D-glucosamine or D-galactosamine). Disaccharides of chondroitin sulfate contain D-GalNAc and D-GlcA, whereas those from dermatan sulfate contain D-GalNAc and either D-GlcA or L-IdoA. Disaccharides from heparin and heparan sulfate contain D-GlcN, which may be either N-acetylated or N-sulfated, and either D-GlcA or L-IdoA. Thus, if one has identified a glycosaminoglycan that is free of other glycosaminoglycans, the primary purpose of monosaccharide analysis is to determine the relative proportions of the two uronic acid types. However, when glycosaminoglycans are isolated from natural sources, they are often recovered as mixtures of several types of glycosaminoglycans that are difficult to resolve completely. In such cases, monosaccharide analysis can often demonstrate the nature of the mixtures by showing the relative proportions of GlcNAc and GalNAc as well as the specific disaccharide unit in which they are found. Individual glycosaminoglycans in a mixture can be recognized by their susceptibility to cleavage by specific enzymes (UNIT 17.13B) or nitrous acid (UNIT 17.22A). In the present method, the glycosaminoglycans are cleaved by acid hydrolysis, which results in loss of the sulfates. Procedures for determination of glycosaminoglycan disaccharides that have retained their sulfate substituents are described in UNITS 17.13B & 17.22A.

Following acid hydrolysis and nitrous acid cleavage of unlabeled glycosaminoglycans, it would be equally feasible to analyze the products of this cleavage reaction sequence by gas chromatography or HPLC without use of NaB³H₄. Although such an analytical scheme has not been developed, it would represent a way to avoid use of radioisotopes. The paper chromatographic procedure used here does offer the possibility of analyzing many samples simultaneously, which cannot be done with the GC or HPLC approaches where samples must be analyzed sequentially. Furthermore, when unknown peaks occur in this analysis, it is clear that the relative amounts of the unknowns are reflected by the amounts of ³H in the peaks, because (1) ³H labeling of carbohydrates is

identical for all reducing carbohydrates when expressed on a molar basis and (2) carbohydrates are virtually the only naturally occurring compounds that can be reduced by NaBH₄ or NaB³H₄. Moreover, it is easy to elute labeled products from the paper segments after analysis for further characterization. This is readily accomplished by rinsing the segments in toluene (to remove the diphenyloxazole remaining from the scintillation cocktail), then eluting the dried segment with water or buffer.

Critical Parameters

The challenge in analyzing the monosaccharide composition of glycosaminoglycans is not in the quantitation of the monosaccharides but in the depolymerization step. The impossibility of obtaining complete hydrolysis of glycosaminoglycans to monosaccharides without decomposition of some of the monosaccharide residues cannot be emphasized too strongly. The labilities of the glycosidic bonds of N-acetylated amino sugars (Shively and Conrad, 1970) and L-iduronic acid (Conrad, 1980) are similar to those for neutral hexoses, but the well-known stability of glucuronic acid glycosides virtually precludes the complete hydrolysis of these bonds without destruction of these residues as well as the other monosaccharide components of the glycosaminoglycan samples. Furthermore, hydrolytic release of the N-acetyl groups of the amino sugars occurs at a rate similar to that for the GlcNAc or GalNAc glycosides, so that many of the acetyl groups are released prior to complete hydrolysis of the amino sugar glycosidic bonds. This precludes complete hydrolysis of the amino sugar glycosides, as the glycosidic bonds of the N-unsubstituted GlcN and GalN are extremely stable to acid (Shively and Conrad, 1970). For the N-sulfated GlcN residues in heparin and heparan sulfate, this problem is particularly serious, as the N-sulfate substituents are very labile and are removed during the first few minutes of hydrolysis.

The tack taken here is to circumvent these hydrolysis problems by taking advantage of the elimination reaction that occurs when N-unsubstituted amino sugars are treated with nitrous acid (in spite of the misstatements often seen in the literature, this is not a hydrolysis reaction), thus cleaving these amino sugar glycosides under extremely mild conditions. This approach requires only that hydrolysis be continued long enough for complete removal of N-sulfate and N-acetyl groups. This avoids the

destruction of monosaccharide residues that occurs when forcing conditions of hydrolysis are used and allows almost stoichiometric recovery of these glycosaminoglycans as mono- and disaccharides, which can be analyzed together as described. Identical results for the analytical procedure described here are obtained whether the acid hydrolysis is carried out for 4, 6, or 8 hr before adding the nitrous acid reagent (Conrad, 1980). This is a reflection of the fact that all N- and O-sulfate groups and all N-acetyl groups will have been completely removed after 4 hr of hydrolysis. During the subsequent period (from the fourth to the eighth hour) there is some further hydrolysis, which reduces the yields of disaccharides and increases the yield of monosaccharides in the assay mixture, but this does not change the final analytical results.

For accurate results, it is advisable to first separate the glycosaminoglycan chains from the core protein and to isolate the free glycosaminoglycan chains for the analysis (UNIT 17.15). This avoids the possibility of loss of monosaccharides due to the Browning reaction, which occurs when carbohydrates and amino acids are heated together in acid.

The nitrous acid reaction is virtually stoichiometric for β -linked amino sugars (Shively and Conrad, 1970). Consequently, disaccharides are obtained in stoichiometric yields from glycosaminoglycans that contain β -linked amino sugars (chondroitin sulfate, dermatan sulfate, hyaluronic acid, and keratan sulfate). However, a side reaction, the ring contraction reaction, occurs at a frequency of 10% to 15% for α -linked amino sugars such as those found in heparin and heparan sulfate (Shively and Conrad, 1970; 1976). The ring contraction reaction results in deamination without bond cleavage and may convert a heparin tetrasaccharide into a new tetrasaccharide instead of two disaccharides. Thus, heparin and heparan sulfate yield significant amounts of ring contraction tetrasaccharides (Bienkowski and Conrad, 1985). However, there seems to be little structural selectivity for the ring contraction: the ring contraction tetrasaccharides contain disaccharide units in the same proportions as are found in the original glycosaminoglycan. Thus, even for heparin and heparan sulfate, the disaccharides formed during nitrous acid cleavage are obtained in the same proportions that are found in the original glycosaminoglycan. Consequently, when yields are expressed in percent of total uronic acids or percent of total amino

sugars, the ring contraction reaction does not interfere with the quantitation, and the yields of di- and monosaccharides are truly representative of their proportions in the starting glycosaminoglycan. Some of these heparin ring contraction tetrasaccharides have been identified (UNIT 17.22B).

Troubleshooting

In order to obtain reproducible migration of peaks, it is necessary to have chromatography tanks well-equilibrated with freshly prepared solvents. If many strips are placed in the tank, it may be necessary to add more chromatography solvent after the first day of the 40-hr development.

Anticipated Results

The results obtained here yield the distribution of labeled monosaccharides in metabolically labeled starting material or the monosaccharide compositions of the unlabeled glycosaminoglycan starting material. This is possible even though complete hydrolysis is not achieved, because one can separate and quantify disaccharides of known composition.

Time Considerations

The analytical procedure can be completed in 3 days, with 1 day for the depolymerization and NaB^3H_4 reduction, two overnight periods for paper chromatography, and finally scintillation counting and calculations. The procedure can be interrupted at any stage. A major advantage of the paper chromatography procedure over HPLC or GC methods is that many samples can be analyzed simultaneously. The only sequential phase of the analysis is scintillation counting, but the conditions described are designed to yield the mono- and disaccharides in sufficient yields (i.e., total ^3H cpm in each peak) so that 30-sec counting times for each paper segment result in good counting statistics.

Analysis of Oligosaccharide Negative Charge by Anion-Exchange Chromatography

UNIT 17.20

This unit presents the analysis of negative charge on labeled N- or O-linked oligosaccharides. These protocols may be used in the initial screening of oligosaccharides to detect negative charge, for analytical or preparative separation of oligosaccharides based on their negative charge, or to analyze the type of negative charge found on the oligosaccharides. The Basic Protocol describes the use of anion-exchange (QAE-Sephadex) chromatography with stepwise elution for estimating the number of negative charges on an oligosaccharide sample derived from glycosidase treatment of a glycoprotein. In the Alternate Protocol, gradient elution is used for the preparative separation of oligosaccharides based on negative charge. The Support Protocol describes a method for measuring loss of or change in negative charge after treatment of the oligosaccharide sample with mild acid and/or phosphatases.

SEPARATION AND ANALYSIS OF ANIONIC OLIGOSACCHARIDES BY QAE-SEPHADEX CHROMATOGRAPHY WITH STEPWISE ELUTION

**BASIC
PROTOCOL**

Negative charges on peptide-free radioactive N- or O-linked oligosaccharides can be detected by binding the molecules to the strong anion exchanger QAE-Sephadex (see also UNIT 10.10). Stepwise batch elution (as described in this protocol) or gradient elution (see Alternate Protocol) with salt separates the bound molecules according to the approximate number of negative charges. Loss or change of negative charge following treatment with sialidases (UNIT 17.12), solvolysis (UNIT 17.23), mild acid (UNIT 17.16), or phosphatase (see Support Protocol) can also be monitored (see Fig. 17.20.1). Because of charge-to-mass effects, this method gives only a general estimate of the number of negative charges on an oligosaccharide. If more precise analysis is desired, protocols using high-performance liquid chromatography (HPLC; UNIT 17.21) are recommended.

Materials

Radiolabeled mixture of oligosaccharides released from glycoprotein
(UNITS 17.12-17.17)

Equilibrated QAE-Sephadex chromatography resin (see recipe)

2 mM Tris base

Elution buffers (see recipe)

1- to 2-ml Pasteur pipets plugged with glass wool *or* 1- to 2-ml disposable plastic columns

Sintered-glass funnel

Additional reagents and equipment for metabolic radiolabeling (UNIT 17.4) and autoradiography (APPENDIX 3A)

1. Pour 0.75-ml column of equilibrated QAE-Sephadex in a 1- to 2-ml Pasteur pipet plugged with glass wool or in a 1- to 2-ml disposable plastic column. Wash with 5 ml of 2 mM Tris base.

It is acceptable to let the top of the column bed go dry during washing.

2. Dilute or dissolve the sample in 0.75 ml of 2 mM Tris base and load onto the column. Wash with seven 0.75-ml aliquots of 2 mM Tris base and collect 1.5-ml fractions.

Try not to disturb the top of the column bed during application. Allow the top of the column bed to go dry between aliquots.

The concentration of salts in the applied sample should be <5 mM and the pH must be >7. If the original sample contains acidic buffers or other salts, it may be necessary

Supplement 32

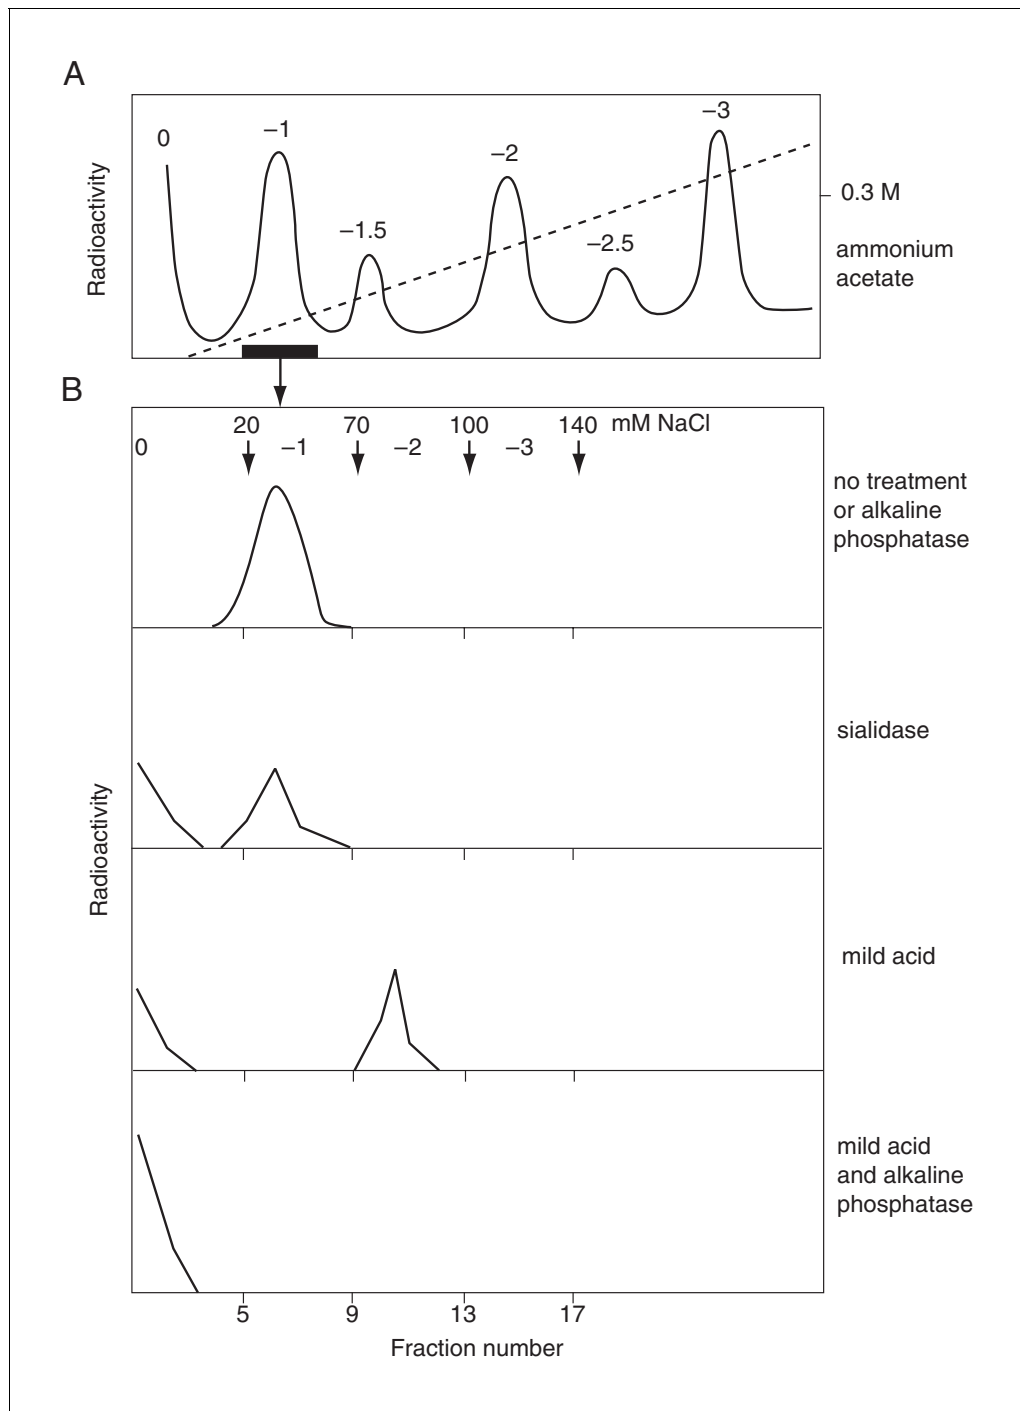

Figure 17.20.1 Schematic examples of QAE-Sephadex analysis (based on Varki and Kornfeld, 1983). Numbers in italics indicate the charges on the high mannose-type oligosaccharides eluting at that position. **(A)** Gradient fractionation of mixture of N-linked oligosaccharides with different combinations of sialic acid phosphomonoesters or phosphodiester. **(B)** Peak marked “-1” consists of a mixture of oligosaccharides with one negative charge due to either one sialic acid residue (acid- or sialidase-sensitive) or one phosphodiester (increased negative charge after mild acid, sensitive to alkaline phosphatase only after mild acid treatment). The procedures used to evaluate oligosaccharide mixtures are listed on the right with examples of resulting shifts in the elution peaks for each type of treatment illustrated on the left.

to neutralize with Tris base and/or dilute the sample to >0.75 ml to reduce the salt concentration. In these cases, the first wash-through tube will contain >1.5 ml fluid.

3. Elute sample from the column with elution buffers containing increasing concentrations of salt (i.e., 20, 70, 100, 140, 200, 400, and 1000 mM NaCl) in 2 mM Tris base. For each salt concentration, use eight 0.75-ml aliquots and collect four 1.5-ml fractions.

The salt elution series suggested above was devised for analysis of phosphorylated high mannose-type oligosaccharides from lysosomal enzymes. Salt concentrations may need to be adjusted to optimize the separation of other types of oligosaccharides (see Critical Parameters).

4. Monitor elution of the oligosaccharides by analyzing aliquots of the collected fractions (or the entire fractions) for radioactivity. In the latter case, collect the eluate directly into large-sized scintillation vials. If the first wash fraction is >1.5 ml (see step 2 annotation), monitor only an aliquot.

When comparing different treatments of the same oligosaccharide—e.g., sialidase (UNIT 17.12), mild acid, and alkaline phosphatase (see Support Protocol)—it is convenient to run all samples and controls in parallel. Approximately ten columns can be easily run at the same time. A repeating pipettor makes the process more reproducible and less taxing.

- 5a. The first time the experiment is done, and anytime it is possible that some of the oligosaccharides may not elute with the highest concentration of salt, add 1.5 ml of 2 mM Tris base to the column and transfer the contents of the column into a scintillation vial. Add scintillation fluid and monitor for any remaining radioactivity.
- 5b. Otherwise, discard the column contents (do not reuse).

SEPARATION AND ANALYSIS OF ANIONIC OLIGOSACCHARIDES BY QAE-SEPHADEX CHROMATOGRAPHY WITH GRADIENT ELUTION

**ALTERNATE
PROTOCOL**

After the initial studies of a mixture of oligosaccharides on a QAE-Sephadex column, it may be desirable to preparatively separate the oligosaccharides with better resolution. Although HPLC methods are preferable (see UNIT 17.21), the following protocol can be used if an HPLC unit or column is not available or if a large capacity is needed.

Additional Materials (also see Basic Protocol)

5- to 20-ml disposable plastic column
Gradient mixer

Additional materials and equipment for salt gradient preparation (UNIT 10.10)

1. Prepare a 3- to 10-ml column of QAE-Sephadex (see Basic Protocol, step 1, but use 5- to 20-ml disposable plastic column). Wash column with 10 column volumes of 2 mM Tris base.
2. Prepare and load the oligosaccharide sample (see Basic Protocol, step 2).
3. Place 50 ml of 2 mM Tris base in the first chamber of the gradient mixer; place 50 ml of an appropriate concentration of NaCl dissolved in 2 mM Tris base in the second chamber (choose salt concentration based on the results of the Basic Protocol).

An ammonium acetate gradient at pH 5.3 can be used to fractionate phosphomonoesters and phosphodiester (see Critical Parameters).

The concentration of NaCl or ammonium acetate in the second chamber is selected based on prior knowledge of the concentration required to elute the most anionic species in the mixture.

**Preparation and
Analysis of
Glycoconjugates**

17.20.3

**SUPPORT
PROTOCOL**

4. Elute the sample from the column with the selected linear gradient regimen. Collect 1-ml fractions and monitor for radioactivity.

**DETECTION AND REMOVAL OF PHOSPHODIESTERS OR
PHOSPHOMONOESTERS**

Oligosaccharide samples thought to contain phosphodiester and phosphomonoesters (e.g., released from lysosomal enzymes) can be treated with mild acid and alkaline phosphatase to detect and remove them. Phosphomonoester-containing molecules will lose negative charge upon phosphatase treatment. Phosphodiester-containing molecules are resistant to alkaline phosphatase alone, but will increase in negative charge following mild acid treatment because of the generation of phosphomonoesters. A combination of mild acid and phosphatase treatment will neutralize phosphodiester; the mild acid conditions used here will also result in removal of sialic acids (see Fig. 17.20.1).

Additional Materials (also see *Basic Protocol*)

Radiolabeled mixture of oligosaccharides released from glycoprotein (*UNITS* 17.12-17.17), desalted and lyophilized
10 U/ml *E. coli* alkaline phosphatase
2 M acetic acid
200 mM Tris·Cl, pH 8.0 (*APPENDIX 2*)

Strong 10-ml conical glass tubes *or* 1-ml Reacti-Vials (Pierce)
Water bath or heating block 80°C

1. Dissolve the oligosaccharide sample in 0.5 ml of 2 M acetic acid in a strong 10-ml conical glass tube or 1-ml Reacti-Vial. Tightly cap or stopper the tube and heat 120 min at 80°C.

This step is designed to detect phosphodiester. A second, identical sample should be prepared and processed starting with step 3; if phosphodiester are present, the acid-treated sample will show a higher negative charge than this non-acid-treated control upon analysis.

2. Flash-freeze and lyophilize the sample.
3. Dissolve in 20 µl water, using a pipettor to wash the walls of the tube. Vortex well and centrifuge briefly at room temperature to get sample to bottom of tube.
4. Remove a 10-µl aliquot of sample and dilute to 1.5 ml with 2 mM Tris base. Apply to a 0.75-ml QAE-Sephadex column for analysis (see *Basic Protocol*).
5. To the remaining sample, add 10 µl of 200 mM Tris·Cl (pH 8.0) and mix. Add 1 µl of 10 U/ml *E. coli* alkaline phosphatase (10 mU). Incubate 1 hr at 37°C.
6. Dilute sample to 1.5 ml with water and apply to a 0.75-ml QAE-Sephadex column (see *Basic Protocol*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Ammonium acetate (pH 5.3), 1 M

Dissolve 38.54 g ammonium acetate in H₂O. Add H₂O to 500 ml. Adjust pH to 5.3 with 1 M acetic acid. Store at 4°C.

Elution buffers

Prepare stock solutions of 1 M Tris base (pH unadjusted; store at 4°C) and 2 M NaCl (store at room temperature). Use these stocks to make elution buffers containing 2 mM Tris base and different concentrations of NaCl. For gradient elution, make appropriate dilutions of the 1 M ammonium acetate (pH 5.3) stock solution (see recipe). It is not necessary to check the final pH of the diluted solutions.

QAE-Sephadex chromatography resin, equilibrated

Swell QAE-Sephadex (Pharmacia Biotech) in 1 M Tris base (using 1 g dry resin/20 ml Tris) overnight at 4°C, then decant. Repeat once. Pour slurry over a sintered-glass funnel and wash with >20 vol of 2 mM Tris base. Check the pH of the final wash with pH paper to make sure it is similar to that of the Tris base; if not, wash again until appropriate pH is achieved. Store equilibrated resin in 2 mM Tris base at 4°C.

There is no need to remove “fines” (small particles) from the resin because the columns used are small and flow rates are not limiting. With storage and exposure to air, the pH of the Tris base will drift towards neutral; however, this is not of serious concern.

COMMENTARY

Background Information

Negatively charged monosaccharides and highly anionic oligosaccharides bind well to most anion-exchange resins. However, large oligosaccharides with very few negative charges have a poor charge-to-mass ratio and may fail to bind to some anion-exchange resins. The strong anion exchanger QAE-Sephadex was first used (Tabas and Kornfeld, 1980) to permit analysis of high mannose-type N-linked oligosaccharides with single phosphodiester. The column was equilibrated in 2 mM Tris base to ensure that the pH was above neutral (maximizing the deprotonation of all anions) and to limit the amount of salt competing for binding sites. The protocol described here is based upon modifications of this method (Varki and Kornfeld, 1980, 1983; Goldberg and Kornfeld, 1981).

In the time since the original description, modifications have been developed to separate a wide variety of anionic oligosaccharides, including O-linked oligosaccharides, N-linked glycopeptides, and sulfated oligosaccharides (Roux et al., 1988; Fukuda, 1989; Cummings et al., 1989). In each case, column sizes and elution conditions were adjusted to allow appropriate separations and yield. In recent years, Mono-Q FPLC columns (Pharmacia Biotech) have permitted the use of the same QAE exchanger group for more rigorous and complete separations (van Pelt et al., 1987; *UNIT 10.10*).

Critical Parameters

The QAE-Sephadex resin must be thoroughly equilibrated in 2 mM Tris base. The initial loading must be carried out in a minimum

amount of salt (<2.5 mM) to ensure that weakly charged molecules do not escape binding. This can be achieved by desalting samples thoroughly (*UNIT 10.9*) and/or diluting them sufficiently with water or 2 mM Tris base before loading. To make the dilution volume reasonable, the preceding steps (e.g., enzyme reactions) should be carried out in the minimum volumes and lowest salt concentrations possible. Acid treatments are carried out with volatile acids that can be lyophilized before analysis. The charge-to-mass ratio of an oligosaccharide affects the amount of NaCl required for elution. Thus, a high mannose-type N-linked oligosaccharide with a single mannose-6-phosphate residue will elute with 50 to 70 mM NaCl, while free mannose-6-phosphate (with the same anionic group) requires 100 to 120 mM NaCl. The amount of salt needed to elute a particular charge or size class of molecules must be determined empirically. Thus, this technique is most useful when a related series of oligosaccharides with a limited range of size and charge (e.g., phosphorylated N-linked oligosaccharides with one to four negative charges) are being separated and analyzed. However, even when there is very extensive heterogeneity in size and charge (e.g., sulfated sialylated N-linked oligosaccharides), information can be obtained by following relative shifts in the elution position of groups of molecules (Roux et al., 1988). Gradient elution gives more defined separation between individual types of molecules, and is used primarily for preparative separations. If the molecules contain mixtures of phosphomonoesters and phosphodiester, separation can be obtained with a

gradient of ammonium acetate adjusted to pH 5.3 (close to the pK_a of the second negative charge of a phosphomonoester).

Analysis of glycopeptides by QAE-Sephadex chromatography is less satisfactory, because the peptide portion of the molecules can carry variable amounts of negative and/or positive charge. However, if complete proteolytic cleavage is performed (see UNIT 17.14A), each glycopeptide should have only one carboxyl group and separations can be made on the basis of the additional negative charges on the oligosaccharide. Molecules with very high charge density (e.g., heparin chains) are not well resolved on QAE columns because they are difficult to elute.

Troubleshooting

If molecules known to be anionic do not bind to the QAE-Sephadex column, the most likely problems are failure to properly equilibrate the column in 2 mM Tris base and the presence of excessive salt in the sample. If peaks are broad and slurred, the most likely problem is excessive disturbance of the top of the column bed during the application of elution buffers.

Anticipated Results

The method presented in this unit can be used for the following analyses.

1. *Initial screening of oligosaccharides for the presence of negative charge.* The sample is applied and the column washed and then directly eluted with 1 M NaCl in 2 mM Tris base. As a control, a known neutral oligosaccharide and an anionic oligosaccharide should be run under exactly the same conditions to obtain background numbers. A small quantity of the anionic oligosaccharide (<5%) can be expected to escape binding to the column, and a small amount of label from the neutral molecule (<2%) will be nonspecifically found in the salt eluate.

2. *Analytical separation of oligosaccharides by negative charge.* A mixture of oligosaccharides is applied and sequentially eluted batchwise with a defined series of salt elution steps (e.g., 20, 70, 100, 140, 200, 400, and 1000 mM NaCl), and the profile is monitored.

3. *Preparative separation of oligosaccharides by negative charge.* This is based upon the profile obtained by analytical separation. Gradient elution using NaCl or ammonium acetate may be preferred. Peaks are pooled, dried, and desalted on columns of Sephadex G-25 in water.

4. *Analysis of the type of negative charge on oligosaccharides.* Individual peaks obtained by preparative separation are analyzed before and after treatment or combinations of treatments with mild acid (see Support Protocol), with sialidase (UNIT 17.12), by solvolysis (UNIT 17.23), and/or with alkaline phosphatase (see Support Protocol). Fig. 17.20.1 schematically depicts an example of such analyses.

Time Considerations

The initial setup of small columns should take 10 to 20 min. The setup for gradient elution takes somewhat longer. Stepwise elutions of approximately ten samples can usually be carried out in parallel in ~1 hr. If sample preparation for scintillation counting is performed during time gaps in the elution procedure, the entire process can be completed in 2 to 3 hr. The time for scintillation counting will depend upon the amount of radioactivity available in each sample.

HPLC Methods for the Fractionation and Analysis of Negatively Charged Oligosaccharides and Gangliosides

UNIT 17.21A

This unit describes the fractionation and analysis of anionic oligosaccharides (Basic Protocol 1) and gangliosides (Basic Protocol 2) using anion-exchange high-performance liquid chromatography (HPLC). The sample is loaded onto the column in a low-ionic-strength solvent. The anionic saccharides or gangliosides are retained by the positively charged matrix by ionic interactions; the more negative charge on the compound, the more tightly it binds to the column. Neutral molecules pass through the column unretained. Elution is effected by a gradient of increasing ionic strength that progressively disrupts the ionic interactions between the analyte and the column. Saccharides or gangliosides are eluted in order of the number of negative charges they possess, although the charge-to-mass ratio can also contribute to elution position. Hence, a molecule with a high charge-to-mass ratio may elute later than one with the same net charge but a smaller charge-to-mass ratio. Those unfamiliar with the basic principles of HPLC are referred to *UNITS 10.12-10.14* or to Snyder et al. (1988).

FRACTIONATION OF RELEASED N-LINKED OLIGOSACCHARIDES ON DEAE HPLC COLUMNS

**BASIC
PROTOCOL 1**

The use of DEAE HPLC columns to separate sialylated N-linked oligosaccharides is described. The DEAE column is equilibrated in water and eluted with a gradient of increasing NaCl concentration. Sialic acids are detected based on their radioactivity (if previously radiolabeled) or by the TBA assay for sialic acids (if unlabeled) and comparison with known standards.

Materials

HPLC-grade or high-quality deionized water (e.g., 18 M Ω Milli-Q type)

0.5 M sodium chloride (NaCl) in HPLC-grade water (see recipe)

Oligosaccharide sample (Peptide N:glycosidase F–released and desalted;
UNIT 17.13A)

Sialylated oligosaccharide standards (e.g., Dionex or Oxford Glycosystems)

HPLC apparatus capable of two-component gradient formation

DEAE HPLC column (TosoHaas TSK-gel DEAE-2SW, 25-cm \times 4.6-mm i.d.,
5-mm particle size, or equivalent)

Additional reagents and equipment for desalting sample (*UNITS 17.13A & 17.14A*) and
(if analyzing unlabeled sample) TBA assay (*UNIT 17.18*)

1. Before using any column, wash the column thoroughly. First, wash with at least 10 column volumes of water. Next, wash the column with a linear gradient from 0 to 0.5 M NaCl over 100 min, and then from 0.5 M NaCl to 100% water over 100 min. Use a flow rate of 0.4 to 0.6 ml/min for all washes.

The water and all buffers used should be prefiltered through a 0.45- μ m filter and degassed. Column prefilters and/or guard columns provide additional protection for the HPLC column and increase its productive lifetime.

A flow rate of 0.4 to 0.6 ml/min is recommended for all column washings and elutions. Do not exceed the manufacturer's recommendations for either the flow rate or maximum pressure.

**Preparation and
Analysis of
Glycoconjugates**

17.21.1

2. Thoroughly clean the injection loop with water.
3. Equilibrate the column at room temperature with 100% water at a flow rate of 0.6 ml/min. Wash with at least 10 column volumes of water.
4. Check the baseline obtained with the detection method to be used for the sample. Do not proceed until a stable baseline is obtained.

For analytical work, on-line radioactivity detectors or UV detectors may be used. For UV detection, absorbance at 190 to 210 nm is measured. Because many compounds absorb at these wavelengths, this method of detection demands high purity of the sample. Alternatively, individual fractions may be collected and analyzed by one of several methods (see step 8). Collect a portion of the eluate and establish that the solvents do not interfere with the detection method chosen and that the baseline is stable.

5. Set up a program from the pump control unit for washing unbound material, eluting the bound species, and bringing the column back to the starting conditions, as indicated in Table 17.21A.1.

The NaCl gradient should be shallow for two reasons. First, the difference in NaCl concentration needed to elute oligosaccharides differing by a single negative charge is ~20 mM NaCl, depending on the column. Second, the DEAE resin will shrink and swell with increasing and decreasing NaCl concentrations, respectively. Therefore, rapid changes in ionic strength may damage the column and degrade its performance.

6. Make a “sham” run (injecting water in place of sample), monitoring the eluant, if an on-line detection system is used. If fractions are collected and individually analyzed, collect them every 1 min. Load the water into the injection loop using a syringe with a flat-tip needle compatible with the HPLC injector. Inject the water onto the column and start the gradient program.

If contaminant peaks are observed (peaks >5% full scale when using the detector settings required for the sample), the column must be washed until the peaks disappear. (When using UV detection, a peak will be observed at the void volume, indicating the change in absorbance produced when the water injected passes through the column.) To wash, repeat the gradient and hold at the maximum concentration of NaCl for at least 10 column volumes. Wash extensively with water, then repeat the blank run.

7. Inject and analyze the sialylated oligosaccharide standards individually as indicated in step 6. Determine the elution time for each of the standards. If the separation of the individual standards is adequate, proceed to the analysis of the samples. If not, it may be necessary to adjust the rate of increase in the NaCl concentration to obtain better separation.

The column should be routinely standardized. At least one standard run, preferably with a mixture of sialylated oligosaccharide standards, should be performed at the start of each day.

Table 17.21A.1 DEAE HPLC Elution Regimen for Analysis of N-Linked Oligosaccharides

Time (min)	Eluant
0	100% H ₂ O
5	100% H ₂ O
95	50% 0.25 M NaCl
100	50% 0.25 M NaCl
140	100% H ₂ O
155	100% H ₂ O

- Analyze the desalted samples using the optimum conditions determined in step 7. If the amount of sample is small or the column is being used to obtain individual species for subsequent analysis, collect and analyze fractions every 0.5 to 1.0 min. Analyze the individual fractions by using either liquid scintillation counting or the TBA assay for sialic acids (UNIT 17.18).

The sample must be desalted (as described in UNITS 17.13A & 17.14A) prior to analysis, because even low concentrations of NaCl can prevent the initial binding of the anionic oligosaccharides to the cationic matrix. The desalted oligosaccharides can be concentrated by lyophilization and resuspended in a small volume of water. The main factor in determining the appropriate sample volume is the size of the injection loop, although injection loops of $\leq 500 \mu\text{l}$ are preferred.

- Estimate the number of sialic acid residues present by comparing the elution position of each peak to that of the sialylated oligosaccharide standards run in the same conditions.

*The linkage of the sialic acid residues can also be determined using sialidase digestion (UNIT 17.12) in combination with repeated anion-exchange HPLC. If, for instance, a sample that originally comigrated with a trisialylated triantennary oligosaccharide standard is treated with Newcastle disease virus sialidase, under conditions in which only $\alpha 2$ -3-linked sialic acids are released, and now comigrates with a monosialylated species, it can be inferred that the oligosaccharide in question has two $\alpha 2$ -3-linked sialic acid residues. Additionally, if the oligosaccharide in question is not retained by the DEAE column following treatment with the broad-spectrum sialidase from *Arthrobacter ureafaciens*, it can be inferred that the negative charge on the oligosaccharide in question was due solely to sialic acid residues. Although this type of analysis can be performed on a mixture of oligosaccharides, it is preferable to first isolate the individual HPLC peaks and then to treat with sialidase and reanalyze each separately.*

CAUTION: Remember to desalt the samples submitted to sialidase digestion prior to ion-exchange HPLC analysis.

FRACTIONATION OF GANGLIOSIDES ON DEAE HPLC COLUMNS

The use of DEAE HPLC columns to separate gangliosides from neutral lipids and glycolipids and fractionate them according to the number of sialic acid residues is described. Total lipid extracts, partially fractionated negatively charged glycolipids (total lipid extracts or the fraction enriched in polar lipid obtained by Folch partitioning of the total lipid extracts; see UNIT 17.3), or the total ganglioside fraction eluted from a DEAE anion-exchange column (see UNIT 17.3) can be further fractionated and analyzed by this method. The DEAE column is equilibrated in organic solvent and eluted with a gradient of increasing ammonium acetate concentration. Fraction components are detected based on their radioactivity (if previously radiolabeled) or by HPTLC analysis with chemical or immunological detection (if unlabeled) and gangliosides identified by comparison with known standards.

Materials

- HPLC-grade or high-quality deionized (e.g., 18 M Ω Milli-Q type) water
- HPLC-grade chloroform
- HPLC-grade methanol
- 1:8:1 (v/v/v) chloroform/methanol/1 M aqueous ammonium acetate (see recipe)
- Ganglioside sample (extracted and desalted; UNIT 17.3)
- Ganglioside standards (G_{M1} , G_{D1a} and G_{T1b} ; e.g., Sigma, Boehringer Mannheim, or Calbiochem)
- HPLC apparatus capable of two-component gradient formation
- DEAE HPLC column (TosoHaas TSK DEAE-2SW, or comparable)

BASIC PROTOCOL 2

Preparation and Analysis of Glycoconjugates

17.21.3

Additional reagents and equipment for high-performance thin-layer chromatography (HPTLC; if analyzing unlabeled sample, UNIT 17.17A) with chemical detection (UNIT 17.10B) and for TBA assay (UNIT 17.18)

1. Equilibrate the column in organic solvent by running a linear gradient from 100% water to 1:8:1 (v/v/v) chloroform/methanol/water at 1 ml/min, over 1 hr. If the column was stored in buffer, first wash extensively with water.

The water and all aqueous buffers used should be prefiltered through a 0.45- μ m filter and degassed. Do not degas mixtures containing organic solvents prior to chromatography; moreover, for systems that require continuous helium bubbling during chromatography, a low flow is sufficient. Column prefilters and/or guard columns provide additional protection for the HPLC column and increase its productive lifetime. When using a guard column, be sure to connect it prior to performing the equilibration with organic solvent.

2. Convert the column to the acetate form by running a 1-hr linear gradient from 1:8:1 (v/v/v) chloroform/methanol/water to 1:8:1 (v/v/v) chloroform/methanol/1 M aqueous ammonium acetate at 1 ml/min, and holding at this concentration of salt for another 1 hr. Wash the column extensively with 1:8:1 (v/v/v) chloroform/methanol/water to remove the salt. Use a flow rate of 1 ml/min throughout this step.
3. Flush out the injection loop with water, then methanol, then chloroform, and finally with 1:8:1 (v/v/v) chloroform/methanol/water.
4. For columns previously used to analyze radioactive samples, check the background with an on-line radioactivity detector or by collecting fractions and counting.
5. Set up a program from the pump control unit for washing unbound material, eluting the bound species, and bringing the column back to the starting conditions at 1 ml/min flow as indicated in Table 17.21A.2.

The DEAE resin will shrink and swell with increasing and decreasing salt concentrations, respectively. Therefore, transition from high salt concentration to no salt has to be done slowly. Rapid changes in ionic strength may cause damage to the column and degrade column performance.

Table 17.21A.2 DEAE HPLC Elution Regimen for Analysis of Gangliosides

Step	Time (min)	Eluant
Wash	0	1:8:1 (v/v/v) chloroform/methanol/water
Elution	10	1:8:1 (v/v/v) chloroform/methanol/water
	70	1:8:1 (v/v/v) chloroform/methanol/aqueous 1 M ammonium acetate
Reequilibration	100	1:8:1 (v/v/v) chloroform/methanol/water
	130	1:8:1 (v/v/v) chloroform/methanol/water

- Dissolve equivalent amounts of the ganglioside standards in 1:8:1 (v/v/v) chloroform/methanol/water. Load the solution of the standards into the injection loop using a syringe with a flat-tip needle compatible with the HPLC injector.

Solutions of these standards in 2:1, 1:1, or 1:2 (v/v) chloroform/methanol can also be used. When using a solvent other than the running solvent, keep the injection volume as small as possible.

- Inject the solution onto the column and start the gradient program. When analyzing radiolabeled standards, use an on-line radioactivity detector or route the eluate to a fraction collector (collecting 1-min fractions), remove aliquots of each fraction, add scintillation fluid, and measure radioactivity by counting in a scintillation counter. When analyzing nonradioactive standards, collect fractions and analyze one aliquot of each fraction by HPTLC, detecting the bands chemically (UNIT 17.10B) or by overlaying with monoclonal antibodies when available.

When using an on-line radioactivity detector, determine the required ratio of scintillation cocktail to eluant to avoid excessive quenching by the organic solvents.

- Determine if the separation of the ganglioside standards obtained is as expected (see Table 17.21A.3).

Separation is typically very reproducible, and it is not necessary to run standards each time the column is used.

Table 17.21A.3 Expected Retention Times of Ganglioside Standards

Ganglioside standard	Retention time (min)
G _{M1}	26–30
G _{D1a}	39–43
G _{T1b}	60–64

- Analyze the individual fractions by liquid scintillation counting, by the TBA assay (UNIT 17.18), or by HPTLC as indicated in step 7.

Normally, total lipid extract is obtained free of salts (UNITS 17.3 or UNIT 17.10B) and can be directly analyzed. Samples submitted to previous fractionation steps using salts must be desalted by dialysis or by loading onto a Sep-Pak C₁₈ cartridge prior to analysis (salts are washed off with water and anionic molecules eluted with organic solvents), because even low concentrations of salt can prevent binding of the anionic oligosaccharides to the cationic matrix (UNIT 17.3). Desalted gangliosides can be concentrated by lyophilization and redissolved in a small volume of 1:8:1 (v/v/v) chloroform/methanol/water.

When analyzing radioactive labeled samples, a peak in the void volume indicates the presence of neutral species (e.g., neutral lipids or glycolipids) that are also radioactive. These neutral species should not react in the TBA assay (UNIT 17.18) or with resorcinol spray (UNIT 17.10B). If TBA- or resorcinol-positive species are present at the void volume, the column capacity has been exceeded.

CAUTION: Dry down the organic solvent prior to performing the TBA assay.

When analyzing a large portion of each fraction by HPTLC, the water in the elution solvent will take some time to evaporate. Transfer the aliquot to a microcentrifuge tube, evaporate the solvent to dryness (i.e., use a Speedvac evaporator system), and redissolve in 2:1, (v/v) chloroform/methanol to spot the plate.

- Determine the type of ganglioside (e.g., mono-, di-, or trisialylated) present by comparing the elution position of each peak to that of known ganglioside standards run in the same conditions.
- Determine the number of gangliosides in each fraction by analyzing the HPTLC patterns obtained with resorcinol staining (*UNIT 17.10B*).
- When doing semipreparative chromatography, pool the fractions according to the profile obtained. Concentrate under vacuum, dissolve in a small volume of 1:8:1 (v/v/v) chloroform/methanol/water, dilute with 10 vol water, and desalt by overnight dialysis against water using 500- or 1000-MWCO tubing. Recover the gangliosides by lyophilization.

Alternatively, dry sample, resuspend in water, and desalt using a Sep-Pak C₁₈ cartridge previously washed successively with 20 ml each chloroform, dimethyl sulfoxide, acetonitrile, methanol, and water (see also UNIT 17.3).

IMPORTANT NOTE: *Semipreparative chromatography is defined as the fractionation of the individual species obtained by HPLC with a standard-sized column.*

REAGENTS AND SOLUTIONS

Use HPLC-grade or other high-quality deionized water (e.g., 18 MΩ Milli-Q type) in all recipes and protocol steps, and filter through a 0.45-μm filter and degas before use. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Chloroform/methanol/1 M aqueous ammonium acetate, 1:8:1 (v/v/v)

Dissolve 77 g ammonium acetate in HPLC-grade water. Adjust the volume to 1 liter and filter through a 0.45-μm filter. Combine 1 vol of this solution with 1 vol chloroform and 8 vol methanol, mix, and use for HPLC. Store in a tightly capped bottle.

Sodium chloride (NaCl), 0.5 M

Dissolve 29.25 g NaCl in 900 ml water. Adjust the volume to 1 liter and filter through a 0.45-μm filter before use.

COMMENTARY

Background Information

Ion-exchange HPLC using weak anion exchange chromatography columns has been used to analyze and/or fractionate a variety of anionic oligosaccharides and glycoconjugates. Negatively charged saccharides bind to the positively charged resin of the column and are eluted in order of increasing negative charge with a gradient of increasing ionic strength. DEAE HPLC columns have been run in water for the fractionation of released N- and O-linked oligosaccharides and in organic solvents for the fractionation of gangliosides. Although HPLC analysis requires more equipment than chromatography on QAE-Sephadex (*UNIT 17.19*), the profiles obtained are sharper and saccharides containing few negative charges can be better resolved.

DEAE and amine-bonded (Baenziger and Natowicz, 1981) HPLC columns have been used to fractionate released N-linked oligosac-

charides that differ in their number of sialic acids. Sialidase digestion (*UNIT 17.12*) followed by repeated anion-exchange chromatography yields information about the number and linkage of the sialic acid residues on the oligosaccharide. The decrease in negative charge following sialidase treatment indicates the number of sialic acid residues removed, and the linkage is inferred from knowledge of sialidase specificity. Similarly, oligosaccharides can be analyzed for the presence of phosphate by subjecting them to ion-exchange HPLC analysis following alkaline phosphatase digestion with and without prior mild acid treatment (Varki and Kornfeld, 1983). If the phosphate is “covered” by *N*-acetyl-D-glucosamine (GlcNAc), it will be resistant to alkaline phosphatase. Treatment with mild acid removes the GlcNAc residue and exposes the phosphate for removal by alkaline phosphatase.

Sulfated and sialylated/sulfated oligosaccharides have also been separated using weak anion-exchange HPLC columns. Amine-bonded columns (Micropak AX-5, Varian) have been used to analyze sulfated/sialylated oligosaccharides (Green and Baenziger, 1986). When the column eluant is buffered to pH 4, both sialic acid and sulfate have one negative charge. However, at pH 1.7 sialic acid is only partially ionized and, therefore, has a net negative charge of <1. Thus, performing the HPLC analysis at two different pHs, near the pK of one of the anionic species, permits the fractionation of sulfated and sulfated/sialylated oligosaccharides. This approach has been adapted to DEAE HPLC columns by buffering the column with phosphate buffer at pH 2.5 for the separation of dermatan sulfate fragments (Hayes and Varki, 1993a).

The separation of more negatively charged saccharides requires the use of strong anion-exchange columns. Polysialic acids with 2 to 20 sialic acids have been separated using a Mono-Q column (Hallenbeck et al., 1987).

Several methods to detect oligosaccharides are available. The choice depends upon the nature of the sample. Radiolabeled oligosaccharides can be detected using an on-line radioactivity detector or by collecting fractions and analyzing all or a portion of the individual fractions by liquid scintillation counting. Oligosaccharides can be radiolabeled, either metabolically (UNIT 17.4), enzymatically (UNIT 17.6), or chemically (UNIT 17.5). Oligosaccharides can also be detected spectrophotometrically, as many monosaccharides absorb between 190 and 205 nm. This method, though simple, requires quantities of oligosaccharide that are often prohibitive (>5 nmol). Moreover, the sample and HPLC solvents must be of high purity and the elution medium cannot contain salts that absorb at these wavelengths (e.g., acetate). An alternative approach is to assay the fractions for the presence of sialic acid using the TBA assay (UNIT 17.18), or, in the case of gangliosides, by HPTLC with chemical detection (UNIT 17.10B).

Interpretation of data depends on the use of appropriate standards. Several sialylated N- and O-linked oligosaccharide standards are commercially available. The same standards used to calibrate the HPLC column can be used as controls for sialidase digestions. It should be noted that several distinct oligosaccharide structures may have equivalent net negative charge, resulting in coelution; therefore, DEAE

HPLC is only one facet of oligosaccharide structural analysis.

DEAE HPLC is also useful for separating gangliosides according to the number of sialic acids they contain. All monosialylated gangliosides coelute, although some fractionation can occur because of other structural differences. The same is true for the higher-order (e.g., di- or trisialylated) gangliosides. Complete purification of individual species usually requires a further chromatographic step based on other principles (e.g., HPLC columns of a special silica gel called Iatrobeads, from Iatron Laboratories). This method has been used for the analysis and semipreparative fractionation of labeled and unlabeled gangliosides (Manzi et al., 1990; Sjoberg et al., 1992). When gangliosides contain sulfate groups, interaction is stronger and, in some cases, it is necessary to keep eluting at maximum salt concentration for long periods (A. Manzi, unpub. observ.).

Critical Parameters

The separation of anionic oligosaccharides is greatly affected by the steepness of the NaCl gradient. If the concentration of NaCl is increased too rapidly, the resolution of the differently charged species will be reduced. Additionally, the column may be damaged because of shrinking and swelling of the matrix, which occur with changes in ionic strength. A final concentration of 125 mM NaCl should be sufficient to elute saccharides with up to five negative charges. More negatively charged species can be eluted by increasing the final salt concentration. The highest concentration of NaCl compatible with a given column is indicated by the supplier (e.g., some DEAE columns should not be exposed to NaCl concentrations >1 M).

Failure of acidic saccharides to bind to the column can be caused by several factors. Salt in the sample may impair the ionic interactions responsible for binding to the column. Desalting the sample prior to analysis should prevent this. Alternatively, the acidic moieties may be protonated and hence uncharged. This is unlikely, because the pK_a of the carboxylic acids of acidic sugars is typically <3, with sulfates having even lower pK_a values. On the other hand, phosphodiester have pK_a values around 5, and CO₂ dissolved in column buffers may lower the pH of the column eluant sufficiently to protonate them. This is easily addressed by buffering the column to a pH >6 with 2 to 5 mM Tris base, pH 9.5. In this case, UV cannot be used for detection.

It is not advisable to change the solvent from aqueous to organic and back to analyze anionic oligosaccharides and gangliosides, because the performance of the column in both applications is markedly affected. If both types of analyses are regularly done, two different columns must be used.

Anticipated Results

Oligosaccharides or gangliosides with sialic acid as their only anionic moiety can be separated using the above protocols. When one to four sialic acids/molecule are present, the species are readily resolved. Sialidase treatment of released N-linked oligosaccharides with repeated HPLC analysis provides information about the linkage of the sialic acid residues. In the case of gangliosides, the method is particularly useful for semipreparative purposes.

Time Considerations

A typical separation of released N-linked oligosaccharides requires 1 to 2 hr, depending on the length and steepness of the gradient and the length of time the column is allowed to wash. At least one standard run, preferable with a mixture of standards, should be performed at the start of each day. Thus three to six samples can be analyzed in an 8-hr day. When analyzing gangliosides, one run and equilibration of the column back to the starting conditions usually takes 2 hr.

Fractionation and Analysis of Neutral Oligosaccharides by HPLC

UNIT 17.21B

This unit describes the fractionation and analysis of neutral oligosaccharides by high-performance liquid chromatography (HPLC) on bonded amine columns. Separation is achieved with gradients of acetonitrile and water and is based upon hydrogen bonding between the NH_2 groups of the column and the hydroxyl groups of the oligosaccharides, as described in the Basic Protocol. The Support Protocol describes the reduction and desalting of neutral oligosaccharides with sodium borohydride. The basic principles of HPLC are discussed in *UNITS 10.12-10.14* and in Snyder et al. (1988).

SEPARATION OF NEUTRAL OLIGOSACCHARIDES ON A BONDED AMINE HPLC COLUMN

**BASIC
PROTOCOL**

Neutral oligosaccharides bind to amine-bonded HPLC columns because of hydrogen bonding via hydroxyl groups, which is promoted by acetonitrile and disrupted by water. The sample is loaded in a high concentration of acetonitrile and the column is developed with a gradient of increasing water. Neutral oligosaccharides are initially retained by the column and elute in order of increasing size (increasing numbers of hydroxyl groups). Oligosaccharides are detected based on their radioactivity (if previously radiolabeled) or by physical or chemical means (if unlabeled). Information about the number and size of oligosaccharide species in a mixture is thus obtained.

Materials

- Oligosaccharide sample
- Oligosaccharide standards (e.g., Dionex or Oxford Glycosystems)
- HPLC-grade water
- HPLC-grade acetonitrile
- HPLC apparatus capable of two-component gradient formation
- Bonded amine HPLC column (e.g., Varian Micropak AX-5 or Rainin LC-NH₂)
- Additional reagents and equipment for exoglycosidase digestion (optional; *UNITS 17.13 & 17.18*), and reduction and desalting of neutral oligosaccharides (see Support Protocol)

1. Reduce and desalt the sample prior to analysis (see Support Protocol). If desired, prepare parallel samples treated by sequential or combined exoglycosidase digestion (*UNIT 17.13 & 17.18*) chosen to help elucidate the structure.

Reduction of samples gives sharper peaks and better baseline resolution.

The column is also a weak anion exchanger. Salts or buffers can compete with the oligosaccharide for binding sites, altering elution time and resolution. Anionic oligosaccharides will bind to the column and will not elute with water. However, the method can be adapted to study anionic oligosaccharides.

2. Equilibrate the column in 70% acetonitrile/30% water at a flow rate of 1 ml/min.

*Water and acetonitrile should be prefiltered through a 0.45- μm filter and degassed. See *UNIT 10.12* support protocol for preparation and degassing of solvents. Column prefilters and/or guard columns provide additional protection and increase the productive lifetime of the column.*

All common neutral oligosaccharides should bind to the column in 70% acetonitrile. If an oligosaccharide fails to bind, the starting concentration of acetonitrile should be increased.

**Preparation and
Analysis of
Glycoconjugates**

17.21.9

3. Dissolve the sample in a small volume of water and add 3 vol acetonitrile.

The main factor determining the appropriate sample volume is the size of the injection loop. Injection loops of $\leq 500 \mu\text{l}$ are preferred.

4. Load and inject the sample. Immediately start a 70% to 30% acetonitrile gradient over 80 min, maintaining the flow rate of 1 ml/min.

Typical neutral N-linked oligosaccharides elute at water concentrations of $< 70\%$. A second gradient of 30% to 0% acetonitrile over 30 min may be included to elute unexpectedly large neutral oligosaccharides and to help keep the column clean.

5. Detect the oligosaccharides by physical, chemical, or radiometric methods. For analytical work, in-line radioactivity detectors or UV detectors may be used. If the amount of radioactive sample is low, or if the column is being used to obtain individual species for subsequent analysis, collect and analyze fractions every 0.3 to 0.5 min. For UV detection, measure absorbance at 190 to 210 nm. Determine the number of oligosaccharide species present and compare their retention times to those of known standards prepared similarly.

Because many compounds absorb at 190 to 210 nm, UV detection demands a sample of high purity.

6. Infer features of the oligosaccharide structure from the retention time relative to standards and from changes in retention caused by sequential or combined exoglycosidase digestion.

Because retention time is also a reflection of column performance, it is important to properly care for the column. Routine washing with water (step 4 annotation) helps remove contaminants that are hydrogen bonded to the column. Salts or other ionic contaminants can be removed by periodic washing with 0.5 M potassium phosphate, pH 1.7. Column performance will deteriorate over time, even with washing, due to gradual dissolution of the bonded phase. Standards must therefore be run at the beginning and end of each set of samples.

SUPPORT PROTOCOL

SODIUM BOROHYDRIDE REDUCTION AND DESALTING OF NEUTRAL OLIGOSACCHARIDES

Oligosaccharides with a reducing sugar at their inner terminus elute as broader peaks than those that have been reduced to alditols. Whenever possible, therefore, oligosaccharides should be reduced prior to HPLC analysis. Samples and standards should be similarly treated. Recoveries of oligosaccharides after reduction and desalting are typically $\sim 70\%$. Note that a radioactive label can be introduced at this stage if ^3H -labeled sodium borohydride ($[^3\text{H}]\text{NaBH}_4$) is used (UNIT 17.5) and that *O*-*N*-acetyl-D-galactosamine (*O*-GalNAc)-linked oligosaccharides are reduced during their release by β -elimination (UNIT 17.15).

Additional Materials (also see Basic Protocol)

1 M sodium borohydride (NaBH_4) in 0.2 M sodium borate ($\text{Na}_2\text{B}_4\text{O}_7$; see recipe)
5% acetic acid/95% methanol
Mixed-bed anion and cation resin (Amberlite MB-3 or equivalent)

1. Dissolve NaBH_4 to 1 M final concentration in 0.2 M $\text{Na}_2\text{B}_4\text{O}_7$ (pH 9.5) immediately before use. Dissolve the dried oligosaccharides in 100 μl of this reagent and incubate 3 hr at room temperature. Because hydrogen gas may be evolved by decomposing NaBH_4 , cautiously vent the tube occasionally or use a tall, loosely capped tube.

Sodium borate buffer at pH 9.5 is preferred to more basic NaOH solutions, because the latter promote epimerization of the core N-glucosamine to N-mannitosamine, which can result in doublet peaks in the HPLC analysis.

2. Stop the reduction by adding dropwise a 5% acetic acid/95% methanol mixture. The sample will bubble due to evolution of hydrogen gas. Continue until no more gas is evolved.
3. Dry the sample under a stream of N₂ or using a shaker/evaporator, Speedvac evaporator, or similar device. Take to complete dryness.
4. Repeat steps 2 and 3 three times using 0.5 ml of 5% acetic acid/95% methanol each time.

Under acidic conditions the methanol and Na₂B₄O₇ form volatile methyl borates. The salt left behind is sodium acetate.

5. Prewash a 2 to 5 ml column of mixed-bed resin with at least 10 column volumes of water. Dissolve the dried sample in water, load, and elute with water. Collect a single 10 to 15 ml fraction.

Only neutral reduced oligosaccharides should pass through the column unretarded.

6. Lyophilize or dry the sample. Store the oligosaccharide at -20°C, either dry or in water.

Presence of white powder following lyophilization indicates that not all the salt was removed by the resin. If so, repeat the desalting. A 26-G needle added to the column outlet can slow the flow and increase the time for the salts to interact with the resin. Alternatively, an anion-exchange column (e.g., Dowex 3×4a, hydroxide form, prewashed with ≥10 vol water) can be used followed by a cation-exchange column (e.g., Dowex 50, hydrogen form, prewashed with ≥10 vol water).

REAGENTS AND SOLUTIONS

Use HPLC-grade or other high-quality deionized water (e.g., 18 MΩ Milli-Q type) in all recipes and protocol steps, and filter through a 0.45-μm filter and degas before use. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

1 M sodium borohydride in 0.2 M sodium borate

Prepare 0.2 M sodium borate by dissolving 7.63 g sodium borate (Na₂B₄O₇·10H₂O) in 90 ml H₂O. Adjust pH to 9.5 with NaOH and volume to 100 ml. Store at room temperature.

Immediately before use, dissolve 37.8 mg sodium borohydride (NaBH₄) per ml 0.2 M sodium borate, pH 9.5. Do not mix excessively.

COMMENTARY

Background Information

The fractionation and analysis of neutral oligosaccharides on the basis of size using this HPLC method yield several important pieces of information. A minimum estimate of the number of species present is obtained from the number of peaks observed. The size of an N-linked oligosaccharide may be indicative of the extent to which it has been processed. Single or sequential exoglycosidase digestion(s) (UNIT 17.18), in conjunction with repeated HPLC analysis, yield information about the identity and linkage of the monosaccharides present. Although HPLC analysis requires more equipment than conventional chromatography on Bio-Gel P-4, the elution profiles obtained are

sharper and larger oligosaccharides can be better resolved.

Bonded amine HPLC columns have free NH₂ groups that hydrogen bond to the hydroxyl groups of oligosaccharides. Elution is accomplished by increasing the water content, which progressively disrupts the hydrogen bonds. Other factors affecting elution time include the monosaccharide composition and the branching pattern of the oligosaccharide. Several methods of detecting the oligosaccharides are available. Radiolabeled molecules can be detected with an in-line radioactivity detector or by liquid scintillation counting of fractions. Oligosaccharides can be radiolabeled, either metabolically (UNIT 17.4), enzymatically (UNIT

17.6), or chemically (UNIT 17.5). Because some monosaccharides absorb UV light between 190 and 205 nm, they can also be detected spectrophotometrically. However, this requires quantities of oligosaccharide that are sometimes prohibitive (>5 nmol) and a sample of high purity. An alternative approach is to label the reducing terminus of the oligosaccharide with a fluorescent tag (see Tomiya et al., 1988, and references therein). However, some hydrophobic tags can produce anomalous behavior on these HPLC columns.

Interpretation of the data is dependent on the use of appropriate standards. Complex, hybrid, and high-mannose N-linked oligosaccharides and several O-linked oligosaccharide standards are commercially available. The same standards used to calibrate the HPLC column can also be used as controls for exoglycosidase digestions.

The use of bonded amine HPLC columns to separate neutral oligosaccharides was introduced in the early 1980s. Since then several articles have been published describing the behavior of model oligosaccharides on these columns and elucidating the factors that affect elution time (Mellis and Baenziger, 1981; Blanken et al., 1985). Such systems have been used to study the substrate specificity of glycosyltransferases (e.g., Schachter et al., 1989; Brockhausen et al., 1988; Koenderman et al., 1989) and to deduce the order of release of monosaccharides from oligosaccharides by exoglycosidase digestion (e.g., Tomiya et al., 1991). Sequential exoglycosidase digestion coupled with HPLC analysis has been used extensively to elucidate oligosaccharide structure (e.g., Sampath et al., 1992).

A modification of this method has been described for the fractionation of anionic oligosaccharides on the basis of size (Mellis and Baenziger, 1983). Triethylamine acetate is used to suppress the charge of sialic acid, phosphate, and sulfate, thus allowing separation of oligosaccharides on the basis of monosaccharide content alone. The reader is referred to the original description (and to UNIT 17.17B) for further details.

Critical Parameters

The most important parameter is column performance. There is some variability in the quality of separation by columns from different manufacturers and between columns from a given manufacturer. Decreases in column performance can be expected to occur over time due to the gradual dissolution of the bonded

phase (Blanken et al., 1985). Improper care can greatly accelerate the decay of column performance. Inadequate cleaning, the use of unfiltered solvents, and the presence of contaminants in the sample can lead to higher back pressure, broader peaks, and decreased retention time.

The nature of the gradient also affects the ability of the column to resolve individual oligosaccharide species (Mellis and Baenziger, 1981). Most oligosaccharides are retained by the column if the starting acetonitrile/water ratio is 70:30. Typical gradients increase the water content by 0.5%/min. However, for separation of larger oligosaccharides the water content may need to be increased by only 0.3%/min (Blanken et al., 1985). Oligosaccharides that have not been reduced and desalted give broader peaks than reduced molecules. Reduction should be performed in sodium borate buffer and not in NaOH, as strongly alkaline conditions promote the epimerization of the GlcNAcitol to ManNAcitol, which can lead to doublet peaks (Mellis and Baenziger, 1981). Reduced oligosaccharides may have longer retention times than their unreduced counterparts (Koenderman et al., 1989). Thus, the standards used to calibrate the column should be treated the same way as the samples.

Anticipated Results

Homopolymers of increasing size of GlcNAc (chitin) and glucose (dextrans) have been separated into a series of well-spaced peaks, corresponding to oligomers that differ in size by one monosaccharide unit (Mellis and Baenziger, 1981). The elution time of oligosaccharides depends on the number of monosaccharides present and their composition. GlcNAc- and fucose-containing oligosaccharides elute sooner than oligosaccharides having an equal number of hexoses (Blanken et al., 1985), presumably because GlcNAc and fucose have one fewer hydroxyl group. The branching pattern of an oligosaccharide also affects its elution time. Oligosaccharides containing a β 1-6 linkage elute later, presumably because the flexibility of this linkage allows a stronger interaction with the column (Blanken et al., 1985). Thus, it is possible to separate isomers of the same size given good column performance.

Time Considerations

A typical separation requires 1 to 2 hr, depending upon the length and steepness of the gradient and the length of time the column is

allowed to wash. At least one standard run, preferably with a mixture of standards, should be performed at the start of each day. Thus three to six samples can be analyzed in an 8-hr day.

Nitrous Acid Degradation of Glycosaminoglycans

UNIT 17.22A

**BASIC
PROTOCOL**

Glycosaminoglycans (GAGs) are made up of disaccharide units that are distinguished from each other by the monosaccharide units of which they are composed and by the degree and position of sulfation. These disaccharide units represent the monomeric units of the GAG; thus, measurement of the disaccharide composition of a GAG represents the first step in the characterization of the polymer—just as an amino acid analysis represents the first step in characterization of a protein.

In this protocol, alternative sets of steps are presented—the first set for cleavage of the glycosidic bonds of the N-sulfated GlcN residues in heparin and heparan sulfate, and the second set for cleavage of the bonds between the N-acetylated amino sugar residues in heparin, heparan sulfate, chondroitin sulfate, dermatan sulfate, and keratan sulfate, as well as hyaluronic acid. The glycosidic bonds of N-sulfated GlcN residues can be rapidly cleaved with nitrous acid at pH 1.5 at room temperature to yield oligosaccharides. N-acetylated amino sugar residues do not react with nitrous acid. However, these residues can first be deacetylated by hydrazinolysis to generate GalN or GlcN residues, and the glycosidic bonds of these N-unsubstituted amino sugar residues can then be cleaved at room temperature with nitrous acid at pH 4. The N-sulfate groups in heparin and heparan sulfate are stable under the hydrazinolysis conditions. Thus, following N-deacetylation by hydrazinolysis, all GAGs can be converted completely to their constituent disaccharides by treatment with nitrous acid at pH 4 alone (for chondroitin, dermatan, , and keratan sulfates, as well as hyaluronic acid) or with nitrous acid at pH 4 and then at pH 1.5 (for heparin and heparan sulfates). The resulting cleavage products contain reducing-terminal 2,5-anhydro-D-mannose residues (from GlcN) or 2,5-anhydro-D-talose residues (from GalN), which can be reduced stoichiometrically with tritiated sodium borohydride ($\text{NaB}[^3\text{H}]_4$) to ^3H -anhydromannitol or ^3H -anhydrotalitol residues—thus labeling the disaccharides so that they can be assayed qualitatively or quantitatively. The procedure described in the Basic Protocol may also be used to analyze metabolically labeled GAGs (with or without the use of $\text{NaB}[^3\text{H}]_4$).

Materials

- Reference standard (see recipe)
- Unknown sample suspected of containing N-sulfated *or* N-acetylated GAG
- Internal standard (see recipe)
- Nitrous acid reagent, pH 1.5 (see recipe)
- 1 M Na_2CO_3
- 10 $\mu\text{g}/\mu\text{l}$ hydrazine sulfate in anhydrous hydrazine
- 3 M H_2SO_4
- Nitrous acid reagent, pH 4.0 (see recipe)
- 0.5 M tritiated sodium borohydride ($\text{NaB}[^3\text{H}]_4$; ~500 mCi/mmol) in 0.1 M NaOH
- 100- μl Reacti-Vials (Pierce)
- Sand bath: heating block (e.g., Pierce) with wells filled with sand

Cleave GAGs

To cleave N-sulfated GAGs

- 1a. Mix 20 μl of reference standard solution for N-sulfated GAG assay with 5 μl D- ^{14}C glucose internal standard. Prepare the same reaction mixture using 20 μl of unknown sample suspected of containing N-sulfated GAG in place of the standard, and carry both mixtures through all steps in parallel.

**Preparation and
Analysis of
Glycoconjugates**

Supplement 32

- 2a. Cool a 5- μ l aliquot of the reaction mixture to 0°C and add 20 μ l nitrous acid reagent, pH 1.5.
- 3a. Let mixture warm to room temperature for 10 min to complete the deamination reaction.
- 4a. Bring cleaved reaction mixture to pH 8.5 with 1 M Na₂CO₃.

The cleaved product is then subjected to borohydride reduction and analysis (steps 5 and 6). After borohydride reduction but prior to analysis, it may be desirable to separate the reaction products (a mixture of di- and tetrasaccharides) according to size by gel filtration (see UNIT 10.9) on a Bio-Gel P-10 column, eluting with 1 M Na₂CO₃.

To cleave N-acetylated GAGs

- 1b. Mix 200 μ l of reference standard for N-acetylated GAG assay with 50 μ l of [¹⁴C]glucitol internal standard. Prepare the same reaction mixture using 20 μ l of unknown sample suspected of containing N-acetylated GAG in place of the standard, and carry both mixtures through all steps in parallel.
- 2b. Place a 15- μ l aliquot of the reaction mixture in a 100- μ l Reacti-Vial and evaporate to dryness in a stream of air. Redissolve dried sample in 20 μ l of 10 μ g/ μ l hydrazine sulfate in anhydrous hydrazine, then cap the vial and incubate 6 hr at 100°C in a sand bath.

CAUTION: Hydrazine is a toxic, corrosive, and flammable reagent and should be handled accordingly.

- 3b. Cool reaction mixture, evaporate until as dry as possible in a stream of air, then lyophilize partially dried sample to remove as much hydrazine as possible. Add 20 μ l nitrous acid reagent, pH 4 to the dried sample. Check pH with pH paper and adjust to pH 4 using 5 to 10 μ l of 3 M H₂SO₄, if necessary. Let stand 15 min at room temperature.

Because of residual hydrazine sulfate and hydrazine, the solution is usually at ~pH 6 before adjustment.

The hydrazinolysis procedure removes N-acetyl substituents from the N-acetylated amino sugar residues, but the N-sulfated substituents in heparin or heparan sulfate remain. Hence, steps 1b to 3b result in cleavage at the N-deacetylated hexosamine residues but not at the N-sulfated hexamines. Deamination (step 4b) cleaves at the N-sulfated residues as well; thus, steps 1b to 4b result in the complete conversion of heparin and heparan sulfate (as well as all of the other GAGs) to disaccharides.

- 4b. Adjust reaction mixture to pH 1.5 with 3 M H₂SO₄, then cool solution to 0°C, carry out the deamination reaction, and adjust the reaction mixture to pH 8.5 as in steps 2a to 4a.

The cleaved product is then subjected to borohydride reduction and analysis (steps 5 and 6). All of the products obtained after hydrazinolysis and nitrous acid cleavage are disaccharides, and therefore may be analyzed without further sample purification.

Reduce cleavage products with sodium borohydride

5. Mix cleaved sample with 10 μ l of 0.5 M Na[B³H]₄ in 0.1 M NaOH and incubate 15 min at 50°C.

CAUTION: Carry out all NaB³H₄ manipulations in a well-ventilated fume hood designated for radioactive use.

6. Add 5 μl of 3 M H_2SO_4 and evaporate samples to dryness in a stream of air, then redissolve sample in water and again evaporate to dryness in a stream of air to remove as much $[\text{}^3\text{H}]_2$ as possible.

The sample is now ready for analysis. For analysis by paper chromatography or paper electrophoresis, it should be redissolved in 60 μl of water. For analysis by HPLC, it should be dissolved in the starting buffer to be used the chromatographic run (see UNIT 17.22B for both procedures).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Internal standards

D- $[\text{}^{14}\text{C}]$ glucose standard for N-sulfated GAG assay: Prepare a stock solution containing 20 $\mu\text{Ci}/\text{ml}$ D- $[\text{}^{14}\text{C}]$ glucose (specific activity >40 mCi/mmol; Amersham or Du Pont NEN). Dilute an aliquot of the stock solution in water to obtain a solution containing $\sim 1 \times 10^5$ cpm/ μl of radioactivity.

$[\text{}^{14}\text{C}]$ glucitol standard for N-acetylated GAG assay: Reduce D- $[\text{}^{14}\text{C}]$ glucose with sodium borohydride as in steps 5 and 6 of the Basic Protocol, except use cold NaBH_4 . Dilute the resulting $[\text{}^{14}\text{C}]$ glucitol in water to obtain a solution containing $\sim 1 \times 10^5$ cpm/ μl of radioactivity.

Because D- $[\text{}^{14}\text{C}]$ glucose reacts with hydrazine, it cannot be used directly as an internal standard in the hydrazinolysis reaction. Consequently, it must be reduced for use in the N-acetylated GAG assay.

Nitrous acid reagent, pH 1.5

Prepare 0.5 M H_2SO_4 and 0.5 M $\text{Ba}(\text{NO}_2)_2$ (114 mg/ml) and cool separately to 0°C in an ice bath. Prepare a mixture containing 1 ml of each solution—i.e., 0.5 mmol each of H_2SO_4 and $\text{Ba}(\text{NO}_2)_2$ —at 0°C , then pellet the BaSO_4 precipitate in a clinical centrifuge. Draw off the supernatant with a Pasteur pipet, and keep on ice until ready to use.

This reagent should be prepared when needed and used immediately.

Nitrous acid reagent, pH 4.0

Add 5 ml of 5.5 M NaNO_2 to 2 ml of 0.5 M H_2SO_4 .

This reagent should be prepared when needed and used immediately.

Reference standards

For N-sulfated GAG assay: 25 mg/ml aqueous solution of heparin or heparan sulfate.

For N-acetylated GAG assay: 25 mg/ml aqueous solution of chondroitin-4-sulfate (chondroitin sulfate type A), chondroitin-6-sulfate (chondroitin sulfate type C), dermatan sulfate (chondroitin sulfate type B), or keratan sulfate.

All of the above GAGs are available from Sigma. The standard solutions are stored frozen at -20°C .

COMMENTARY

Background Information

Glycosaminoglycans (GAGs) are families of structurally related polymers composed of sequences of different disaccharides that represent the monomeric units of these polymers. Chondroitin sulfates, dermatan sulfates, and hyaluronic acid represent one family of GAGs.

Chondroitin sulfates contain only GlcA and GalNAc residues, and are sulfated at positions 4 and/or 6 of the GalNAc (and on some of the uronic acid residues as well). In dermatan sulfates, the amino sugar is GalNAc, but both GlcA and IdoA are present in varying proportions. Hyaluronic acid contains GlcNAc and

GlcA. Keratan sulfate contains Gal and GlcNAc, both of which may be sulfated at the 6 position. Thus, in contrast to heparin and heparan sulfate, which contain both N-acetylated and N-sulfated amino sugars as described below, chondroitin sulfate, dermatan sulfate, hyaluronic acid, and keratan sulfate contain only N-acetylated amino sugars. The glycosidic bonds of these N-acetylated amino sugar residues are not cleaved by nitrous acid.

Heparan sulfate and heparin represent another family of glycosaminoglycans, which contain GlcN as the amino sugar and both GlcA and IdoA in varying proportions. A unique structural feature of heparin and heparan sulfate is that a large proportion of their GlcN residues are N-sulfated (85% to 90% in heparin; 40% to 60% in a typical heparan sulfate); the rest are N-acetylated. The glycosidic bonds of these N-sulfated GlcN residues can be cleaved rapidly at room temperature with nitrous acid at pH 1.5 to yield oligosaccharides. This nitrous acid susceptibility distinguishes heparin and heparan sulfate from all other glycosaminoglycans. Because of the low percentage of GlcNAc residues in heparin, the GlcNAcs are found in isolated disaccharide units, surrounded by disaccharides that have N-sulfated GlcNs. Thus, the pH 1.5 nitrous acid cleavage reaction products of heparin are primarily disaccharides, with much smaller quantities of tetrasaccharides from sequences in which the GlcNAcs are located. However, heparan sulfate contains sequences with multiple contiguous GlcNAc-containing disaccharide units, and these sequences yield larger oligosaccharides among the nitrous acid cleavage products. Thus, to analyze the disaccharides formed following cleavage with the pH 1.5 nitrous acid reagent, the saccharides are first separated from the larger oligosaccharides by gel filtration on a BioGel P-10 column using 1 M Na₂CO₃ for elution. The products are then analyzed by paper chromatography, paper electrophoresis, or high-performance liquid chromatography (HPLC) as described in *UNIT 17.22B*.

The N-acetylated amino sugars can be deacetylated by hydrazinolysis to generate GalN or GlcN residues, and the glycosidic bonds of these N-unsubstituted amino sugars can then be cleaved at room temperature with the pH 4 nitrous acid reagent. Thus, following N-deacetylation by hydrazinolysis, those glycosaminoglycans containing only N-acetylated amino sugars are converted completely to disaccharides by the pH 4 nitrous acid reagent (in contrast to heparin and heparan sulfate,

which yield higher oligosaccharides in addition to disaccharides). To convert heparin and heparan sulfate completely to disaccharides, these GAGs must first be N-deacetylated and then treated with nitrous acid at both pH 4 and pH 1.5.

Critical Parameters

The nitrous acid reagents are prepared by mixing nitrite salts with acid to yield the desired pH. Once the nitrite and acid are mixed, a series of complex reactions occurs involving the resulting oxides of nitrogen. Within a short time, the active species of "nitrous acid" undergoes changes that result in the loss the reagent's ability to cleave the glycosidic bonds of the amino sugar (Shively and Conrad, 1976). Consequently, the nitrous acid reagents must be used within a few minutes after preparation. This is of less concern for the pH 4 reagent than for the pH 1.5 reagent, because the pH 4 reagent has a higher concentration of nitrite.

Also, pH is important for maintaining the selectivity of the cleavage. Although there is good selectivity for N-unsubstituted GlcNs and N-sulfated GlcNs at pH 4 and pH 1.5, respectively, the glycosidic bonds of both types of GlcN residues are cleaved at pHs between these values. Thus, it is desirable to let the reactions at the respective pHs proceed only for 10 to 15 min. Also, when samples are derived from buffered solutions, it is necessary to check the pH with pH paper before addition of the nitrous acid reagent. In fact, it is desirable to dialyze the glycosaminoglycan solution to remove all salts before beginning the cleavage step. Another reason for the pre-dialysis is that the NaB[³H]₄ reagent is catalytically destroyed by oxyanions, such as PO₄³⁻ (Conrad et al., 1973).

Anticipated Results

When samples containing mixtures of different glycosaminoglycans are treated with nitrous acid at pH 1.5, only heparin and heparan SO₄ are cleaved; thus, the total amount of glycosaminoglycan that is reduced in molecular size by pH 1.5 nitrous acid represents the heparin/heparan sulfate family. Just as the nitrous acid cleavage is diagnostic for the heparin/heparan sulfate family, the chondroitin sulfate/dermatan sulfate/hyaluronic acid family is specifically cleaved by chondroitinases (or chondroitin lyases) ABC or AC (*UNIT 17.13B*). These selective cleavages can be used for characterization of glycosaminoglycans that are metabolically labeled (e.g., with [³⁵S]O₄²⁻ or [³H]glucosamine). The use of nitrous acid and

the chondroitinases for more definitive characterization of glycosaminoglycans is described in *UNIT 17.22B*.

Time Considerations

The nitrous acid cleavage is complete within a few minutes after the reagent is added to the sample. When hydrazinolysis precedes the nitrous acid cleavage, an additional 6 to 8 hr is required for the hydrazinolysis step and preparation of the sample for nitrous acid cleavage. The overall procedure can be interrupted after hydrazinolysis, nitrous acid cleavage, or $\text{NaB}[\text{}^3\text{H}]_4$ reduction without any loss of precision in the analytical stage.

Analysis of Disaccharides and Tetrasaccharides Released from Glycosaminoglycans

Glycosaminoglycans (GAGs) are converted to disaccharides by cleavage with lyases or by treatment with nitrous acid either before or after N-deacetylation. Enzymatic (lyase) cleavage of GAGs to disaccharides is described in *UNIT 17.13B*. Nitrous acid cleavage of GAGs to release disaccharides (or tetrasaccharides, from heparin and heparan sulfate), and the $\text{NaB}[^3\text{H}]_4$ reduction of these products is described in *UNIT 17.22A*.

As described in this unit, individual disaccharides are separated by paper chromatography or paper electrophoresis (Basic Protocol 1) or high-performance liquid chromatography (HPLC; Basic Protocol 2). Lyase-released disaccharides can also be monitored by UV absorbance as described in Background Information. The disaccharides can be radiolabeled for subsequent detection either by metabolic labeling of the cells that produce them (*UNIT 17.4*) or by reduction of the disaccharides from unlabeled GAGs with $\text{NaB}[^3\text{H}]_4$ to incorporate one gram atom of ^3H per mole of disaccharide (*UNIT 17.22A*). The label incorporated into the separated disaccharides can then be used for qualitative or quantitative assay of each disaccharide.

Support Protocol 1 describes mild conditions for borohydride reduction of alkali-labile disaccharides obtained by cleavage of GAGs with lyases. Support Protocol 2 describes scintillation counting of samples obtained from HPLC separation of radiolabeled saccharides, and Support Protocol 3 describes calculations for the quantitation of disaccharides.

BASIC PROTOCOL 1

ANALYSIS OF DISACCHARIDES AND OLIGOSACCHARIDES FROM GLYCOSAMINOGLYCANS BY PAPER CHROMATOGRAPHY AND PAPER ELECTROPHORESIS

Materials

- Sample of lyase-degraded (*UNIT 17.13B*; also see Support Protocol 1) or nitrous acid-degraded glycosaminoglycan (*UNIT 17.22A*)
- Paper chromatography or paper electrophoresis system appropriate to saccharide mixture to be analyzed (see Table 17.22B.1 and Table 17.22B.2; also see recipe in Reagents and Solutions)
- Apparatus for paper electrophoresis

NOTE: [^{14}C]glucose can be added as an internal standard. See *UNIT 17.22A* for details.

1. Run descending paper chromatograms and paper electrophoretograms on 1×22 -in. strips of chromatography paper in the appropriate solvent system for the saccharide mixture to be analyzed. Spot the desired volume of each sample on a 0.5-in. segment of the strip that has been marked off in advance. For paper electrophoresis, dampen the paper strips with the solvent up to the point where the sample was spotted and electrophorese the samples toward the anode at 25 V/cm for 2.5 hr.
2. Count radioactivity on 0.5-in. segments from the paper strips.

^b R_{glucitol} = ratio of migration distance of compound to migration distance of [¹⁴C]glucitol internal standards.

^cThe HPLC gradient for both SAX and WAX columns consisted of a 30-min isocratic segment at 40 mM KH₂PO₄, followed by a 40-min linear gradient of 400 mM KH₂PO₄. HPLC separations are performed at a flow rate of 1 ml/min.

**BASIC
PROTOCOL 2**

**ANALYSIS OF DISACCHARIDES AND OLIGOSACCHARIDES FROM
GLYCOSAMINOGLYCANS BY HPLC**

Samples to be analyzed by high-performance liquid chromatography (HPLC) are obtained by nitrous acid cleavage of N-deacetylated glycosaminoglycans at pH 4 (UNIT 17.22A), by direct cleavage of heparin or heparan sulfate with nitrous acid at pH 1.5 (UNIT 17.22A), or by enzymatic cleavage with lyases (UNIT 17.13B). For HPLC, all samples must be free of particulate matter and should be dissolved in the initial solvent used to elute the HPLC column.

Materials

Sample: mixture of saccharides obtained from glycosaminoglycan by nitrous acid cleavage (UNIT 17.22A) or lyase cleavage (UNIT 17.13B)

4.5-mm × 25-cm Partisil SAX strong anion-exchange column (Whatman) or 4-mm × 30-cm Varian MicroPak AX-5 weak anion-exchange column (Varian Analytical)

HPLC solvents (see recipe and Tables 17.22B.1-17.22B.5)

Gradient solutions for HPLC (Tables 17.22B.1-17.22B.5)

Bio-Gel P-10 gel filtration column (Bio-Rad)

4.6 × 250-mm Hi-Chrom S-5 ODS C-18 column (Regis Technology)

Fraction collector or in-line radioactivity flow detector (e.g., Packard Instrument)

Additional reagents and equipment for gel-filtration chromatography (UNIT 10.9), ion-exchange HPLC (UNIT 10.13), and reversed-phase HPLC (UNIT 10.12)

**Analysis of
Disaccharides and
Tetrasaccharides
Released from
Glycosamino-
glycans**

17.22.8

For disaccharides obtained from chondroitin sulfate, dermatan sulfate, and keratan sulfate by nitrous acid cleavage

- 1a. Run HPLC on a 4.5-mm × 25-cm Whatman Partisil SAX strong ion-exchange column or 4-mm × 30-cm Varian MicroPak AX-5 weak anion exchange column using the appropriate isocratic elution conditions (see Table 17.22B.1). Proceed to step 3.

For disaccharides obtained from chondroitin sulfate and dermatan sulfate by lyase cleavage

- 1b. Reduce the disaccharide mixture with borohydride as in Support Protocol 1.
- 2b. Run HPLC on a 4.5-mm × 25-cm Whatman Partisil SAX strong ion-exchange column or 4-mm × 30-cm Varian MicroPak AX-5 weak anion exchange column using the appropriate elution conditions.

The maximum sample volume for injection is 500 μl for both nitrous acid- and lyase-cleaved GAGs.

For strong ion-exchange separation of di- and tetrasaccharides obtained from heparin and heparan sulfate by nitrous acid cleavage

- 1c. Prior to chromatographic separation of individual oligosaccharides, separate the oligosaccharides according to size by gel-filtration chromatography (UNIT 10.9) on a Bio-Gel P-10 column in 1 M Na₂CO₃.
- 2c. Analyze di- and tetrasaccharides on a 4.5-mm × 25-cm Whatman Partisil SAX strong ion-exchange column using step gradients at a flow rate of 1 ml/min (see Table 17.22B.3). For disaccharide separation, use an initial 40 mM KH₂PO₄ isocratic segment for 25 min to resolve unsulfated and monosulfated disaccharides, followed by a 1-min linear step gradient to 185 mM KH₂PO₄, and a 40-min isocratic segment at 185 mM KH₂PO₄ to resolve the disulfated disaccharides. For samples with high salt content, it is advisable to run an initial 10-min isocratic segment with 20 mM KH₂PO₄ to wash the excess salt through the column, thus avoiding any possible effect of the high salt on the elution profiles. For tetrasaccharide separation, use a step gradient with five isocratic segments: 40 mM KH₂PO₄ for 25 min; 100 mM KH₂PO₄ for 35 min; 175 mM KH₂PO₄ for 30 min; 360 mM KH₂PO₄ for 25 min; and 400 mM KH₂PO₄ for 25 min. Connect each isocratic segment by a 1-min step gradient from one isocratic segment to the next.

For reversed-phase ion-pairing HPLC separation of di- and tetrasaccharides obtained from heparin and heparan sulfate by nitrous acid cleavage

- 1d. Prior to chromatographic separation of individual oligosaccharides, separate the oligosaccharides according to size by gel-filtration chromatography (UNIT 10.9) on a Bio-Gel P-10 column in 1 M Na₂CO₃.
- 2d. Analyze di- and tetrasaccharides on a 4.6 × 250-mm Hi-Chrom S-5 ODS column at a flow rate of 1 ml/min (Tables 17.22B.4 and 17.22B.5). Isocratic separations of groups of monosaccharides and disaccharides are obtained by isocratic elution with the solvent mixtures shown in Table 17.22B.4. Connect the isocratic segments shown in Table 17.22B.4 as in Table 17.22B.5 to achieve the separation of all of the disaccharides in a single run. Note that GlcA-AManR(SO₄) and IdoA-AManR(SO₄) are not separated under these conditions; for separation of these two disaccharides, the strong-anion exchange HPLC must be used. Isocratic separations of groups of tetrasaccharides are obtained by isocratic elution with the solvent mixtures shown in Table 17.22B.4. Connect the isocratic segments shown in Table 17.22B.4 as in Table 17.22B.5 to achieve the separation of all of the tetrasaccharides.

For details of the reversed-phase ion-pairing procedure, see Guo and Conrad (1988).

^aAbbreviations: AMan, anhydro-D-mannose; GlcA, D-glucuronic acid; GlcN, D-glucosamine; GlcNAc, N-acetyl-D-glucosamine; IdoA, L-iduronic acid.

^bHPLC separations are obtained using step gradients. Details of gradients used for disaccharides and oligosaccharides are given in Basic Protocol 2; the KH₂PO₄ concentrations are those at which each oligosaccharide emerges during the gradient. Columns are run at a flow rate of 1 ml/min; see Guo and Conrad (1989) for details.

^cTetrasaccharide designations (t1-t16) are described in Bienkowski and Conrad, 1985. Those tetrasaccharides for which no monosaccharide sequences are given (t6, t10-t13, and t16) are "ring-contraction tetrasaccharides," which are formed in relatively low yields (see Commentary).

		192→193	39→70
		193→220	70

^aOligosaccharides are chromatographed on a C-18 reversed-phase column using the ion-pairing systems described in Basic Protocol 2. Mixtures of standards are chromatographed with increasing percentages of solvent B (disaccharides) or solvent C (tetrasaccharides) in solvent A (see recipes for solvents A, B, and C in Reagents and Solutions). Details of the gradients used are described in Basic Protocol 2.

- Count radioactivity in 5-ml fractions collected in scintillation vials (see Support Protocol 2) or use an in-line radioactivity flow detector. Identify disaccharides on the basis of their chromatographic migration properties by referring to Tables 17.22B.1-17.22B.5. Quantify di- and tetrasaccharides (see Support Protocol 3).

**SUPPORT
PROTOCOL 1**

**BOROHYDRIDE REDUCTION OF ALKALI-LABILE DISACCHARIDES
OBTAINED BY CLEAVAGE WITH LYASES**

Disaccharides formed by cleavage of glycosaminoglycans with specific lyases (*UNIT 17.13B*) can be analyzed by reduction with NaB^3H_4 and separation of the labeled products either by paper chromatography (Basic Protocol 1; Glaser and Conrad, 1979) or HPLC (Basic Protocol 2; Delaney et al., 1980; Shaklee and Conrad, 1986). However, the lyase-generated disaccharides are quite labile under the alkaline conditions required for their reduction with NaB^3H_4 . Thus, a milder procedure than the 50°C reduction procedure described in *UNIT 17.22A* must be used for the reduction. These labile disaccharides (or higher oligosaccharides that may be obtained when the lyase does not convert the glycosaminoglycan completely to disaccharides) can be reduced at 0°C without cleavage.

Materials

Sample of lyase-degraded glycosaminoglycan
1 M Na_2CO_3 , pH 9.0 (ice-cold)
Sodium borohydride reagent (see recipe)
3 M H_2SO_4
6 × 150-mm test tubes

- Place lyase-degraded GAG sample in a 6 × 150-mm test tube, dry sample in a stream of air, then chill tube in an ice bath.
- Add 5 μl ice-cold 1 M Na_2CO_3 (pH 9.0) to sample, then add 10 μl of sodium borohydride reagent. Cork or cap the tube and let it sit on ice 90 min.

IMPORTANT NOTE: If samples are already labeled by metabolically labeling of the GAG, 0.5 M cold NaBH_4 is used in preparing the sodium borohydride reagent instead of 0.5 M $\text{NaB}[^3\text{H}]_4$.

Carry out all $\text{NaB}[^3\text{H}]_4$ manipulations in a well-ventilated fume hood designated for radioactive use.

- Add 2.5 μl of 3 M H_2SO_4 to destroy excess NaB^3H_4 and let sample stand ~30 min.
- Neutralize sample with 1 M Na_2CO_3 and dry it in a stream of air. Redissolve sample in water, then dry again to remove excess $[\text{H}^3]_2$ gas. Finally dissolve sample in 50 μl water.

Aliquots of the sample may be analyzed by paper chromatography (Basic Protocol 1) or HPLC (Basic Protocol 2).

SCINTILLATION COUNTING OF FRACTIONS FROM HPLC ANALYSIS OF SACCHARIDES RELEASED FROM GLYCOSAMINOGLYCANS

SUPPORT
PROTOCOL 2

Effluent from the HPLC column is collected in 0.5-ml fractions in scintillation vials using a fraction collector. Alternatively the effluent may be run directly through an in-line radioactivity flow detector (e.g., Radiomatic). If the total cpm in each peak are high enough to obtain good counting statistics in short counting intervals, a stream splitter may be used to collect the bulk of each fraction (e.g., 0.4 ml) in a test tube while only a portion of each fraction (e.g., 0.1 ml) is taken in scintillation vials for counting. Add an appropriate volume (4 to 5 ml) of any commercial scintillation fluid designed to accommodate the salt and solvent concentrations in the eluants. Alternatively, add 4 ml of a scintillation cocktail containing 3 g diphenyloxazole in a mixture of 250 ml Triton X-114, 750 ml xylene, and 10 ml concentrated HCl. For KH_2PO_4 concentrations >10 mM, add 1 drop concentrated HCl to the xylene-based scintillation fluid to redissolve the salt precipitate that begins to form in the scintillation vial.

CALCULATIONS FOR QUANTITATION OF DISACCHARIDES

SUPPORT
PROTOCOL 3

Procedures described here allow calculation of the number of μmol of each disaccharide in the original sample taken for analysis. These calculations apply primarily to analyses in which disaccharides obtained from unlabeled glycosaminoglycans are mixed with a $[^{14}\text{C}]\text{D}$ -glucose internal standard and reduced with NaB^3H_4 (see UNIT 17.22A), but can also be applied to metabolically labeled materials if the specific radioactivity of the radiolabeled precursor that appears in the metabolically labeled glycosaminoglycan is determined independently.

Calibrate NaB^3H_4 used in the analysis of unknowns

Because the counting efficiency for ^3H varies in each type of counting experiment, cpm/ μmol of a standard reducing sugar must be determined separately for each type of separation procedure. Mix a measured amount of a standard sugar (usually D-glucose) with the $[^{14}\text{C}]\text{D}$ -glucose internal standard (see UNIT 17.22A). Enough $[^{14}\text{C}]\text{glucose}$ should be added so that $\sim 1 \times 10^5$ ^{14}C cpm will be recovered in the final separation step. Reduce an aliquot of this mixture with the same NaB^3H_4 reagent to be used in the analysis (see UNIT 17.22A). If NaB^3H_4 with a specific activity of ~ 500 mCi/mmol (recommended) is used, the $[^3\text{H}]\text{D}$ -glucitol formed by reduction of the D-glucose should have a specific activity of 125 mCi/mmol, and 1 μmol of the standard D-glucose should yield 778×10^6 dpm per μmol of $[^3\text{H}]\text{glucitol}$. Counting efficiency for ^3H in some of the separation steps may be as low as 5%. Chromatograph the resulting $[^3\text{H}]\text{D}$ -glucitol/ $[^{14}\text{C}]\text{glucitol}$ mixture in the same type of analytical separation procedure that is being used for the unknowns (paper chromatography or HPLC). Determine the number of $[^{14}\text{C}]\text{glucitol}$ and $[^3\text{H}]\text{glucitol}$ cpm in the separated peak by scintillation counting under conditions optimized for dual-label counting. The ^3H cpm must be corrected for the number of ^{14}C cpm that spill over into the ^3H counting channel. From the number of $[^{14}\text{C}]\text{glucitol}$ cpm, calculate the number of μmol of D-glucitol in the peak as described below.

When a known number of μmol of glucose are mixed with a known number of cpm of the $[^{14}\text{C}]\text{glucose}$ internal standard, the number of ^{14}C cpm recovered in the analytical stage (e.g., in paper chromatography or HPLC) can be used to calculate the proportion of original μmol of the standard glucose that are recovered in the analytical stage. For example, if the original D-glucose solution contained 1×10^5 μmol of the D-glucose standard and 5×10^5 cpm of $[^{14}\text{C}]\text{glucose}$, and if 1×10^5 cpm of $[^{14}\text{C}]\text{glucitol}$ were recovered in the analytical run, then 2×10^4 μmol of the D-glucitol standard would be recovered in the analytical run. Thus, if 1×10^9 ^3H cpm in the $[^3\text{H}]\text{glucitol}$ were recovered in the analytical run, the number of ^3H cpm/ μmol for glucose would be 5×10^4 .

Preparation and
Analysis of
Glycoconjugates

17.22.13

Using the [^3H]glucitol cpm in the separated peak and the number of μmol of D-glucitol in the peak, calculate the number of [^3H]glucitol cpm/ μmol , which will be the same as the number of ^3H cpm/ μmol for all mono-, di- or tetrasaccharides obtained in the analytical run, as all reducing sugars incorporate the same number of equivalents of ^3H per μmol from the $\text{NaB}[^3\text{H}]_4$. Consequently, when the total number of ^3H cpm is determined for any peak in the analytical run, division of this number by the ^3H cpm/ μmol of the D-glucose standard yields the value for the number of μmol of the compound in the peak.

Calibrate internal standard [^{14}C]glucose

Because the counting efficiency for ^{14}C varies in each type of counting experiment, the number of ^{14}C cpm in a given aliquot of the [^{14}C]glucose internal standard must be determined separately for each type of separation procedure. Reduce an aliquot of the [^{14}C]glucose internal standard using the same reduction conditions used for the unknowns (see UNIT 17.22A for nitrous acid cleavage products; see Basic Protocol 2 for lyase cleavage products). To calibrate [^{14}C]glucose for paper chromatography, transfer the resulting [^{14}C]glucitol solution quantitatively to a paper chromatography strip and run the chromatogram in the solvent for which the [^{14}C]glucose calibration is being made. Develop the chromatogram, cut the strip into 0.5-in. segments for scintillation counting, then determine the total number of ^{14}C cpm in the original aliquot taken for analysis.

To calibrate [^{14}C]glucose for HPLC, inject a measured aliquot of the [^{14}C]glucitol solution quantitatively into an HPLC column injector, elute the column as in a typical analytical run, then determine the number of ^{14}C cpm in the [^{14}C]glucitol peak. The [^{14}C]glucose will emerge in the void volume of the column in the HPLC procedures described here.

Chromatographic and electrophoretic properties of various glycosaminoglycan oligosaccharides are listed in Tables 17.22B.1-17.22B.5.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

HPLC solvents

For anion-exchange chromatography: HPLC solvents for chromatography on weak anion-exchange or strong ion-exchange columns range from 0 mM to 400 mM KH_2PO_4 . Degas and filter 1 liter distilled water by gently heating it to 80°C in a 2-liter vacuum-filtration flask, sealing the flask with a stopper, then placing it in an ice-water bath and evacuating with a water aspirator while gently stirring with a magnetic stirrer. Continue aspirating until no further bubbles are apparent (15 min), then transfer to a volumetric flask containing the amount of KH_2PO_4 required to give the desired concentration. Gently stir the solution, then filter through a 0.45- μm Millipore filter under vacuum into a clean 500-ml bottle, which will serve as a reservoir for the solvent.

For HPLC systems that allow continuous degassing during the run, it is not necessary to degas solvents before making the solutions.

For reversed-phase ion-pairing chromatography: Prepare solvents A, B, and C as follows. Mix or deliver in gradient as described in Table 17.22B.4 and Table 17.22B.5.

Solvent A: Prepare 38 mM $\text{NH}_4\text{H}_2\text{PO}_4$, 2 mM H_3PO_4 , and 1 mM tetrabutylammonium phosphate in water. Adjust pH to 3.6 with 0.1 M NaOH or HCl.

Solvent B: Prepare 38 mM $\text{NH}_4\text{H}_2\text{PO}_4$, 2 mM H_3PO_4 , and 1 mM tetrabutylammonium phosphate in 30/70 (v/v) acetonitrile/water. Adjust pH to 4.2 with 0.1 M NaOH or HCl.

continued

Solvent C: Prepare 38 mM $\text{NH}_4\text{H}_2\text{PO}_4$, 2 mM H_3PO_4 , and 1 mM tetrabutylammonium phosphate in 50:50 (v/v) acetonitrile /water. Adjust pH to 4.4 with 0.1 M NaOH or HCl.

Paper chromatography and paper electrophoresis systems

Use the following paper chromatography or paper electrophoresis systems in conjunction with the data in Table 17.22B.1 or Table 17.22B.2:

Paper chromatography system 1: 3:2:1 (v/v/v) 1-butanol/glacial acetic acid/1 M NH_4OH . Use 1 × 22-in. Whatman no. 3 paper chromatography strips.

Paper chromatography system 2: 3:2:1 (v/v/v) ethyl acetate/pyridine/5 mM boric acid. Use 1 × 22-in. Whatman cellulose phosphate paper chromatography strips.

Paper electrophoresis system 1: 50 ml glacial acetic acid and 10 ml pyridine in 4 liters water (pH 4.0). Use 1 × 22-in. cellulose phosphate paper chromatography strips.

Paper electrophoresis system 2: 350 ml of glacial acetic acid and 100 ml of 88% formic acid in 4 liters water (pH 1.7). Use 1 × 22-in. cellulose phosphate paper chromatography strips.

Sodium borohydride reagent

Just prior to use, dissolve 1.89 mg $\text{NaB}[^3\text{H}]_4$ in 100 μl chilled 0.2 M Na_2CO_3 , pH 10.2, to give a 0.5 M $\text{NaB}[^3\text{H}]_4$ solution. Keep on ice until use.

COMMENTARY

Background Information

A number of high-performance liquid chromatography procedures have been developed to separate and quantitate the disaccharides formed by deaminative cleavage of N-deacetylated glycosaminoglycans with nitrous acid (*UNIT 17.22A*) or cleavage with lyases (*UNIT 17.13B*). These include chromatography on strong anion-exchange columns (SAX; Bienkowski and Conrad, 1985); weak anion exchange columns (WAX; Shaklee and Conrad, 1986); and reversed-phase ion-pairing columns (Guo and Conrad, 1988). Alternatively, some of the disaccharides can be separated by paper chromatography (Hopwood and Elliot, 1983; Hopwood and Muller, 1983), paper electrophoresis (Hopwood and Elliot, 1983; Hopwood and Muller, 1983), thin-layer chromatography (Edge and Spiro, 1985), or capillary-zone electrophoresis (Al-Hakim and Linhardt, 1991; Desai et al., 1993). When lyases are used to cleave the glycosaminoglycan (*UNIT 17.13B*), the lyase-derived di- and oligosaccharides can be assayed by the absorbance of their unsaturated uronic acid residues at 233 nm. This UV assay has been used for detection of oligosaccharides eluted from SAX HPLC columns with a linear sodium chloride gradient running from 0 to 1 M (Rice et al., 1985; Linhardt et al., 1988). Glycosaminoglycans that have been metabo-

lically labeled with ^3H D-glucosamine or $^{35}\text{S}]\text{O}_4^{2-}$ yield disaccharides with the corresponding labels. Disaccharides from both types of cleavage can also be detected and quantified following their reduction with $\text{NaB}[^3\text{H}]_4$ to incorporate one gram atom of ^3H per mol of disaccharide. In this approach, the elution positions of the ^3H -labeled disaccharide peaks separated by HPLC, paper chromatography, or paper electrophoresis are used to identify the disaccharides, and the ^3H cpm recovered in each peak are used to obtain ratios of disaccharides or quantitative measures of the amounts of each disaccharide present in the glycosaminoglycan.

Critical Parameters

The important parameters for the separations described in this unit are those that must normally be observed for chromatographic separations. The critical parameters for the analytical procedures are primarily those involved in the treatment with nitrous acid and $\text{NaB}[^3\text{H}]_4$. These are described in *UNIT 17.22A*. It may be noted that the elution times given in Tables 17.22B.1-17.22B.5 may vary somewhat, but the relative positions of elution remain the same. Positive identification may require chromatographic runs of mixtures of previously characterized disaccharides before or

after the sample run. As columns age, the elution times become shorter and resolution becomes poorer. When resolution becomes unsatisfactory, the column must be replaced.

Anticipated Results

The nitrous acid reaction (see UNIT 17.22A) is virtually stoichiometric for β -linked amino sugars (Shively and Conrad, 1970). Consequently, the yield of disaccharides is stoichiometric from those glycosaminoglycans that contain β -linked amino sugars (i.e., chondroitin sulfate, dermatan sulfate, hyaluronic acid, and keratan sulfate). However, a side reaction called the "ring-contraction reaction" occurs to the extent of 10% to 15% for α -linked amino sugars—e.g., those found in heparin and heparan sulfate (Shively and Conrad, 1970, 1976). The ring-contraction reaction results in deamination without bond cleavage, and may convert a segment in heparin that contains two disaccharides having N-sulfated GlcN residues into a tetrasaccharide fragment instead of the two disaccharides that would be expected. Thus, heparin and heparan sulfate yield small but significant amounts of the ring-contraction tetrasaccharides (Bienkowski and Conrad, 1985). However, there seems to be little structural selectivity for the ring-contraction reaction, as the ring-contraction tetrasaccharides contain disaccharide units in the same proportions as those found in the original glycosaminoglycan. Thus, even for heparin and heparan sulfate, the disaccharides formed during nitrous acid cleavage are obtained in the same proportions that are found in the original glycosaminoglycan. Consequently, when yields are expressed in percent of total uronic acids or percent of total amino sugars, the ring-contraction reaction does not interfere with the quantitation, and the yields of di- and monosaccharides are truly representative of their proportions in the starting glycosaminoglycan. Some of these heparin ring-contraction tetrasaccharides have been identified (Bienkowski and Conrad, 1985).

Time Considerations

The times for chromatography are apparent from the retention times reported in Tables 17.22B.1 to 17.22B.3. Time for processing of the data will depend in great part on the type of scintillation counter used and the data-processing equipment available on site where the methods will be used.

Analysis of Sulfate Esters by Solvolysis or Hydrolysis

UNIT 17.23

Sulfate esters are found on N- and O-linked sugar chains or glycosaminoglycan (GAG) chains. Few sulfatases are available that can enzymatically remove them, so chemical procedures must be used. These procedures rely on the differential sensitivity of sulfates located in different linkages on the sugar. In comparison to the conditions used for enzymatic digestion, those used for chemical digestion are very harsh and cannot be used on protein-bound carbohydrates (except for analytical purposes, as in Basic Protocol 2). With protein-bound carbohydrates, for preparative purposes, the chains must first be released by one of the procedures described in *UNITS 17.13 & 17.15*. Basic Protocol 1 describes release of sulfate esters by solvolysis. A Support Protocol describes a method for monitoring the efficiency of the solvolysis reaction, and Alternate Protocol 1 provides a scale-up method for using the solvolysis reaction with large amounts of material. Basic Protocol 2 presents a technique for acid hydrolysis to release sulfate esters, and Alternate Protocol 2 describes basic hydrolysis for the same purpose.

SOLVOLYSIS FOR RELEASE OF SULFATE ESTERS FROM GLYCANS

**BASIC
PROTOCOL 1**

Solvolysis is analogous to hydrolysis, except that a nonaqueous solvent is used. Both solvolysis procedures in this unit (also see Alternate Protocol 1) require conversion of the sulfated molecule to the pyridinium salt before heating in dimethyl sulfoxide (DMSO) to remove sulfate. This procedure is for $^{35}\text{SO}_4^-$ - or ^3H -radiolabeled GAG samples, and applies to microgram amounts of material. For scale-up, see Alternate Protocol 1.

Materials

Sulfated sample (*UNIT 17.15*), radiolabeled (*UNIT 17.4* or *UNIT 17.5*)
Glucose-6-sulfate (Sigma)
0.5 × 50-cm Sephadex G-25 gel-filtration column (Pharmacia Biotech)
2-cm column of Dowex-50 X8 (hydrogen form; see recipe for washing procedure)
packed in a Pasteur pipet plugged with glass wool
Pyridine
1 M NaCl
9:1 (v/v) dimethyl sulfoxide (DMSO; reagent grade)/methanol
QAE-Sephadex (Pharmacia Biotech)
Thick-walled conical glass tubes
Heating block
Lyophilizer or shaker-evaporator
Additional reagents and equipment for desalting by gel-filtration chromatography
(*UNIT 10.9*)

1. Desalt sample on a 0.5 × 50-cm Sephadex G-25 column, eluting with water.

It is essential to remove all nonvolatile salts from the sample. If free $^{35}\text{SO}_4$ is present in the sample, sulfate will run through the water-eluted Sephadex G-25 column with an apparent molecular weight much larger than its actual molecular weight, and may overlap with small $^{35}\text{SO}_4$ -labeled oligosaccharides. It may be therefore be necessary to remove free $^{35}\text{SO}_4$ by dialysis from the protein-bound $^{35}\text{SO}_4$ prior to the release of the carbohydrate chains from the protein.

2. Add 5 μg of glucose-6-sulfate to the sample, which will be in a volume of 1 to 5 ml of water. Pass the sample through a 2-cm column of water-washed Dowex-50 X8 (hydrogen form) packed in a glass wool-plugged Pasteur pipet. Wash column with

Supplement 32

5 ml water and combine washings with the original flowthrough of the column. Check pH of the combined washings with pH paper; it should be within one unit of the pH of the combined sample and wash water that will be used in the subsequent steps.

The Dowex-50 column removes any residual cations and replaces them with protons. The glucose-6-sulfate provides further insurance that any residual cations will not interfere with the solvolysis reaction, but the amount of this reagent must be kept low to prevent unwanted side reactions.

3. Add 50 μ l pyridine to the sample and split it into two aliquots. Add 2 μ l of 1 M NaCl to one sample and nothing to the other. Transfer samples to thick-walled glass conical tubes and lyophilize or dry on a shaker-evaporator.

The sample with the NaCl serves as a negative control for desulfation and for the side effects of the DMSO-treatment step (step 4), because solvolysis does not proceed when the salt is present. In the experimental (i.e., no-salt) sample, most of the pyridine evaporates during lyophilization, except for that which forms the pyridinium salt with the sample or glucose-6-sulfate.

4. Add 0.2 ml of 9:1 (v/v) DMSO/methanol to each sample. Using a heating block, heat 2 hr at 85° to 90°C for O-sulfate esters or at 55°C for N-sulfate esters.
5. Remove DMSO under vacuum using a lyophilizer or shaker-evaporator.

Depending upon the next step—e.g., in the case of QAE-Sephadex chromatography (UNIT 17.20)—it may not be necessary to remove the solvent. If it is necessary to do this, it should be noted that DMSO is not very volatile and will take several hours to evaporate under vacuum. In some cases the sample may need to be diluted.

SUPPORT PROTOCOL 1

MONITORING SOLVOLYSIS REACTION

If it is important to monitor the efficiency of the reaction in Basic Protocol 1, this can be done by running a sample of [³H]glucitol-6-sulfate in parallel with the experimental samples.

Additional Materials (also see Basic Protocol 1)

[³H]glucitol-6-sulfate: glucose-6-sulfate (Sigma) reduced with NaB[³H]₄ (UNIT 17.5)
2-cm QAE-Sephadex column (Pharmacia Biotech)
35 mM and 200 mM NaCl
Scintillation fluid compatible with aqueous samples
Additional reagents and equipment for QAE-Sephadex analysis (UNIT 17.20)

1. Carry out steps 1 and 2 of Basic Protocol 1, running ~10,000 cpm of [³H]glucitol-6-sulfate in parallel with the experimental sample. In step 3, split the pyridine treated column effluent from this glucitol-6-sulfate sample into three aliquots instead of two. Add 2 μ l of 1 M NaCl to one aliquot. Dry all three aliquots as described in Basic Protocol step 3. Keep one of the non-salt-treated aliquots in reserve, then carry out steps 4 and 5 (solvolysis) on the remaining salt-treated and non-salt-treated aliquots.

Alternatively, this ³H-labeled material may be added directly to the sample itself as an internal control. This cannot, however, be done if it interferes with subsequent analysis of the sample products (e.g., if the sample itself is labeled with ³H).

2. Dilute the three [³H]glucitol samples to 1.5 ml with water and treat each of them as follows. Load on a 2-cm QAE-Sephadex column. Wash column three times using 1.5 ml of water each time and collect each effluent in a scintillation vial. Wash three more times using 1.5 ml of 35 mM NaCl each time, and collect the effluents in three more

separate vials. Finally, wash once with 1.5 ml of 200 mM NaCl and collect the effluent in another vial.

Ten vials will thus be obtained for each of the three [³H] glucitol samples.

3. Add 15 ml of an aqueous-compatible scintillation fluid to each vial and count on a scintillation counter.

The [³H] glucitol in untreated sample and the solvolysis control incubation should elute in the 35mM NaCl wash. The [³H] glucitol in solvolysed desulfated sample should elute with water showing that it no longer carries a charge. Very little radioactivity will be seen in the high-salt wash. The efficiency of sulfation is then calculated as the percentage of [³H] glucitol eluted with water compared to the total [³H] glucitol recovered.

SCALE-UP OF SOLVOLYSIS FOR LARGE AMOUNTS OF MATERIAL

Basic Protocol 1 is used to desulfate trace amounts of material, but it can be applied to larger amounts of material such as glycosaminoglycans (GAGs). As with Basic Protocol 1, the extent of the reaction can be monitored by the desulfation of [³H]glucitol-6-sulfate if the presence of this labeled compound will not interfere with the subsequent use of the product. The steps and the preparations of the procedure are essentially the same as described for the Basic Protocol 1, except that no control incubation (i.e., with NaCl; see Basic Protocol 1, step 3) is done on the material. This procedure describes the solvolysis of 10 mg of GAG (or other sulfated sugar chains) and can be further scaled up if necessary.

Additional Materials (also see Basic Protocol 1)

[³H]glucitol-6-sulfate: glucose-6-sulfate (Sigma) reduced with NaB[³H]₄ (UNIT 17.5)
Dialysis tubing (3000 MWCO)

Additional reagents and equipment for dialysis (APPENDIX 3C)

1. Desalt material containing 10 mg GAGs or other sulfated molecules on a Sephadex G-25 column and pool the fractions that contain GAGs.

Free GAG chains can be monitored by the carbazole reaction (see UNIT 17.12) or by amino sugar tests. Follow the normal procedures for gel filtration and pool conservatively to avoid any salt.

2. Mix material with an appropriate amount of [³H]glucitol-6-sulfate and pass the mixture over a 5 × 0.5-cm column of well-washed Dowex-50 X8 (hydrogen form). Wash with 2 to 3 column volumes water, then add 0.1 ml pyridine to the combined eluates. Lyophilize.

The amount of [³H]glucitol-6-sulfate to be added will depend upon the fraction of the total sample that can be sacrificed for the QAE-Sephadex analysis described in Support Protocol 1. The pH of the eluate may be lower than that found in Basic Protocol 1 because the chains, which will be in protonated form, are found at a higher concentration.

3. Dissolve the lyophilized material in 1.0 ml of 90% dimethyl sulfoxide/10% methanol and heat 2 hr at 90°C.

The [³H]glucitol-6-sulfate can be used to confirm desulfation of the GAG chains and to follow the course of the reaction. Take aliquots at different times and monitor its elution from QAE-Sephadex as described in Support Protocol 1. Use <1% of the sample (100 μg) so that the 2-cm QAE-Sephadex column is not overloaded (see Support Protocol 1). The GAG chains may remain bound to the column, but this does not matter because only the desulfation of the [³H]glucitol-6-sulfate is monitored.

ALTERNATE PROTOCOL 1

- Cool the reaction tube. Dialyze the sample against 3 liters of water using 3000-MWCO dialysis tubing.

Alternatively, remove the reagents on a Sephadex G-25 gel-filtration column. Either procedure will work, but the choice is determined by the future plans for the sample. The apparent size of the molecules will decrease because the sulfate contributes disproportionately to their apparent size, and some breakdown of chains may also occur.

ACID HYDROLYSIS FOR RELEASE OF SULFATE ESTERS FROM GLYCOSAMINOGLYCANS

This protocol measures the amount of bound $^{35}\text{SO}_4$ that remains soluble after the precipitation of hydrolyzed sulfate as the barium salt. In this procedure, we assume that the released oligosaccharide is $^{35}\text{SO}_4$ -labeled, but the sugars may also be labeled with ^3H . If the sugars are not labeled with tritium, a tritiated molecule—e.g., ^3H -labeled glucose-6-sulfate should be included as an internal standard for normalizing recovery of the material.

Materials

Sample: $^{35}\text{SO}_4$ -labeled oligosaccharide or glycopeptide
0.50 N HCl (freshly diluted from 12 N reagent grade acid)
0.50 N NaOH (accurately titrated)
4 M NaCl
0.01 N HCl in 1 M NaCl (diluted from 0.50 N HCl above)
2 mM Na_2SO_4 in 2 M KCl
20 mM barium acetate
Heating block with wells filled with oil

- Dispense ≥ 1000 to 2000 cpm of $^{35}\text{SO}_4$ -labeled oligosaccharide or glycopeptide in 50 μl water into a series of 8 to 10 microcentrifuge tubes. Add 50 μl of 0.50 N HCl to each tube.
- Incubate the tubes in a heating block with wells filled with oil at 98° to 100°C for a series of different time periods.

The amount of time will vary depending upon the sample. A preliminary experiment with time points at 1 and 3 hr will help determine the best time points to try. All sulfate esters will eventually be hydrolyzed and even the most resistant ones will be 75% degraded after 3 hr. A reasonable set of time points to try is 0, 5, 15, 30, 60, 90, 120, 150, and 180 min.

- At each time point, remove the tube from the oil, wipe it clean and place it on ice for 1 min. Microcentrifuge 2 sec at maximum speed to collect the liquid in the bottom of the tube and add sufficient 0.5 N NaOH to neutralize the sample. Also add 50 μl of 4 M NaCl to maintain high salt concentration. Keep completed samples on ice while remaining samples are incubating.

Determine the exact volume of 0.5 N NaOH (~50 μl) to add to the samples by first neutralizing a dummy sample containing 50 μl of 0.50 N HCl and 0.50 N water and checking with pH paper. Acceptable pH after neutralization is 3 to 9.

- After the time course has been completed for all samples and all samples have been neutralized, add sufficient 0.01 N HCl in 1 M NaCl to each sample to adjust the pH to 2 to 3. Check with pH paper using 1 to 2 μl of sample.

Determine the exact amount of 0.01 N HCl (~100 μl) to add by adjusting the pH of the dummy sample neutralized above (see step 3, annotation). It is still necessary, however, to check the pH of the actual samples.

Figure 17.23.1 Examples of kinetics of loss of $^{35}\text{SO}_4$ from N-linked oligosaccharides of *Dicystostelium discoideum*. Two different types of N-linked oligosaccharides were isolated from secreted glycoproteins. **(A)** One type was sensitive to endo H digestion and consisted entirely of a single kinetic class, probably a 6-O sulfate ester with a $t_{1/2}$ of 120 min. **(B)** The other kinetic class was released only by peptide:N-glycosidase F (PNGase F) digestion and not by endo H. It consists of two classes of sulfate esters: the major class (~80%) has a $t_{1/2}$ similar to that of the endo H-sensitive oligosaccharide type (in panel A), but a minor class (~20%) shows a different $t_{1/2}$ (and may be in equatorial linkage).

5. Add 100 μl of 2 mM Na_2SO_4 in 2 M KCl (for a total volume of 400 μl) and mix. Remove 20% of the sample and determine total counts of $^{35}\text{SO}_4$.
6. Add 150 μl of 20 mM barium acetate to the remaining material in each sample and incubate 15 min on ice. Microcentrifuge 5 min at $10,000 \times g$, then remove 90% of the solution (~400 μl) and determine total counts of $^{35}\text{SO}_4$.
7. Normalize the amount of $^{35}\text{SO}_4$ radioactivity that remains soluble as a percentage of the total counts present in the original sample.

Initially, without hydrolysis essentially all of the $^{35}\text{SO}_4$ should remain soluble. Hydrolysis yields fewer soluble counts (more precipitation of $\text{Ba}^{35}\text{SO}_4$).

8. Using the "0" time point as 100% soluble material (this should be >90% of the total counts), plot the decrease in soluble $^{35}\text{SO}_4$ on a log scale for typical first-order decay kinetics. Determine if single or multiple kinetic classes exist, as indicators of the number of types of sulfate esters in the sample.

See Figure 17.23.1 for examples of single and multiple kinetic classes.

BASE HYDROLYSIS FOR RELEASE OF SULFATE ESTERS FROM GLYCOSAMINOGLYCANS

This method will release sulfate esters that are sensitive to base hydrolysis (see Background Information).

Additional Materials (also see Basic Protocol 2)

Sample: $^{35}\text{SO}_4$ -labeled, borohydride-reduced (*UNIT 17.5*) oligosaccharide or glycopeptide

2 N NaOH

2 N HCl (freshly diluted from 12 N reagent-grade acid)

1. Dispense 1000 to 2000 cpm $^{35}\text{SO}_4$ -labeled, borohydride-reduced oligosaccharide or glycopeptide in 50 μl water into a series of at least six microcentrifuge tubes. Add 50 μl of 2 N NaOH to each tube and mix.
2. Incubate the tubes at 80°C in a heating block with wells filled with oil for 0, 1, 2, 4, 6, and 10 hr.

IMPORTANT NOTE: Use prerduced oligosaccharides; otherwise the base may degrade the oligosaccharide chain. The base hydrolysis occurs at about the same rate as the loss of primary-linked sulfates ($T_{1/2} = \sim 1$ to 2 hr).

3. At each time point remove the tube, wipe it clean, and place it on ice for a few minutes. Microcentrifuge 2 sec at $10,000 \times g$ to collect the dispersed droplets. Add 50 μl of 2 N HCl to adjust the pH to 3 to 9, checking 1 to 2 μl of solution with pH paper.
4. After the time course has been completed for all samples and all samples have been neutralized, perform steps 5 to 8 of the acid hydrolysis protocol (see Basic Protocol 2) to precipitate the solubilized $^{35}\text{SO}_4$.

Completeness of any hydrolysis will be indicated by a flattening of the decay curve.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Dowex-50 X8 resin

Prewash Dowex-50 resin by stirring 50 to 100 g into 2 liters of water, allowing it to stand 1 hr, then discarding water. Repeat twice, then leave overnight at room temperature. Pour off the final water and resuspend the resin in 3 to 4 vol water. The resin may be stored at 4°C for months under these conditions.

COMMENTARY

Background Information

Solvolysis

The conditions of the solvolysis reaction can be adjusted to preferentially remove either N- or O-linked sulfate esters, because N-sulfates (e.g., GlcNSO_4 in heparin; not to be confused with sulfated N-linked oligosaccharides) are more sensitive than O-sulfate esters (Inoue and Nagasawa, 1976; Nagasawa et al., 1977).

Acid hydrolysis

It is possible to get an accurate compositional analysis of "sulfated sugars" by doing

an acid hydrolysis because the sulfate esters are cleaved faster than most glycoside bonds. By selecting the right conditions, acid hydrolysis can give information about the number and locations of sulfate esters because they are cleaved at different rates depending upon their location on the individual sugar residues (Freeze and Wolgast, 1984). The kinetics of sulfate liberation (see Fig. 17.23.1) can help to determine the number of classes of sulfate esters present and what their likely locations may be. These properties are not strongly influenced by other substituents on the sulfated sugar or by the position of the sugar within an oligosac-

charide chain. Since the hydrolysis can also cleave glycosidic linkages and partially destroy the sugar chain, only the release of sulfate can be measured.

The acid hydrolysis procedure differentiates between sulfates linked to different hydroxyl groups on the sugar ring. Under the hydrolysis conditions in Basic Protocol 2, the $T_{1/2}$ of sulfates linked to equatorial hydroxyl groups (e.g., glucose-3-sulfate, galactose-3-sulfate, *N*-acetylglucosamine-3-sulfate, and mannose-3-sulfate) is 6 to 25 min; that of those linked to axial hydroxyl groups (e.g., galactose-4-sulfate, *N*-acetylglucosamine-4-sulfate, and mannose-2-sulfate) is 60 to 84 min, and that of those linked to primary hydroxyl groups (e.g., glucose-6-sulfate, galactose-6-sulfate, *N*-acetylglucosamine-6-sulfate, and mannose-6-sulfate) is 90 to 120 min (Rees, 1963). All 6-OH positions are primary, and all of the hydroxyl groups in glucose are equatorial. Any hexose isomer of glucose (e.g., mannose or galactose) will change one of the equatorial positions to an axial position. Even though the time ranges for hydrolysis listed above have not been extensively documented for sulfate-labeled oligosaccharides, they are useful because they will clearly differentiate between multiple classes of sulfate es-

ters. Using the acid hydrolysis technique, it is not possible to determine which sugar is sulfated or where it is found in the chain. If other data are available on the structure of the oligosaccharide, this information may provide likely possibilities for the location of sulfate groups, especially if certain residues are resistant to exoglycosidase digestion.

Base hydrolysis

Only certain types of sulfate esters are sensitive to base hydrolysis (Freeze and Wolgast, 1984; Percival, 1978). Sensitivity is determined by the location of the sulfate on the sugar residue and—in contrast to acid hydrolysis described above—by the other substituents linked to that sugar residue.

Base treatment will release sulfate esters from intact oligosaccharides under two different conditions. The first is when sulfate is located in the 6 (or 3)-OH position and the 3 (or 6)-OH group of the same sugar residue is not substituted. The second is when the sulfate ester is adjacent to an unsubstituted *trans* OH group. In the first case, the sulfate is eliminated and an acid-labile 3,6-anhydrosugar is formed (see Fig. 17.23.2). In the second case, the sulfate is released with the formation of an epoxide

Figure 17.23.2 Formation of 3,6-anhydromannose by base treatment of an oligosaccharide containing mannose-6-sulfate. The formation of the anhydro sugar makes the glycosidic linkage very sensitive to acid; mild hydrolysis causes cleavage. Stronger hydrolysis degrades the usual glycosidic linkages, but leaves the anhydrosugar. When reduced with sodium borohydride, the modified sugar can be quantified to show how much mannose-6-sulfate was originally present.

ring on the sugar. This is destroyed during subsequent acid hydrolysis of the oligosaccharide. The modified sugar can be identified if it is metabolically labeled—e.g., as in the discovery of mannose-6-sulfate (Freeze and Wolgast, 1984)—but this is not routinely done. On the other hand, the loss of sulfate is easily measured. When data on the acid and base hydrolysis of sulfate esters are combined with other structural information on the molecules, several potential structures can be eliminated or supported, but these procedures will not provide proof of the structure.

Critical Parameters

Solvolytic desulfation is a harsh treatment that also removes sialic acids and probably fucose residues. If these sugars are normally present, their loss may be an unacceptable side effect of this procedure. On the other hand, hexoses, hexuronic acids, and hexosamines in glycosidic linkages are mostly stable to solvolysis. The incubated control is very important because it will monitor for any nonspecific destruction of the sugar chain.

For acid hydrolysis, the most critical points to observe are that the pH should be kept between 2 and 3 and that the salt concentration be kept very high during the precipitation of sulfate with barium. Only then is the precipitation specific for sulfate. Under less stringent conditions, the oligosaccharides or even monosaccharide sulfates can be precipitated.

Anticipated Results

Expect ~80% to 90% efficiency in desulfation, and <20% in the control incubation (Freeze and Wolgast, 1984).

Time Considerations

Solvolytic desulfation itself takes only a few hours to complete. The rate-limiting step is the time needed to remove the water after the sample has passed through the Dowex-50 column and the pyridine has been added. This will only take a few minutes using a shaker-evaporator, but will require an overnight lyophilization.

Beginning with the hydrolysis step, the procedure can be completed within a day. If necessary, the procedure can be stopped after taking all of the time points and neutralizing them with base prior to precipitation. Where this is done, the reaction mixtures can be stored at 0°-4°C for 24 hr or more.

CHAPTER 18

Analysis of Protein Phosphorylation

INTRODUCTION

Most proteins undergo covalent modification of their amino acid side chains during or after synthesis. This modification, particularly if it is reversible, can provide an extraordinarily sensitive means by which the activity of a protein can be enhanced or diminished. Protein phosphorylation is probably the most common and important form of protein modification.

Thirty years ago, only a few protein kinases had been identified and only a limited number of processes were suspected of being regulated by protein phosphorylation. The increasing power of molecular biology has facilitated the identification and characterization of the genes of literally thousands of protein kinases and protein phosphatases in diverse species, while advances in cell and biochemical techniques have allowed the detailed elucidation of complex cellular regulatory pathways. Today, many aspects of the regulation of cell function are known to be controlled by protein phosphorylation. Proliferation, differentiation, signal transduction, and metabolism are all regulated by the balance of activity of protein kinases and protein phosphatases upon critical target proteins. Both extracellular ligands, such as polypeptide growth factors, and key intracellular signaling elements such as the concentration of cyclic AMP or calcium closely regulate the activities of kinases and phosphatases, which are themselves subject to modification by phosphorylation.

This chapter presents an overview of protein phosphorylation and provides detailed methods designed to detect and identify phosphorylated proteins and analyze their specific sites of modification using both isotopic and nonisotopic approaches. The overview (*UNIT 18.1*) provides specific examples of regulatory processes controlled by phosphorylation and provides a description of and rationale for the various approaches to studying protein phosphorylation. Succeeding units describe the labeling of eukaryotic cells with inorganic phosphate and preparation of lysates for immunoprecipitation (*UNIT 18.2*), phosphoamino acid analysis (*UNIT 18.3*), and detection of protein phosphorylation using immunologic or enzymatic techniques (*UNIT 18.4*).

To examine the functional effects of phosphorylation patterns, phosphoproteins can be dephosphorylated *in vitro*. *UNIT 18.5* presents specific strategies and protocols for the use of enzymes that allow either general or selective reversal of phosphorylation, as well as methods for subsequent detection by analysis of loss of ^{32}P -labeled phosphate or change in electrophoretic migration. The next unit provides yet another, somewhat more sophisticated, approach to the detection of phosphorylation. The state of phosphorylation of a given sequence can be detected quite specifically by antibodies that recognize a protein only in its phosphorylated state, and that do not cross-react with either the unphosphorylated form or other phosphoproteins, thus providing a good measure both of the amount of a specific protein and of its functional state. Strategies and methods for producing and purifying these anti-phosphopeptide antibodies are presented in *UNIT 18.6*.

A survey of the most common protein kinase assays (*UNIT 18.7*) provides readers with the conditions needed to detect and measure their activities. Tyrosine kinase,

cyclic-nucleotide dependent kinases, casein kinases, protein kinase C, and the Ca²⁺/calmodulin-dependent kinases are the major enzymes described here.

Brief chemical permeabilization of cells allows the introduction of labeled cell-impermeable reagents into the extracellular component to study signal-transduction processes. This process, described in *UNIT 18.8*, complements the labeling procedure described in *UNIT 18.2*. Standard approaches for more detailed studies of the labeled products are described in *UNIT 18.9*, which includes methods to generate and analyze phosphopeptide products from a particular protein of interest, as well as the use of manual Edman degradation to define precise positions of phosphorylated residues within labeled peptides.

UNIT 18.10 focuses on protein phosphatase inhibitors as tools for the study of protein phosphorylation. The ability of these reagents to amplify the transient effects of protein kinases can facilitate the elucidation of signaling pathways *in vivo*. Phosphatase inhibitors are also used to promote the isolation of desired phosphoproteins from cell homogenates and in other *in vitro* applications. This unit provides background on the different protein phosphatase enzymes as well as both *in vivo* and *in vitro* methods for specific inhibition of protein phosphatases 1 and 2A, protein phosphatase 2B/calcineurin, and protein tyrosine phosphatases.

UNIT 18.11 describes a powerful technology for studying the function of individual kinases. The ATP binding site of the kinase of interest is mutated in such a way that bulkier ATP analogs can be utilized by the enzyme. Such “analog-sensitive” mutant kinases are uniquely able to phosphorylate their substrates when provided with an appropriate radiolabeled ATP analog that cannot bind to other kinases. The analog-sensitive alleles can also bind highly specific inhibitors that do not affect other kinases. These inhibitors can be used for functional studies in genetically tractable organisms in which the wild-type allele can be replaced with the analog-sensitive allele. This unit describes not only the strategy for generation of desired analog-sensitive alleles, but also protocols for the synthesis of inhibitors and radiolabeled ATP analog.

UNIT 18.12 presents several approaches for the analysis of kinase activation, with a particular emphasis on the important mitogen-activated protein kinases (MAPKs). Protocols are described for measurement of kinase activity after either specific immunoprecipitation of activated MAPKs with phospho-specific antibodies or affinity purification with a specific kinase substrate, such as c-jun. These approaches depend on substantial characterization of the kinase, but this is not necessary for the *in-gel* assay, in which a particular substrate of interest is incorporated into an SDS-polyacrylamide gel. After the samples of interest are resolved, proteins are renatured and kinase activity is detected by soaking the gel in [γ -³²P]ATP. This provides information on the activity of one or more kinases of interest and also reveals their molecular weights.

Overview of Protein Phosphorylation

UNIT 18.1

HISTORY

Phosphorylation is the most common and important mechanism of acute and reversible regulation of protein function. Studies of mammalian cells metabolically labeled with [^{32}P]orthophosphate suggest that as many as one-third of all cellular proteins are covalently modified by protein phosphorylation. Protein phosphorylation and dephosphorylation function together in signal transduction pathways to induce rapid changes in response to hormones, growth factors, and neurotransmitters. Most polypeptide growth factors (platelet-derived growth factor and epidermal growth factor are among the best studied; Heldin, 1995) and cytokines (e.g., interleukin 2, colony stimulating factor 1, and γ -interferon; Ihle et al., 1994) stimulate phosphorylation upon binding to their receptors. Induced phosphorylation in turn activates cytoplasmic protein kinases, such as raf, MEK, and MAP kinases (Marshall, 1995). Additionally, in all nucleated organisms, cell cycle progression is regulated at both the G1/S and the G2/M transitions by cyclin-dependent protein kinases (Doree and Galas, 1994).

Differentiation and development are also controlled by phosphorylation. Development of the R7 cell in the *Drosophila* retina (Simon, 1994) and of the vulva in *Caenorhabditis elegans* (Eisenmann and Kim, 1994) are both dependent on the function of receptor and cytoplasmic protein kinases. Finally, metabolism—in particular, the interconversion of glucose and glycogen and the transport of glucose—is regulated by phosphorylation (Cohen, 1985). Biologists of all stripes therefore find, often unexpectedly and occasionally reluctantly, that they must study protein phosphorylation in order to understand the regulation and function of their favorite gene and its product.

In the early 1940s, soon after their discovery that glycogen phosphorylase existed in two distinct forms in skeletal muscle, Carl and Gerty Cori identified a cellular activity that converted active phosphorylase *a* into a less active phosphorylase *b*. Initial studies of what they called the prosthetic-group removing (PR) enzyme suggested that the inactivation of phosphorylase *a* was mediated via proteolysis (Cori and Cori, 1945). More than ten years later, this converting enzyme was shown to be a protein phosphatase. Thus, a protein phosphatase was studied nearly 20 years prior to the identifica-

tion of the first protein kinase. The finding that phosphorylase phosphatases were more widely expressed in tissues than phosphorylase *a* led to the current realization that these enzymes have a broad substrate specificity and regulate many physiological processes. The use of substrates other than phosphorylase *a* also identified several other protein serine/threonine phosphatases.

LABELING STUDIES

Protein phosphorylation is usually studied by biosynthetic labeling with ^{32}P -labeled inorganic phosphate ($^{32}\text{P}_i$; UNIT 18.2). This is intrinsically quite simple—the label is just added to growth medium. It is this step of an experiment, however, that makes many investigators the most nervous, given the perceived danger of radioactive exposure and the real danger of contamination of laboratory equipment with radioactivity. Neither problem is insurmountable. With proper shielding and technique, exposure of the investigator can be limited to the hands and contamination of the laboratory can be avoided. A general protocol for biosynthetic labeling with $^{32}\text{P}_i$ that maximizes incorporation and minimizes radioactive exposure of workers in the lab and contamination of lab equipment is described in UNIT 18.2. (For a general discussion of radiation safety consult Safe Use of Radioisotopes, APPENDIX 1F.)

Many protein kinases can be assayed by the transfer of radiolabel from [^{32}P]ATP to surrogate protein and peptide substrates. Synthetic peptide substrates have been particularly useful in establishing consensus motifs that define the substrate for protein kinases. By comparison, protein phosphatases show very low activity against synthetic phosphopeptides, greatly preferring the phosphoprotein substrates (Shenolikar and Ingebritsen, 1984). Therefore, attempts to define structural requirements for protein dephosphorylation using synthetic phosphopeptides have failed to establish the molecular basis for substrate specificity of the major cellular protein phosphatases.

The rate of ^{32}P incorporation into proteins *in vivo*, at either basal or hormone-stimulated levels, depends heavily on the rate of turnover of phosphate in the protein. For example, low phosphatase activity against specific sites or proteins will reduce the turnover of protein-bound phosphates and hinder their metabolic labeling in the intact cell. Conversely, physi-

Analysis of
Protein
Phosphorylation

18.1.1

Supplement 33

ological stimuli that increase phosphatase activity may facilitate metabolic labeling of proteins, allowing rapid replacement of endogenous “cold” phosphate with the radiolabel. Thus, ^{32}P incorporation by itself gives no indication about the extent of phosphorylation of a particular protein. As most phosphoproteins are phosphorylated on multiple sites, this also makes it difficult to correlate changes in protein function with ^{32}P labeling of a given protein in the intact cell.

SITES OF PHOSPHORYLATION

Most proteins are found to be phosphorylated at serine or threonine residues, and many proteins involved in signal transduction are also phosphorylated at tyrosine residues. These three hydroxyphosphoamino acids exhibit sufficient chemical stability at acidic pH that they can be recovered after acid hydrolysis and identified in a straightforward manner. Proteins that contain covalently bound phosphate at histidine, cysteine, and aspartic acid residues, either as phosphoenzyme intermediates or as stable modifications, have also been described. Each of these phosphoamino acids is chemically labile and impossible to study with the standard techniques used for the acid-stable phosphoamino acids. Indeed, they are often identified by inference or elimination. A technique for identifying phosphoserine, phosphothreonine, and phosphotyrosine by acid hydrolysis and two-dimensional thin-layer electrophoresis is described in *UNIT 18.3*. Techniques for analyzing acid-labile forms of protein phosphorylation are described in Ringer, 1991; Kamps, 1991; and Duclos et al., 1991.

Phosphotyrosine is not an abundant phosphoamino acid. Therefore, its detection in samples labeled with $^{32}\text{P}_i$ is often difficult, especially if the samples contain large quantities of proteins phosphorylated at serine residues or are contaminated with RNA. Detection of phosphotyrosine, as well as of phosphothreonine, can be enhanced considerably by incubation of gel-fractionated samples in alkali. This hydrolyzes RNA and dephosphorylates phosphoserine, allowing visualization of minor tyrosine- and threonine-phosphorylated proteins. A simple procedure for alkaline treatment is described in the alternate protocol of *UNIT 18.3*.

DETECTION OF UNLABELED PHOSPHOAMINO ACIDS

If a protein is modified by phosphorylation, identification of the phosphoamino acid can

often be accomplished without resorting to biosynthetic labeling. For example, tyrosine phosphorylation can be studied because proteins containing this rare phosphoamino acid can be detected with great specificity and sensitivity by antibodies to phosphotyrosine (*UNIT 18.4*). By comparison, the quantitation of phosphoserine and phosphothreonine is more difficult and requires partial acid hydrolysis of the phosphoprotein and subsequent separation of phosphoamino acids by high-voltage electrophoresis on thin-layer cellulose acetate plates. Attempts to generate antibodies that recognize phosphoserine or phosphothreonine have failed to produce reagents with the required specificity and/or sufficient sensitivity to be useful. However, once the primary sequence around a phosphorylation site containing phosphoserine or phosphothreonine has been determined, it is possible to make antibodies against synthetic phosphopeptides modeled on these phosphorylation sites (Czernik et al., 1991). Such anti-phosphopeptide antibodies have been very useful tools for monitoring the phosphorylation of the parent protein at specific sites. The phospho-specific antibodies have also been used to inhibit the dephosphorylation of individual sites and demonstrate their role in protein function. Several recent studies have produced phospho-specific antibodies against phosphorylation sites predicted solely by the primary sequence of a protein. These reagents have provided new insights into phosphorylations that control protein function.

More generally, because phosphorylation often alters the mobility of a protein during SDS–polyacrylamide gel electrophoresis and almost always alters its isoelectric point, the presence of phosphorylated residues in an unlabeled protein can be deduced from altered gel mobility after incubation of the protein with a phosphatase. Most phosphorylation sites are thought to reside near the surface of phosphoproteins. Therefore, they are equally accessible to phosphatases and proteases. Indeed, limited proteolysis often produces functional changes in phosphoproteins that closely mimic their *in vitro* dephosphorylation by phosphatase. As monitoring the release of radioactivity from a ^{32}P -labeled phosphoprotein does not distinguish between a phosphatase and a protease reaction, additional steps must be taken to differentiate orthophosphate from small phosphopeptides. This is particularly important when dephosphorylation reactions are carried out in crude extracts (*UNIT 18.5*).

PROTEIN KINASES

Protein kinases exhibit a strict specificity for phosphorylation of either serine/threonine or tyrosine residues. Yet these enzymes share structural homology in several domains such as the ATP-binding and catalytic sites, emphasizing their common function as phosphotransferases. A third group of protein kinases more closely resembles the serine/threonine kinases in their primary sequence but phosphorylate both serine/threonine and tyrosine residues. MEK, a MAP kinase activator (Crews and Erickson, 1992) and *wee1*, an inhibitor of *cdc2* kinase (Parker et al., 1992) are examples of such dual-specificity protein kinases that phosphorylate threonine and tyrosine residues which are closely located in substrate proteins.

Kinases have been used in a number of ways to analyze protein phosphorylation. Mutations that abrogate ATP-binding inactivate protein kinases. Such inactive kinases retain the ability to recognize substrates and therefore act as dominant-negative reagents to analyze the physiological function of kinases in the intact cell (Thorburn et al., 1994; Alberola-Ila et al., 1995). Cell-permeable compounds modeled on ATP also inhibit selected kinases in the intact cell.

Growth factors promote dimerization and activation of transmembrane receptor kinases. Mutant receptors that can dimerize in the absence of the natural ligand offer a novel approach to activate receptor kinases and initiate the cellular responses to growth factors (Spencer et al., 1993). Several cytoplasmic kinases are also activated by binding of intracellular second messengers. The allosteric activation of these kinases results from conformation changes that eliminate internal autoinhibitory interactions which silence the kinases in the absence of ligand. Deletion of the autoinhibitory sequences generates a constitutively active kinase that provides important insights into its physiological role (Planas-Silva and Means, 1992). Synthetic peptides modeled on the autoinhibitory sequences can also be used to selectively inhibit these kinases and reveal their role in controlling protein phosphorylation.

Still other kinases, which are not directly regulated by ligand binding, are activated by phosphorylation. Some of these kinases participate in cascades of sequential phosphorylations that amplify physiological signals. Substitution of the amino acids phosphorylated during the activation of these kinases with nonphosphorylated residues generates dominant-negative enzymes that can block the functions of such

kinases in intact cells. Alternately, acidic amino acids may be substituted for phosphoamino acids to produce a constitutively active kinase (Brunet et al., 1994). Such reagents have been used to validate the role of protein kinases in specific phosphorylation events.

PROTEIN PHOSPHATASES

Many protein phosphatases also show a strict specificity for either phosphoserine/phosphothreonine or phosphotyrosine residues. However, unlike kinases, the serine/threonine and tyrosine phosphatases are not evolutionarily related and exhibit no primary sequence homology (Shenolikar and Nairn, 1991; Charbonneau and Tonks, 1992). Acid and alkali phosphatases can also dephosphorylate phosphoproteins *in vitro* but share no structural homology with protein phosphatases. A new family of phosphatases, such as *cdc25* and *CL100*, are distantly related to the tyrosine phosphatases but dephosphorylate both phosphotyrosine and phosphothreonine in their target substrates. Mutation of an essential cysteine in tyrosine phosphatases has produced dominant-negative enzymes that have been shown to shield their substrates from dephosphorylation by endogenous phosphatases, thereby prolonging the biological effects of protein phosphorylation (Sun et al., 1993). Mutating several conserved amino acids can inactivate a serine/threonine phosphatase (Zhou et al., 1994), but the ability of such mutant phosphatases to modulate serine/threonine phosphorylation in cells has not yet been demonstrated.

A number of potent phosphatase inhibitors have been identified in recent years. Okadaic acid and several other toxins inhibit protein (serine/threonine) phosphatase 1 and 2A, and vanadate and phenylarsenoxide inhibit tyrosine phosphatase. These compounds have implicated reversible phosphorylation as a regulatory mechanism in many physiological processes (Cohen, 1989; Hardie et al., 1991; Shenolikar and Nairn, 1991; Shenolikar, 1994); under certain conditions, they may be the dominant regulators of these cellular processes. These phosphatase inhibitors can also be used to distinguish protein dephosphorylation from proteolysis in crude tissue extracts (Cohen, 1991). However, by far the most important contribution of these reagents has been that they have allowed assessment of the role played by phosphorylation in cellular processes where neither the identity of the phosphoprotein involved nor that of the kinase(s) that regulates its function are known.

The units in this chapter describe techniques that detect protein phosphorylation and identify amino acids that have been covalently modified (UNITS 18.2, 18.3, & 18.4). The next step is to use phosphatases to dephosphorylate the substrate protein in vitro and address the functional relevance of the covalent modification (UNIT 18.5). Once the regulatory role of phosphorylation has been clearly established, the more sophisticated approaches discussed above can be used to identify the specific kinases and phosphatases involved and thereby begin to elucidate the physiological mechanism that regulates the substrate in the intact cell.

Labeling Cultured Cells with $^{32}\text{P}_i$ and Preparing Cell Lysates for Immunoprecipitation

UNIT 18.2

This unit describes $^{32}\text{P}_i$ labeling and lysis of cultured cells to be used for subsequent immunoprecipitation of proteins. The approach is appropriate, however, for labeling any cellular constituent with ^{32}P . This procedure is suitable for insect, avian, and mammalian cells and can be used with both adherent and nonadherent cultures. The same general approach—biosynthetic labeling with $^{32}\text{P}_i$ in medium containing a reduced concentration of phosphate—can also be applied to bacteria and yeast; however, specific techniques to accomplish this are not presented here. This approach can also be used to label any cellular constituents with ^{32}P ; in these cases the basic protocol must be modified beginning with step 8.

The first procedure described (see Basic Protocol) is $^{32}\text{P}_i$ labeling of adherent or nonadherent (e.g., hematopoietic) cells with subsequent lysis in a detergent buffer containing either Nonidet P-40 (NP-40), 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS), or a combination of NP-40, sodium deoxycholate and SDS (RadioImmunoPrecipitation Assay or RIPA buffer). More rigorous lysis conditions to be used for working with proteins that are difficult to solubilize are also described (see Alternate Protocol).

CAUTION: Unshielded ^{32}P will penetrate ~1 cm into flesh. Exposure to the skin and eyes is, therefore, of concern. Gloves and protective eyewear should always be worn when handling significant amounts of ^{32}P . A 1-in.-thick (2.5-cm) Plexiglas shield, tall enough to look through when seated or standing comfortably, should be used when handling samples containing ^{32}P . For more specific precautions, refer to the section on Safe Use of Radioisotopes in *APPENDIX 1*.

LABELING CULTURED CELLS WITH $^{32}\text{P}_i$ AND LYSIS USING MILD DETERGENT

**BASIC
PROTOCOL**

The first six steps of this protocol describe culturing and labeling procedures for cultures of adherent cells; modifications appropriate for nonadherent cells are described in alternate steps. The remaining steps describe lysis of cells in detergent buffer to prepare the sample for immunoprecipitation. For a more detailed discussion of mammalian cell culture conditions and reagents see the introduction to Chapter 9.

Materials

- Cell culture to be labeled
- Labeling medium: phosphate-free tissue culture medium (e.g., DMEM, *APPENDIX 3F*) supplemented with the usual concentration of serum or serum dialyzed against phosphate-free saline, 37°C
- 1 Ci/ml $\text{H}_3^{32}\text{PO}_4$ in HCl (carrier free ICN)
- Tris-buffered or phosphate-buffered saline (TBS or PBS; see recipes), cold
- Mild lysis buffer or RIPA lysis buffer (see recipes)
- 1-in.-thick Plexiglas shield (*APPENDIX 1*)
- Plugged, aerosol-resistant pipet tips
- Plexiglas box (*APPENDIX 1*), warmed to 37°C
- Screw-cap microcentrifuge tubes
- Plugged disposable pipet or disposable one-piece transfer pipet
- Rubber policeman

**Analysis of
Protein
Phosphorylation**

Sorvall refrigerated centrifuge with SM 24 rotor and rubber adaptors, refrigerated microcentrifuge, or equivalent, 4°C

Plexiglas sheet (10 × 10 × ¼-in.) or Plexiglas tube holder, 4°C (APPENDIX 1)

Additional reagents and equipment for cell culture (see Chapter 9, introduction) and gel electrophoresis (UNIT 10.2), immunoprecipitation (UNIT 10.16), or protein purification (UNITS 10.9-10.11)

NOTE: All culture incubations are performed in a humidified 37°C, 10% CO₂ incubator unless otherwise specified.

Label the cell culture

1. Culture the cells to be labeled to an appropriate stage of growth.

Phosphate transport is maximal in rapidly growing cells. Therefore, except in those cases where phosphorylation of a protein in quiescent cells is to be examined, cells to be labeled should be subconfluent (adherent cells) or at less than maximal density (nonadherent cells). It is useful to change the medium to fresh growth medium 3 to 18 hr prior to labeling.

Brief cultivation of cells in low-phosphate medium (to reduce the phosphate pool by starvation prior to labeling) is of minimal value.

For adherent cells:

- 2a. Remove growth medium by aspiration. Wash away any residual phosphate-containing medium by adding 37°C labeling medium supplemented with serum, but lacking the label, and removing the wash medium by aspiration.

Phosphate-free DMEM is routinely used for labeling medium because RPMI has a very high concentration of phosphates.

- 3a. Add prewarmed labeling medium to cultures, using 0.5 to 1 ml per 35-mm dish, 1 to 2 ml per 50-mm dish, or 2 to 4 ml per 100-mm dish of adherent cells.

For nonadherent cells:

- 2b. Gently centrifuge the culture 1 min at 1800 × g and aspirate the medium away from the cell pellet. Resuspend the cells in labeling medium supplemented with serum, but lacking the label. Centrifuge and remove the medium.

- 3b. Add 2 ml medium per 10⁷ cells and transfer to an appropriate size petri dish.

4. Working behind a Plexiglas shield, use a micropipettor with plugged, aerosol-resistant pipet tips to add ³²P_i to a final concentration of 0.1 to 2 mCi/ml.

Use of plugged, aerosol-resistant pipet tips will minimize contamination of the micropipettor. ³²P_i is usually shipped in HCl and is generally sterile, so it is not necessary to sterilize the labeling medium after adding the radioisotope. Additionally, except in the rare cases when steady-state labeling with ³²P is desired, the labeling interval is usually so short (<6 hr) that microbial growth resulting from added isotope is undetectable. Therefore, addition of ³²P to cells can be performed on the lab bench rather than in a tissue culture hood.

5. Place dishes in a warmed Plexiglas box, and put box in the incubator.

Labeling for 1 to 2 hr is usually sufficient, but cells will tolerate as much as 2 mCi/ml for 6 hr and lower concentrations (0.1 to 0.5 mCi/ml) for 18 hr.

Wash and lyse the cells

6. At the end of the labeling period, carry the labeled cells, still in the Plexiglas box, into the cold room. Place the cells behind a Plexiglas shield.

For adherent cells:

- 7a. Take the dish out of the box and remove the labeling medium manually, using either a plugged disposable pipet or a disposable one-piece plastic Pasteur transfer pipet. Discard the medium and pipet as radioactive wastes.

Labeling medium should be removed without using a vacuum aspirator. Vacuum aspiration generates radioactive aerosols and leaves a radioactive film on the equipment.

- 8a. Wash cells once with 2 to 10 ml cold TBS. Remove the wash buffer manually, as in step 7, and discard as radioactive waste.

The uptake of phosphate is efficient and often a majority of the added $^{32}\text{P}_i$ is found within the labeled cells. This necessitates continued shielding of the labeled cells following removal of the labeling medium.

- 9a. Add lysis buffer to cells, using 0.3 ml per 35-mm dish, 0.6 ml per 50-mm dish, or 1.0 ml per 100-mm dish of adherent cells. Dislodge adherent cells by scraping with a rubber policeman, but leave the lysate in the dish. Incubate 20 min at 4°C. With a rubber policeman, scrape the lysate of adherent cells to the side of the dish and transfer lysate to a screw-cap microcentrifuge tube.

If a low background of nonspecific contaminants is critical, use RIPA lysis buffer. If maintenance of enzymatic activity or the structure of protein complexes is critical, use a milder lysis buffer containing either 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS) or Nonidet P-40 (NP-40) as the only detergent. If complete solubilization of the cells and denaturation of the protein is desired, use SDS for lysis (see Alternate Protocol).

For nonadherent cells:

- 7b. Take the dish out of the box, transfer the cells to a screw-cap centrifuge tube, pellet them by centrifugation (1 min at 1800 × g), and remove the medium.

Do not use a vacuum aspirator to remove medium.

- 8b. Resuspend pelleted cells gently in a small volume of cold TBS, transfer to a screw-cap microcentrifuge tube, and pellet the cells by microcentrifuging 1 min at 1800 × g.

Continue to use shielding with cells and lysate.

- 9b. Add 0.5 to 1 ml lysis buffer per 10⁷ cells and resuspend the pellet by gentle agitation with a disposable plastic Pasteur pipet. Incubate 20 min at 4°C.

Choose the lysis buffer as in annotation to step 9a.

10. Cap the tube, and clarify the lysate by centrifuging 30 min at 26,000 × g (17,000 rpm in Sorvall SM24 rotor), 4°C.

Use an ice bucket with a sheet of Plexiglas over it, a chilled Plexiglas tube holder, or a prechilled centrifuge rotor to transport the tube of lysate.

It is best to half-fill the tube to prevent spilling. A Sorvall SM24 rotor with rubber adaptors for microcentrifuge tubes is ideal for clarifying lysates. Alternatively, a refrigerated microcentrifuge can be used for 30 min at maximum speed. Do not use a nonrefrigerated microcentrifuge in the cold room because the centrifuge will warm to 20°C during a 30-min spin.

*Lysates prepared with RIPA buffer often become viscous due to lysis of nuclei. If this occurs, increase the time of centrifugation to 90 min, or add 50 μl of fixed *Staphylococcus aureus* bacteria (Pansorbin, Calbiochem) in RIPA buffer to the lysate prior to centrifugation. Either modification will cause the solubilized DNA to pellet.*

11. After centrifugation, transfer the supernatant (lysate) to a new tube and discard the tube and pellet in radioactive waste.

If the pellet is very viscous, so that it is impossible to remove the supernatant cleanly, suck part of the pellet into a micropipet tip, lift the viscous material out of the tube, and discard it in the radioactive waste. The residual liquid in the tube is the supernatant and can be used for immunoprecipitation.

12. Analyze the labeled lysate using gel electrophoresis, immunoprecipitation, or protein purification. Carry out all analytical procedures at 4°C using adequate shielding.

ALTERNATE PROTOCOL

LYSIS OF CELLS BY BOILING IN SDS

Some proteins, such as eukaryotic RNA polymerase II, are difficult to solubilize with mild lysis buffer or RIPA lysis buffer, and some analytical procedures use antibodies that recognize epitopes exposed only in denatured proteins. In these cases, it is useful to solubilize labeled cells completely in SDS and then adjust the composition of the lysate solution to match that of RIPA buffer for immunoprecipitation. To avoid the formation of spurious disulfide bonds, lysis and washing during immunoprecipitation are carried out in the presence of fresh 1 mM dithiothreitol (DTT). The protocol describes the procedure for adherent cells; modifications for working with nonadherent cells are described as alternate steps.

Additional Materials (also see Basic Protocol)

SDS lysis buffer (see recipe)

RIPA correction buffer (see recipe)

Immunoprecipitate wash buffer (see recipe)

Fixed *Staphylococcus aureus* bacteria (Pansorbin, Calbiochem; optional)

Boiling water bath

1. Label and wash cells (see Basic Protocol steps 1 to 7).
- 2a. *For adherent cells:* Add SDS lysis buffer using 0.1 ml for a 35-mm dish, 0.25 ml for a 50-mm dish, or 0.5 ml for an 100-mm dish. Immediately scrape off the dish with a rubber policeman and transfer the cell lysate to a screw-cap microcentrifuge tube.
- 2b. *For nonadherent cells:* Vortex briefly to loosen the cell pellet, add 1 ml SDS lysis buffer per 5×10^7 cells and vortex again.
3. Boil the samples 2 to 5 min, then add 4 vol RIPA correction buffer and mix well.
4. Clarify the cell lysate by centrifuging 90 min at $26,000 \times g$ (17,000 rpm in Sorvall SM24), 4°C or at maximum speed, 4°C in a refrigerated microcentrifuge.

*Lysate may also be clarified by adding 50 μ l fixed *Staphylococcus aureus* and centrifuging 30 min at $26,000 \times g$, 4°C.*

5. Carry out immunoprecipitation as usual using immunoprecipitate wash buffer for washes.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Immunoprecipitate wash buffer for boiled sample

RIPA lysis buffer (see recipe)

1 mM DTT, added fresh

DTT is added from a 1 M stock solution stored at -20°C.

Mild lysis buffer

10 mM 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS) or 1% (w/w) Nonidet P-40 (NP-40)

0.15 M NaCl

0.01 M sodium phosphate, pH 7.2 (APPENDIX 2A)

2 mM EDTA

50 mM sodium fluoride

0.2 mM sodium vanadate added fresh from 0.2 M stock solution

100 U/ml aprotinin (Trasylol, Pentex/Miles)

Store buffer without vanadate at 4°C up to 1 year

CHAPS is a milder detergent than NP-40, but yields precipitates with a higher background and may solubilize some proteins less efficiently.

Sodium vanadate stock solution can be stored in plastic at room temperature.

Phosphate-buffered saline (PBS)

Dissolve the following in 800 to 900 ml H₂O:

8 g sodium chloride (136.8 mM final)

0.2 g potassium chloride (2.5 mM final)

0.115 g dibasic sodium phosphate (anhydrous; 0.8 mM final)

0.2 g monobasic potassium phosphate (anhydrous; 1.47 mM final)

0.1 g calcium chloride (anhydrous; 0.9 mM final)

0.1 g magnesium chloride hexahydrate (0.5 mM final)

Add H₂O to 1 liter

Dispense 50- or 100-ml aliquots into glass bottles

Autoclave and store indefinitely at room temperature

RIPA (RadioImmunoProtection Assay) correction buffer for boiled sample

1.25% (w/w) Nonidet P-40 (NP-40)

1.25% (w/v) sodium deoxycholate

0.0125 M sodium phosphate, pH 7.2

2 mM EDTA

0.2 mM sodium vanadate added fresh from 0.2 M stock solution

50 mM sodium fluoride

100 U/ml aprotinin (Trasylol, Pentex/Miles)

Store buffer without vanadate at 4°C up to 1 year

Sodium vanadate stock solution can be stored in plastic at room temperature.

RIPA (RadioImmunoPrecipitation Assay) lysis buffer

1% (w/w) Nonidet P-40 (NP-40)

1% (w/v) sodium deoxycholate

0.1% (w/v) SDS

0.15 M NaCl

0.01 M sodium phosphate, pH 7.2

2 mM EDTA

50 mM sodium fluoride

continued

0.2 mM sodium vanadate added fresh from 0.2 M stock solution
100 U/ml aprotinin (Trasylol, Pentex/Miles)
Store buffer without vanadate at 4°C up to 1 year

Sodium vanadate stock solution can be stored in plastic at room temperature.

SDS lysis buffer

0.5% (w/v) SDS
0.05 M Tris·Cl, pH 8.0 (APPENDIX 2)
1 mM DTT, added fresh

SDS and Tris·Cl solutions can be made in advance and stored at room temperature. DTT is added from a 1 M stock solutions stored at -20°C.

Tris-buffered saline (TBS)

Dissolve the following salts in 800 to 900 ml H₂O:
8 g sodium chloride (136.8 mM final)
0.38 g potassium chloride (5.0 mM final)
0.1 g calcium chloride (anhydrous; 0.9 mM final)
0.1 g magnesium chloride hexahydrate (0.5 mM final)
0.1 g dibasic sodium phosphate (anhydrous; 0.7 mM final)
Add 25 ml 1 M Tris·Cl, pH 7.4 (APPENDIX 2)
Add H₂O to 1 liter
Dispense 50- or 100-ml aliquots into glass bottles
Autoclave and store indefinitely at room temperature

COMMENTARY

Background Information

The extent to which a protein becomes radiolabeled via biosynthetic labeling with ³²P_i depends on the rate of transport of phosphate into the cells being labeled, abundance of the protein, stoichiometry of phosphorylation of the protein, and rate of phosphate turnover in the protein. The rate of turnover of the protein itself is less important because phosphate in protein usually turns over at a much faster rate than does the protein. Most of the phosphate incorporated into cells is not incorporated into phosphoproteins—the vast majority is incorporated into phospholipid, RNA, and DNA. The efficiency of incorporation of ³²P_i into proteins is therefore low—only ~1% of incorporated radioactivity is found in phosphoproteins.

An obvious and immediate question is how many cells and how much isotope should be used. The answer is that it depends on the protein being studied. If the protein is abundant (i.e., it constitutes 0.5% to 1% of total cellular protein) and highly phosphorylated (i.e., it contains 1 mole of phosphate per mole of protein), it can be labeled by incubating 10⁶ cells with 0.2 to 0.5 mCi ³²P_i in 2 ml labeling medium for 1 hr. In contrast, if the protein is rare or non-abundant, it may be necessary to label 10⁷ cells with 5 to 10 mCi of ³²P_i in 3 to 5 ml labeling medium for 4 to 6 hr. A pilot experiment can

be useful: if 50 cpm are recovered in the protein of interest, use more cells and more isotope; if 200,000 cpm are recovered in the protein of interest, use fewer cells with less isotope.

Critical Parameters

Incorporation of ³²P_i during biosynthetic labeling is greatest if labeling is done in medium lacking any phosphate except the added radioisotope. Labeling can also be accomplished at a somewhat reduced efficiency in complete growth medium. Phosphate-free medium is commercially available but can also be easily formulated in-house by omitting sodium and potassium phosphate from a recipe and replacing them with either sodium chloride or potassium chloride or both. Serum dialyzed against phosphate-free saline can be used instead of complete serum to further reduce the level of phosphate in labeling medium. Dialysis of serum against phosphate-free saline reduces but never entirely eliminates the phosphate in serum. Washing or rinsing cells in reduced-phosphate medium just prior to labeling significantly increases labeling efficiency, but starvation of cells by incubation in reduced-phosphate medium prior to labeling is of very limited value.

Labeling cells with ³²P almost certainly induces radiation damage in the labeled cells and

will affect or arrest cell-cycle progression. If phosphorylation of the protein under study varies during the cell cycle, labeling with ^{32}P may alter its phosphorylation.

At the end of the labeling interval, the radioactive medium should be discarded, except in experiments where labeled virions or labeled secreted proteins are being studied. Labeling medium should be removed *without* using a vacuum aspirator. Vacuum aspiration generates radioactive aerosols and leaves a radioactive film inside the aspirator hose. As a result the hose can become an intense source of radiation exposure. It is best to use a plugged disposable pipet or disposable plastic Pasteur pipet for removing labeling medium. The medium and pipet should be discarded immediately as radioactive wastes.

In general, labeled cells are lysed and subjected to gel electrophoresis, immunoprecipitation, or protein purification. If the labeled cells are to be centrifuged, they should be transferred to capped, disposable centrifuge tubes. Tubes should be no more than half full if they are to be spun in a fixed-angle rotor; tubes that are too full may leak radioactive lysate and contaminate the centrifuge. Screw-cap microcentrifuge tubes are ideal for centrifuging lysates. If large volumes are being handled, multiple partially filled tubes are preferable to tubes filled to the top.

An ice bucket can be used for storage and transport of samples to keep the samples cold and provide considerable shielding. Radiation exposure from the tops of the tubes can be minimized by covering the ice bucket with a 1/4-in. Plexiglas sheet.

RadioImmunoPrecipitation Assay (RIPA) buffer (Brugge and Erikson, 1977) is the lysis buffer of choice because it solubilizes proteins well, gives a low background of nonspecific proteins, and is tolerated by most antigens and antibodies. It does however denature some antigens and disrupt some protein:protein complexes. If 1% (w/w) Nonidet P-40 (NP-40) is used as the only detergent, most of these problems are solved without increasing background unacceptably (Sefton et al., 1980). Some workers like to use digitonin as an extremely mild detergent for cell lysis. Digitonin sometimes is tricky and idiosyncratic, giving erratic results and high backgrounds during immunoprecipitation. 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS; Chen et al., 1990) and Brij 96 (Osman et al., 1992) are mild detergents that appear to give more reproducible results.

Besides the usual concern about proteolysis following cell lysis, the cells must be handled carefully to prevent protein phosphorylation and dephosphorylation following lysis of the cells. Both problems can be minimized by proper formulation of the lysis buffer and by keeping the sample at 4°C. Inclusion of 2 mM EDTA in the lysis buffer will minimize phosphorylation in the lysate by chelating both Mg^{2+} and Mn^{2+} , which are essential for protein kinase activity. Addition of phosphatase inhibitors to the lysis buffer will reduce dephosphorylation significantly. For example, 50 mM sodium fluoride is used to inhibit serine and threonine phosphatases, and 0.2 mM sodium vanadate is used to inhibit all known tyrosine phosphatases. Sodium vanadate appears to lose its effectiveness if it is stored diluted in lysis buffer, so it should be added fresh each time. The concentrated stock solution should be stored in plastic at room temperature.

Anticipated Results

This protocol can be used to label phosphoproteins or other phosphorylated cellular constituents. Phosphoproteins will contain ~1% of incorporated label.

Time Considerations

Proteins can and should be labeled biosynthetically with $^{32}\text{P}_i$ and isolated by immunoprecipitation in a single day. As is the case with all ^{32}P -labeled samples, it is important to work quickly because the specific activity of the sample declines 5% per day. If it is absolutely necessary to stop during the immunoprecipitation, it is best to leave the samples as precipitated pellets after aspiration of the wash buffer. Such samples can be stored at 4°C or -20°C overnight. Freezing the cell lysate tends to increase the background. Frozen lysates should be reclarified by centrifugation prior to immunoprecipitation.

with $^{32}\text{P}_i$ and
Preparing Lysates**

18.2.8

Phosphoamino Acid Analysis

UNIT 18.3

It is often valuable to identify the phosphorylated residue in a protein. In the case of proteins phosphorylated at serine, threonine, or tyrosine, this is readily accomplished by partial acid hydrolysis in HCl followed by two-dimensional thin-layer electrophoresis of the labeled phosphoamino acid (see Basic Protocol). Phosphothreonine and phosphotyrosine are more stable to hydrolysis in alkali than are RNA and phosphoserine. Therefore, mild alkaline hydrolysis of protein samples can be used to enhance the detection of phosphothreonine and phosphotyrosine (see Alternate Protocol).

Although this procedure can be carried out with a protein eluted from a preparative gel and concentrated by trichloroacetic acid (TCA; UNIT 10.18) or acetone (UNIT 17.10) precipitation, it is most easily accomplished by transfer of the protein of interest to a PVDF membrane. This technique is obviously not ideal if the protein being studied does not transfer efficiently.

NOTE: Wear gloves and use blunt-end forceps to handle membranes.

ACID HYDROLYSIS AND TWO-DIMENSIONAL ELECTROPHORETIC ANALYSIS OF PHOSPHOAMINO ACIDS

**BASIC
PROTOCOL**

The protein to be acid hydrolyzed is transferred to a PVDF membrane using the same technique used for immunoblotting (UNIT 10.8) or for microsequencing (UNIT 10.19). It is useful, but not absolutely essential, to keep the filter wet following transfer. Following acid hydrolysis, phosphoamino acids are separated by two-dimensional thin-layer electrophoresis. Because electrophoresis equipment differs considerably in design, the details of the assembly and placement of the plate are not discussed here. It is assumed that a suitable apparatus is available for use by an experienced operator. Electrophoresis conditions are described for using the HTLE 7000 (CBS Scientific). They are almost certainly not correct for other equipment and will need to be altered according to the equipment manufacturer's directions.

Materials

³²P-labeled phosphoprotein (UNIT 18.2)

India ink solution: 1 μl/ml India ink in TBS (UNIT 18.2)/0.02% (v/v) Tween 20, pH 6.5 (prepare fresh or store indefinitely at room temperature); *or* radioactive or phosphorescent alignment markers

6 M HCl

Phosphoamino acid standards mixture (see recipe)

pH 1.9 electrophoresis buffer (see recipe)

pH 3.5 electrophoresis buffer (see recipe)

0.25% (w/v) ninhydrin in acetone in a freon (aerosol, gas-driven) atomizer/sprayer

PVDF membrane (Immobilon-P, Millipore)

110° oven

Screw-cap microcentrifuge tubes

20 cm × 20 cm × 100 μm glass-backed cellulose thin-layer chromatography plate (EM Sciences)

Large blotter: two 25 × 25-cm layers of Whatman 3MM paper sewn together at the edges, with four 2-cm holes that align with the origins on the TLC plate

Glass tray or plastic box

Whatman 3MM paper

Thin-layer electrophoresis apparatus (e.g., HTLE 7000, CBS Scientific)

Fan

Small blotters: 4 × 25-cm, 5 × 25-cm, and 10 × 25-cm pieces of Whatman 3MM paper

Supplement 40

50° to 80°C drying oven
Sheets of transparency film for overhead projector

Additional reagents and equipment for SDS-PAGE (UNIT 10.2), immunoblotting (UNIT 10.8 or UNIT 10.19), staining filters (UNIT 10.7), and autoradiography (APPENDIX 3A)

Prepare sample

1. Run radiolabeled phosphoprotein on a preparative SDS-polyacrylamide gel.
2. Transfer proteins electrophoretically to a PVDF membrane. Wash the membrane several times with water. Do not let the membrane dry.

These washes remove buffer and detergent.

3. Locate the band of interest by staining the filter 5 to 10 min in 30 to 50 ml India ink solution with shaking until bands are detectable, *or* by wrapping the filter in plastic wrap, applying radioactive or phosphorescent alignment markers, and performing autoradiography.
4. Excise the piece of filter containing the band of interest with a clean razor blade. Rewet the piece of filter with methanol for 1 min and then rewet it in >0.5 ml water. Place the piece of filter paper in a screw-cap microcentrifuge tube.

Keep the excised piece as small as possible.

Hydrolyze sample

5. Add enough 6 M HCl to submerge the piece of filter. Screw the cap on the tube tightly and incubate 60 min in 110°C oven.
6. Let cool. Microcentrifuge 2 min at maximum speed. Transfer the liquid hydrolysate to a fresh microcentrifuge tube and dry with a Speedvac evaporator.

Drying takes ~2 hr. Simultaneous drying of the hydrolysate and deblocked oligonucleotides in NH₄OH must be avoided, as this will generate a cloud of ammonium chloride that will collect in the centrifuge tube and render the hydrolysate unsuitable for thin-layer electrophoresis.

7. Dissolve the sample in 6 to 10 µl water by vortexing vigorously. Microcentrifuge 5 min at maximum speed.

Prepare plate for first-dimension electrophoresis

8. Spot 25% to 50% of the sample, in 0.25- to 0.50-µl aliquots, on one origin of a 20 cm × 20 cm × 100 µm glass-backed cellulose thin-layer chromatography plate (see Fig. 18.3.1 for arrangement of samples). Between each application, dry the sample spot with compressed air delivered through a Pasteur pipet plugged with cotton.

Use long, thin plastic micropipet loading tips for loading, and do not let the tip touch the plate.

Four samples can be analyzed simultaneously. The complete hydrolysate can be spotted on a single origin, but some streaking in the first dimension may be observed due to overloading. This problem can be avoided by using a fraction of the sample.

9. Spot 1 µl nonradioactive phosphoamino acid standards mixture (containing phosphoserine, phosphothreonine, and phosphotyrosine) on top of each sample in 0.25- to 0.50-µl aliquots as above.
10. Wet the large blotter (with four holes) by submerging it in pH 1.9 electrophoresis buffer in a large glass tray or plastic box. Briefly allow the excess buffer to drain off. Lower the wet blotter onto the prespotted plate with the origins on the plate in the centers of the four holes in the blotter (Fig. 18.3.1). Press on the blotter gently to

Figure 18.3.1 First-dimension electrophoretic separation of phosphoamino acids at pH 1.9. **(A)** Positions of the four origins on a single 20 × 20-cm plate; **(B)** blotter used for wetting the plate with pH 1.9 electrophoresis buffer; **(C)** placement of the blotter on the plate (underneath; indicated by dashed outline); and **(D)** orientation of the plate between the + and – electrodes with the positions of the phosphoamino acids after electrophoresis.

achieve even wetting of the cellulose and concentration of the samples. When the plate is uniformly wet, remove the blotter.

The blotter should be quite damp but not sopping wet. Excess buffer can be wicked off onto filter paper.

Areas of the plate that are too dry can be seen through the blotter and will appear to be whiter than the rest of the plate. If this happens, dab the blotter with a Kimwipe wetted with pH 1.9 electrophoresis buffer. If there are puddles of buffer on the plate, let them dry before carrying out electrophoresis.

- Place the thin-layer plate in the electrophoresis apparatus and overlap 0.5 cm of the right and left sides of the plate with wicks made of Whatman 3MM paper. If the apparatus has an air bag, be sure to inflate it. Close the cover and start electrophoresis. With an HTLE 7000, double-thickness Whatman 3MM wicks, and a plate with four samples, electrophorese 20 min at 1.5 kV.

For the HTLE 7000 apparatus, use folded-over Whatman 3MM wicks that are 20 cm wide (the same as the plate) and not overly wet. Overly wet wicks will flood the plate and cause sample diffusion.

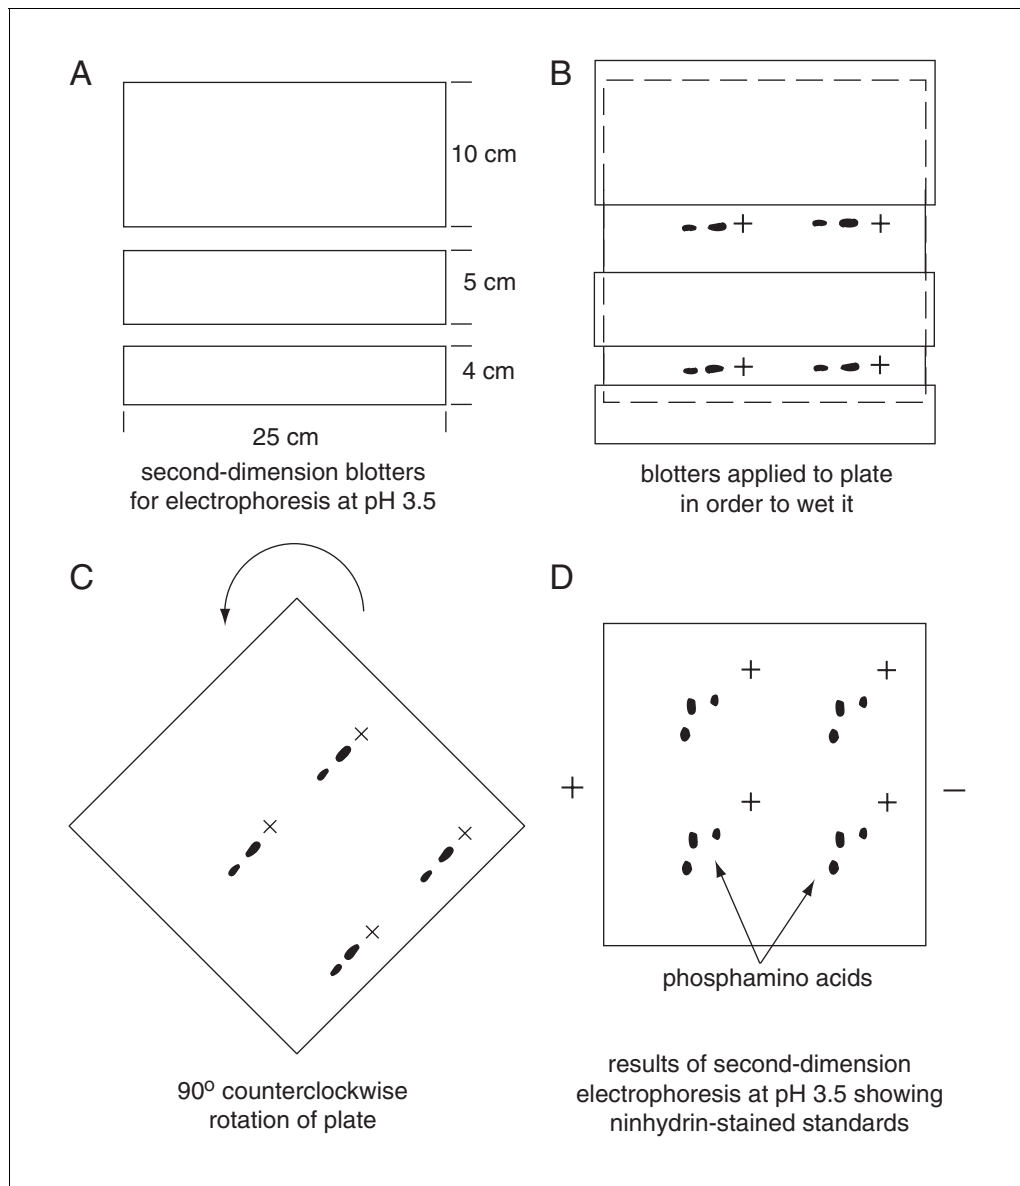

Figure 18.3.2 Second-dimension electrophoretic separation of phosphoamino acids at pH 3.5. **(A)** The three pieces of Whatman 3MM paper used for wetting the plate with pH 3.5 electrophoresis buffer; **(B)** proper placement of the blotters on the plate (underneath; indicated by dashed outline); **(C)** reorientation of the plate for electrophoresis in the second dimension; and **(D)** orientation of the plate between the + and – electrodes with the position of the phosphoamino acids after electrophoresis.

For other electrophoresis apparatuses the appropriate duration of electrophoresis can be determined empirically by examining the rate of migration of the phosphoamino acid standards.

12. Following electrophoresis, remove the plate and quickly air dry with a fan without heating.

It takes ~20 min to dry the plate.

Perform second-dimension electrophoresis

13. Wet the small blotters in pH 3.5 electrophoresis buffer and use them to wet the plate using the method described in step 10 to achieve even wetting without puddling (Fig. 18.3.2).

Figure 18.3.3 Hypothetical autoradiogram of a two-dimensional separation. Four samples of acid-hydrolyzed, ^{32}P -labeled proteins are applied at the origins, one in each of the four quadrants. This diagram shows the origins, the directions of electrophoresis, the positions of phosphoserine, phosphothreonine, and phosphotyrosine, the position of P_i , and the position of partially hydrolyzed fragments of the proteins for the upper right-hand sample. Every protein generates different partial hydrolysis peptide fragments.

After electrophoresis at pH 1.9, phosphoamino acids are present as a streak extending from the origin towards the + electrode. Blotters are not applied directly over the phosphoamino acids to prevent sample blurring or smearing.

14. Remove the blotters, rotate the plate 90° counterclockwise, and electrophorese 16 min at 1.3 kV in pH 3.5 electrophoresis buffer if using the HTLE 7000 apparatus.
15. At the end of the electrophoresis run, remove the plate and dry 20 to 30 min in an oven at 50° to 80°C . When dry, spray with 0.25% ninhydrin in acetone, then reheat in the oven 5 to 10 min to visualize the phosphoamino acid standards.
16. Place radioactive or phosphorescent alignment marks on the plate and autoradiograph with an intensifying screen overnight to 10 days at -70°C .
17. Following autoradiography, trace the alignment markers and the stained phosphoamino acid markers onto a transparent sheet used for overhead projectors. Save this template. Align the film with the plate and identify radioactive phosphoamino acids (Fig. 18.3.3).

ALKALI TREATMENT TO ENHANCE DETECTION OF TYR- AND THR-PHOSPHORYLATED PROTEINS BLOTTED ONTO FILTERS

Because phosphothreonine and phosphotyrosine are much more stable to hydrolysis in alkali than RNA or phosphoserine, detection of proteins containing phosphothreonine and phosphotyrosine can often be enhanced by mild alkaline hydrolysis of gel-fractionated samples. Although this technique was first developed for the treatment of fixed polyacrylamide gels, it is much more easily performed with proteins that have been first transferred to a PVDF membrane.

ALTERNATE PROTOCOL

Analysis of Protein Phosphorylation

18.3.5

Alkaline hydrolysis does not preclude subsequent phosphoamino acid analysis. A band from a blot that has been treated with alkali can be excised and subjected to acid hydrolysis as described in the Basic Protocol.

Additional Materials (also see *Basic Protocol*)

1 M KOH

TN buffer: 10 mM Tris·Cl (pH 7.4 at room temperature)/0.15 M NaCl

1 M Tris·Cl, pH 7.0 at room temperature (*APPENDIX 2*)

Covered plastic container (e.g., Tupperware box)

55°C oven or water bath

1. Run radiolabeled phosphoprotein on a preparative SDS–polyacrylamide gel and transfer proteins electrophoretically to a PVDF membrane (see *Basic Protocol* steps 1 and 2).

A nylon membrane may be used in place of a PVDF membrane, but in that case, the bands cannot subsequently be analyzed by acid hydrolysis, as nylon membrane will dissolve in 6 M HCl.

2. Wash membrane thoroughly with water: three 2-min incubations in 1 liter water are sufficient.

These washes remove buffer and detergent.

3. Incubate membrane 120 min at 55°C in an oven or water bath in sufficient 1 M KOH to cover the filter in a covered Tupperware container.

4. Discard KOH. Wash membrane and neutralize remaining KOH by rinsing once for 5 min in 500 ml TN buffer, once for 5 min in 500 ml of 1 M Tris·Cl (pH 7.0), and twice for 5 min in 500 ml water. Wrap the membrane in plastic wrap and autoradiograph overnight with flashed film and an intensifying screen at –70°C.

REAGENTS AND SOLUTIONS

*Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see *APPENDIX 2*; for suppliers, see *APPENDIX 4*.*

pH 1.9 electrophoresis buffer

50 ml 88% formic acid (0.58 M final concentration)

156 ml glacial acetic acid (1.36 M final concentration)

1794 ml H₂O

Store indefinitely in a sealed bottle at room temperature

pH 3.5 electrophoresis buffer

100 ml glacial acetic acid (0.87 M final concentration)

10 ml pyridine [0.5% (v/v) final concentration]

10 ml 100 mM EDTA (0.5 mM final concentration)

1880 ml H₂O

Store indefinitely in a sealed bottle at room temperature

Phosphoamino acid standards mixture

Prepare a solution of phosphoserine, phosphothreonine, and phosphotyrosine (Sigma) in water at a final concentration of 0.3 µg/ml each. Store in 1-ml aliquots indefinitely at –20°C.

COMMENTARY

Background Information

Phosphoamino acid analysis by the two-dimensional electrophoretic technique described in the basic protocol was first carried out with proteins isolated by elution from unfixed SDS-polyacrylamide gels (Hunter and Sefton, 1980). However, this technique is laborious, especially if it involves grinding up pieces of high-percentage acrylamide gels, and the yields can be disappointing. Additionally, because the eluted protein must be precipitated in the presence of a carrier protein, spotting the whole sample on a single origin usually yields a badly smeared pattern. The grind-and-elute technique is, however, advantageous with proteins that are very refractory to electrophoretic transfer to PVDF membranes.

The alkaline treatment of protein described in the alternate protocol was first developed by Jon Cooper and Tony Hunter, who treated fixed gels with KOH (Cooper and Hunter, 1981). The original technique is tricky because the gel becomes extremely sticky during incubation with KOH and swells. Additionally, the manipulations needed to recover proteins from the gel following treatment are very involved because the proteins are contaminated with products of the hydrolysis of polyacrylamide.

Critical Parameters and Troubleshooting

It is essential to use PVDF membranes to immobilize proteins for acid hydrolysis rather than nylon or nitrocellulose membranes, both of which dissolve in 6 M HCl. Proteins immobilized on either PVDF or nylon membranes may be subjected to alkaline hydrolysis with KOH (Contor et al., 1987), but nitrocellulose membranes are not suitable. Proteins immobilized on nylon cannot subsequently be analyzed by acid hydrolysis because nylon is dissolved by 6 M HCl.

Two-dimensional thin-layer electrophoresis is required for unambiguous identification of phosphorylated residues, as some spots after one-dimensional electrophoresis do not represent pure species. For example, uridine monophosphate, which is generated during acid hydrolysis of RNA (a frequent contaminant of phosphoproteins), comigrates with phosphotyrosine during one-dimensional electrophoresis at pH 3.5.

Streaking of the sample in the first dimension is a symptom of overloading, either with the phosphoprotein itself or with contaminants

in the sample. This problem can be corrected by loading less sample. Streaking in the second dimension is usually the result of problems with wetting or running the plate and cannot be corrected by loading less sample.

Some batches of blotting paper contain calcium, which interferes with electrophoresis of phosphoamino acids (probably by precipitating them). In the author's experience Whatman 3MM paper is quite reliable; other blotting papers are probably suitable as well. Inclusion of EDTA in the pH 3.5 buffer alleviates this problem.

This unit calls for glass-backed cellulose thin-layer plates rather than the plastic-backed variety, which are lighter and less expensive. This is because plastic-backed plates can under some circumstances cause sample streaking. They are, however, probably satisfactory for most experiments. If use of plastic-backed plates results in streaking, try glass-backed plates to see if that corrects the problem.

Anticipated Results

To detect a phosphoamino acid by autoradiography, a minimum of 10 cpm must be spotted and the plate exposed for a week with flashed film and an intensifying screen. Only 15% to 20% of the radioactivity in a phosphoprotein is recovered as phosphoamino acids. The majority is present as $^{32}\text{P}_i$, which is released by dephosphorylation of phosphoamino acids, with the remainder being peptide products resulting from partial acid hydrolysis. As a result, the thin-layer plates will contain a number of radioactive spots that are not phosphoamino acids (see Fig. 18.3.3). Partial hydrolysis products remain near the origin during electrophoresis at pH 1.9, but exhibit some mobility at pH 3.5 (see Fig. 18.3.3). After two-dimensional electrophoresis, they are found above the origin and below the phosphoamino acids. $^{32}\text{P}_i$ has a high mobility at both pH 1.9 and pH 3.5 and is found in the upper left-hand corner of each quadrant of the plate (see Fig. 18.3.3). Because of these additional radioactive spots, it is essential to localize internal phosphoamino acid standards by staining with ninhydrin.

Time Considerations

After the preparative gel has been run and the protein transferred to the membrane, isolation of the membrane fragment containing the protein, followed by acid hydrolysis, takes <2 hr. Two to three hours are required for drying

the sample with a Speedvac evaporator. First- and second-dimension electrophoresis and staining the internal phosphoamino acid standards takes no more than ~2 hr. Overnight autoradiographic exposure with flashed film and an intensifying screen is usually sufficient; however, exposures can be carried out for up to 10 days before the background from the screen becomes objectionable.

Detection of phosphorylated protein after alkali treatment, as described in the alternate protocol, is a very quick procedure requiring little more time than it takes to carry out the alkaline hydrolysis. In general, samples of this sort can be detected after overnight exposure with flashed film and an intensifying screen at -70°C .

Analysis of Phosphorylation of Unlabeled Proteins

UNIT 18.4

Phosphorylation of unlabeled proteins can be detected using immunological or enzymatic techniques. Anti-phosphotyrosine antibodies are used with immunoblots to detect tyrosine phosphorylation. These antibodies can be detected by ^{125}I -labeled protein A (see Basic Protocol 1) or enhanced chemiluminescence (ECL; see Alternate Protocol). Enzymatic dephosphorylation using a general or phosphoamino acid-specific phosphatase is detected by an SDS-PAGE mobility shift (see Basic Protocol 2) or a change in activity. The production of antibodies that recognize specific tyrosine-phosphorylated peptides is described in UNIT 18.6.

IMMUNOBLOTTING WITH ANTI-PHOSPHOTYROSINE ANTIBODIES AND DETECTION USING [^{125}I]PROTEIN A

BASIC
PROTOCOL 1

Initial determination of whether a protein is phosphorylated on tyrosine is carried out by immunoblotting with antibodies to phosphotyrosine. This technique is often superior to the use of biosynthetic labeling with $^{32}\text{P}_i$ because of its sensitivity and low background, and it can be used to detect tyrosine phosphorylation of proteins in tissues that do not incorporate $^{32}\text{P}_i$ efficiently.

Materials

Protein sample: cultured cells, tissue, lysate, or immunoprecipitate

Transfer buffer (UNIT 10.8) containing 100 μM sodium vanadate

Blocking buffer (see recipe)

Anti-phosphotyrosine antibody: 2 $\mu\text{g}/\text{ml}$ rabbit polyclonal anti-phosphotyrosine (UBI) or mouse monoclonal anti-phosphotyrosine—e.g., py20 (Leinco, ICN Biomedicals, Zymed, Transduction Laboratories) or 4G10 (UBI)—in blocking buffer

TN buffer: 10 mM Tris-Cl (pH 7.4 at room temperature)/0.15 M NaCl

TNA solution: TN buffer (recipe above)/0.01% (w/v) sodium azide (store at room temperature)

NP-40 wash solution: 0.05% (v/v) Nonidet P-40 (NP-40)/TNA solution (store at room temperature)

0.5 $\mu\text{Ci}/\text{ml}$ ^{125}I -labeled protein A (30 mCi/mg, ICN) in blocking buffer

India ink solution: 1 μl India ink in TBS (UNIT 18.2)/0.02% (w/v) Tween 20, pH 6.5 (prepare fresh or store indefinitely at room temperature; optional)

Plastic container with lid (e.g., Tupperware box)

Blotting paper

Additional reagents and solutions for SDS-PAGE (UNIT 10.2), immunoblotting (UNIT 10.8), and fluorography (APPENDIX 3A)

NOTE: Wear gloves and use blunt-end forceps to handle membrane.

1. Dissolve cultured cells, tissue, or lysate immunoprecipitate in an equal volume of 2 \times SDS sample buffer and boil 5 min.

Lysates or immunoprecipitates in sample buffer can be stored at -70°C indefinitely. Storage >1 week at -20°C will lead to deterioration. Cells or tissues can be lysed by other means, but care must be taken to prevent phosphorylation or dephosphorylation from occurring following cell lysis. This can be accomplished by using 50 mM sodium fluoride to inhibit serine and threonine phosphatases, 0.2 mM sodium vanadate to inhibit tyrosine phosphatases, and 2 mM EDTA to inhibit kinases. Viscosity resulting from DNA can be reduced

Supplement 40

somewhat by boiling the sample 5 min and/or by shearing the sample by passing it five to ten times through a 22-G needle and five to ten times through a 27-G needle.

2. Electrophorese sample on an SDS-polyacrylamide gel. Transfer proteins to a membrane suitable for immunoblotting using transfer buffer that contains 100 μ M sodium vanadate.

The lysate from $\sim 10^5$ cells can be analyzed in a single 0.5-cm wide lane of a 1-mm-thick SDS-polyacrylamide slab gel.

Sodium vanadate should be included in the transfer buffer to prevent tyrosine dephosphorylation.

3. Incubate membrane in 30 to 50 ml blocking buffer ≥ 30 min at room temperature.

Use of Blotto or other blocking mixtures containing dry milk is unsuitable because anti-phosphotyrosine antibodies bind to a number of the protein constituents of milk (see UNIT 10.8 for a discussion of blocking buffers). Blocking buffer can be reused several times.

4. Incubate the membrane in anti-phosphotyrosine antibody 60 to 120 min at room temperature with occasional agitation.

This step is most conveniently done in a covered plastic box using 30 to 50 ml antibody solution for a typical 15×15 -cm blot. Although the volume of antibody solution seems large, it reduces the background. The antibody solution can be saved in the plastic box, stored at 4°C for at least a month, and reused up to five to ten times.

5. Remove the membrane from the staining box and wick off excess liquid with blotting paper. In a new plastic box, wash the membrane twice for 10 min with 50 ml TBSA, twice for 10 min with 50 ml NP-40 wash solution, and twice for 5 min with 50 ml TBSA. Discard washes.

6. Incubate membrane in 30 to 50 ml of 0.5 μ Ci/ml 125 I-labeled protein A in blocking buffer 60 min at room temperature with gentle agitation in a covered plastic box.

125 I-labeled protein A is used to detect bound antibody.

7. Remove the membrane and wick off excess liquid with blotting paper. Wash the membrane as described in step 5 in a clean plastic box.

The blotting paper and first wash should be discarded as radioactive wastes. The amount of radioactivity in the subsequent washes should not be great, and it is generally acceptable to pour them down the drain.

Protein A solution can be stored at least 1 month at 4°C and reused ~ 3 to 5 times.

8. If desired, stain the membrane 5 to 10 min with 30 to 50 ml India ink solution until bands are detectable. Wash the membrane with water to remove excess ink.

9. Remove excess moisture with blotting paper, wrap in plastic wrap, attach radioactive or fluorescent alignment markers, and expose by fluorography using an intensifying screen and preflashed film for 18 hr to 10 days.

DETECTION OF BOUND ANTIBODIES BY ENHANCED CHEMILUMINESCENCE (ECL)

ALTERNATE PROTOCOL

Bound anti-phosphotyrosine antibodies can also be detected using enhanced chemiluminescence (ECL). This technique uses a second antibody coupled to horseradish peroxidase to detect anti-phosphotyrosine antibodies. The bound second antibody is visualized by ECL and the image is captured on film. The technique is faster than that employing [¹²⁵I]-labeled protein A (Basic Protocol 1) because it requires autoradiographic exposure of only minutes rather than days. It also avoids the use of radioactivity. However, results obtained with the two techniques are not always identical and exhibit quantitative differences. Additionally, if immunoprecipitated proteins are being analyzed, the secondary antibody may stain the precipitating antibodies intensely, making detection of proteins of a size similar to those of the heavy and light chains of immunoglobulin difficult.

The technique is fundamentally the same as that using [¹²⁵I]-labeled protein A, except that azide must be omitted from all solutions because it interferes with chemiluminescence chemistry. This makes storage and reuse of antibodies more difficult. Additionally, the technique appears to work somewhat better with nitrocellulose membranes than with Immobilon-P. Therefore, handling of the membranes requires somewhat more delicacy.

Additional Materials (also see Basic Protocol 1)

- Blocking buffer (see recipe) *without* azide
- 0.05% (v/v) Nonidet P-40 (NP-40)/TN buffer (see Basic Protocol 1)
- Horseradish peroxidase–conjugated secondary antibody: anti-rabbit or anti-mouse antibody diluted 1/1000 to 1/2000 in blocking buffer *without* azide
- ECL detection reagents A and B (Amersham)
- Luminol reagent for ECL detection (Amersham)
- Oxidizing reagent for ECL detection (Amersham)
- Nitrocellulose membrane
- Plastic container slightly larger than the membrane
- Plastic sheet protector

NOTE: The reagents for ECL may be purchased as a kit, the Enhanced Chemiluminescence Western Blotting Detection System, from Amersham.

NOTE: Wear gloves and use blunt-end forceps to handle membrane.

Prepare membrane

1. Electrophoresis sample prepared as described in Basic Protocol step 1 on an SDS-polyacrylamide gel. Transfer proteins to a nitrocellulose membrane using a transfer buffer that contains 100 μ M sodium vanadate.
2. In a plastic container, incubate membrane in blocking buffer without azide \geq 30 min at room temperature.

Expose membrane to antibodies

3. Incubate membrane in 30 to 50 ml anti-phosphotyrosine antibody 60 to 120 min at room temperature with occasional agitation.

The anti-phosphotyrosine antibody can be either polyclonal rabbit serum or mouse monoclonal antibodies.

4. In a clean plastic container, wash the membrane twice for 10 min with TN buffer, twice for 10 min with 0.05% NP-40/TN buffer, and twice for 5 min with TN buffer. Discard the washes.

5. In a plastic container, incubate the membrane in 30 to 50 ml of horseradish peroxidase-conjugated secondary antibody 60 min at room temperature with gentle agitation.

Use a secondary antibody appropriate for the primary antibody.

6. Remove membrane and wash it in a clean plastic container as described in step 4.

Detect bound antibodies with ECL

7. In a plastic container only slightly larger than the membrane, mix equal volumes of the Luminol reagent, and the oxidizing reagent for ECL detection.

Amersham recommends that 0.125 ml of each reagent be used per square centimeter of membrane. This is probably excessive with large blots.

8. Put the membrane, with the side containing protein facing up, into the mixed reagents. Agitate gently 60 sec.

9. Remove the blot, wick off excess moisture, and place it, protein-side up, in a sheet protector.

Alternatively, place the blot on a sheet of transparency film used for overhead projectors and cover with a second sheet of transparency film.

10. In the darkroom, expose the blot to X-ray film.

Exposure times can range from 15 sec to 30 min.

BASIC PROTOCOL 2

IDENTIFICATION OF PHOSPHORYLATED PROTEINS BY PHOSPHATASE DIGESTION

Phosphorylation of a protein often alters its mobility during SDS-polyacrylamide gel electrophoresis. An effect of phosphatase digestion on the gel mobility is therefore diagnostic of phosphorylation and is a useful means to determine whether an unlabeled protein is phosphorylated. Additionally, the effect of phosphorylation on the activity of a protein can be assessed by measuring changes in activity following enzymatic dephosphorylation (see *UNIT 18.5* for detailed protocols).

Enzymatic protein dephosphorylation has traditionally been accomplished with alkaline phosphatase or potato acid phosphatase. Both enzymes dephosphorylate phosphoserine, phosphothreonine, and phosphotyrosine. However, phosphoamino acid-specific phosphatases are now commercially available and offer the ability to dephosphorylate a protein specifically at only serine and threonine residues, or at only tyrosine residues (Anderson et al., 1990).

Enzymatic dephosphorylation is intrinsically quite simple. The protein is dissolved in, or in the case of an immunoprecipitated protein suspended in, a buffer suitable for the phosphatase of interest and incubated with the phosphatase for 30 to 60 min. Table 18.4.1 describes the reaction conditions for a number of phosphatases.

Dephosphorylated protein present in an immunoprecipitate can be recovered by centrifugation and analyzed by gel electrophoresis or an enzymatic assay. Alternatively, soluble protein can be analyzed by adding an equal volume of 2× SDS sample buffer (*UNIT 10.2*) to the reaction mix and subjecting the digested protein to gel electrophoresis. Soluble protein can be assayed enzymatically after dephosphorylation if an inhibitor of the phosphatase is added to the reaction mixture. Okadaic acid (20 μM) is a potent and very specific inhibitor of the serine/threonine-specific phosphatase protein phosphatase 2A (PP2A). Sodium vanadate (200 μM) is an efficient inhibitor of all known tyrosine phosphatases. Sodium phosphate (100 mM) is an inhibitor of all protein phosphatases.

Table 18.4.1 Phosphatase Reaction Conditions^a

Phosphatase (supplier ^b)	Amino acid specificity	Buffer	Amount	Incubation conditions	Inhibitor
Bacterial alkaline phosphatase (Pharmacia Biotech)	Phosphoserine, phosphothreonine, and phosphotyrosine	20 mM HEPES, pH 7.0 150 mM NaCl 0.1% (v/v) Triton X-100 10% (v/v) glycerol	2-4 U per reaction	60 min at 30°C	100 mM sodium phosphate
Potato acid phosphatase (Sigma)	Phosphoserine, phosphothreonine, and phosphotyrosine	40 mM PIPES, pH 6.0 1 mM DTT 20 µg/ml aprotinin 20 µM leupeptin	100 µg/ml	10 min at 30°C or 30 min at 4°C	100 mM sodium phosphate
Protein phosphatase 2A (UBI or Calbiochem)	Phosphoserine and phosphothreonine	20 mM HEPES, pH 7.0 1 mM DTT 1 mM MnCl ₂ 100 µg/ml BSA 50 µM leupeptin	10 U/ml	30 to 60 min at 30°C	20 µM okadaic acid
PTP-1B (UBI) or <i>Yersinia</i> PTP (Calbiochem)	Phosphotyrosine	25 mM imidazole-HCl, pH 7.0 1 mg/ml BSA 0.1% (v/v) 2-ME	0.5 mg per reaction	60 min at 30°C	200 µM sodium vanadate

^aAbbreviations: BSA, bovine serum albumin; DTT, dithiothreitol; HEPES, *N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethanesulfonic acid]; 2-ME, 2-mercaptoethanol; PIPES, piperazine-*N,N'*-bis[2-ethanesulfonic acid]; PTP, protein tyrosine phosphatase.

^bSee APPENDIX 4 for supplier contact information.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Blocking buffer

5% (w/v) BSA
1% (w/v) hen ovalbumin
10 mM Tris-Cl, pH 7.4 at room temperature
0.15 M NaCl
0.01% (w/v) sodium azide
Store ≤6 months at 4°C

For enhanced chemiluminescence, omit the sodium azide.

COMMENTARY

Background Information

Immunoblotting with antibodies to phosphotyrosine is an extremely useful technique for the study of tyrosine phosphorylation. It appears to be very specific. Although there is a report that antibodies to phosphotyrosine recognize phosphohistidine (Frackelton et al., 1983), nonspecific cross-reactivity is rarely seen. It is possible to be misled, however, if a large amount of a single protein is subjected to immunoblotting. For example, nonspecific staining of molecular weight standards is often

observed. This almost certainly does not indicate that they contain phosphotyrosine. Rather, it illustrates the fact that the primary antibodies and the secondary detection reagents exhibit a low level of nonspecific binding that can be detectable if a large amount of a single protein is present in a sample.

Critical Parameters

Not all anti-phosphotyrosine antibodies give the same staining patterns for immunoblots of the same sample. Each antibody ap-

**Analysis of
Protein
Phosphorylation**

18.4.5

pears to react with some proteins more strongly than with others. This presumably reflects the amino acid sequence surrounding the phosphotyrosine residue, but the cause has not been examined carefully. Correspondingly, a given anti-phosphotyrosine antibody will not react equally strongly with all sites of tyrosine phosphorylation. For example, rabbit polyclonal anti-phosphotyrosine antibodies raised against phosphoTyr-Gly-Ala react more strongly with phosphorylated Tyr-394 in the Lck tyrosine protein kinase than they do with phosphorylated Tyr-505. The differential reactivity of phosphotyrosine should be kept in mind when drawing quantitative conclusions.

Diluted polyclonal anti-phosphotyrosine antibodies can be reused several times. Their properties, however, change subtly with reuse. The staining of some bands becomes less intense and the staining of others becomes apparently more prominent. This may be a consequence of preferential removal of high-affinity antibodies during early uses. It should not be a problem with monoclonal antibodies.

Analysis of immunoprecipitated proteins by immunoblotting can be problematic. The reagent used to detect the staining antibody on the membrane will often bind to the heavy and light chains of the precipitating antibodies. This occurs to a varying degree with [¹²⁵I]-labeled protein A, which under some circumstances can bind detectably to the heavy chain of rabbit antibodies even after they have been denatured on a membrane. It is a greater problem when second antibodies reactive with the species of antibody used for immunoprecipitation are used as detection reagents. For example, horseradish peroxidase-conjugated anti-mouse antibodies will, in general, bind strongly to both the heavy and light chains of mouse monoclonal antibodies used for immunoprecipitation. This can complicate the use of enhanced chemiluminescence (ECL) as a means for analyzing immunoblots of immunoprecipitated proteins.

Immunoprecipitates can be run on nonreducing gels to cause interfering antibody bands to migrate near the top of the gel. Unreduced IgG runs as a 150-kDa band. Nonreducing sample buffer is the same as SDS sample buffer except that 50 mM iodoacetamide replaces the reducing agents 2-mercaptoethanol (2-ME) and DTT. The mobility of many, but not all, proteins is altered profoundly under nonreducing conditions and the suitability of nonreducing gel electrophoresis must be evaluated carefully for each case. It is often difficult to analyze

reduced and nonreduced samples on the same gel because 2-ME, which is present in most sample buffers at very high concentrations, diffuses rapidly and can reduce nonreduced samples, even in the presence of 50 mM iodoacetamide.

The enhanced chemiluminescent (ECL) technique (Alternate Protocol) is very rapid and sensitive. It is unclear, however, whether it exhibits the same linearity of response as does autoradiography with [¹²⁵I]-labeled protein A. Immunoblotting should be used with caution for quantitative comparisons. For accurate quantitation, it is essential to determine the linearity of the detection system by measuring the signal obtained from multiple known dilutions of a standard sample.

Not all proteins exhibit altered gel mobility when they undergo phosphorylation or dephosphorylation. Lack of effect of phosphatase digestion on the mobility of a protein is therefore not evidence of lack of phosphorylation.

Potato acid phosphatase (Sigma or Calbiochem) is often supplied as a suspension in ammonium sulfate. It can be collected by centrifugation from ammonium sulfate suspension, dissolved at 1 mg/ml in 10 mM HEPES (pH 7.4)/0.5 mM MgCl₂/0.5 mM DTT/50% (v/v) glycerol for storage, and stored at -20°C. Because of the low pH used with this phosphatase, some proteins are denatured during incubation. For example, p60^{c-src} loses considerable activity by incubation under these conditions (Cooper and King, 1986). This will obviously complicate analysis of the effects of phosphatase on enzymatic activity.

Protein phosphatase 2A (PP2A) is generally considered not to be dependent on divalent cations for activity. Nevertheless, it often exhibits considerably more activity on some substrates in the presence of magnesium and manganese (Scheidtmann et al., 1991).

Protein tyrosine phosphatases (PTP) possess an essential cysteine in their active sites and for this reason 2-ME is included in the reaction mixture. These enzymes, however, exhibit considerable activity in buffers that lack reducing agents.

A serious concern when using phosphatases to detect protein phosphorylation is that the protein of interest will be altered or degraded by contaminants such as proteases in the phosphatase preparation. Inclusion of protease inhibitors such as Trasylol (10,000 IU/ml), leupeptin (40 µg/ml), phenylmethylsulfonyl chloride (PMSF; 400 µM), and soy bean trypsin inhibitor (40 µg/ml) will minimize the effect of

contaminating proteases. It is essential, however, also to carry out control phosphatase reactions in the presence of a specific inhibitor of the phosphatase being used. Alterations in gel mobility or enzyme activity that occur under these conditions are almost certainly nonspecific. Sodium phosphate (100 mM) inhibits most phosphatases but adds a lot of salt to the reaction mixture. Okadaic acid (20 μ M) specifically inhibits protein phosphatase 2A (PP2A); sodium vanadate (200 μ M) inhibits all tyrosine protein phosphatases.

Anticipated Results

Immunoblotting with anti-phosphotyrosine antibodies is very sensitive. Even the extremely low levels of tyrosine phosphorylated proteins present in unactivated lymphoid cells can be detected when total lysates of cells are analyzed by gel electrophoresis and immunoblotting.

Identification of phosphoproteins by digestion with phosphatase is sometimes problematical. The gel mobility of some proteins is unaffected by phosphorylation and therefore, is unaffected by dephosphorylation. Thus, only positive results are meaningful for phosphatase digestions.

Time Considerations

Immunoblotting with enhanced chemiluminescence is the most rapid technique described in this unit, because staining can be accomplished in less than a day and bound antibodies visualized within 30 min. Staining with [125 I]-labeled protein A can also be accomplished in a single day, but autoradiography usually requires 18 to 100 hr.

Phosphatase digestion can be performed in <2 hr. Analysis of the effects of dephosphorylation by gel electrophoresis or enzyme assay can be accomplished in 2 to 4 hr.

Detection of Phosphorylation by Enzymatic Techniques

Reversible protein phosphorylation has been increasingly recognized as an important mechanism for regulating physiological processes in both plant and animal cells. There are a number of techniques to demonstrate the presence of covalently bound phosphate in proteins. Metabolic labeling of cells with ^{32}P and subsequent isolation of the ^{32}P -labeled protein is the most direct method for demonstrating protein phosphorylation. This approach is difficult when the specific polypeptides involved in the physiological phosphorylation event have not been well characterized or when these proteins are present in such low abundance in the cell that significant incorporation of [^{32}P]phosphate cannot be achieved. Metabolic labeling of proteins (UNIT 18.2) may also be compromised by a slow turnover of the protein-bound phosphate in the intact cell. As the extent of phosphorylation of given protein reflects the relative activities of the protein kinases and phosphatases that act on it, knowledge of physiological stimuli that modulate the protein function might be needed to establish the experimental conditions which increase the metabolic labeling of the substrate protein. In the absence of this information, it may be difficult to optimize specific protein phosphorylation in the intact cell. This situation can be further exacerbated by the lack of experimental tools, such as monospecific antibodies or affinity probes, that permit the rapid isolation of the substrate protein and preserve its phosphorylation.

An approach that eliminates the need for metabolic labeling of cells can sometimes be used to monitor *in vivo* protein phosphorylation. This procedure, known as “back” phosphorylation, requires that the protein of interest be at least partially separated from other cellular phosphoproteins under conditions that preserve covalently bound phosphates. The protein is then phosphorylated *in vitro* using radiolabeled ATP. By comparing the extent of radiolabel incorporated into the isolated, phosphorylated protein with that incorporated into the same protein after it has been treated with phosphatases to strip the bound phosphate, it is possible to estimate the phosphorylation state of that protein in the intact cell. This technique requires the identification and availability of the cellular kinases that phosphorylate the protein of interest. Because many phosphoproteins are phosphorylated at multiple sites by several different kinases, back phosphorylation usually monitors only a subset of the endogenous phosphorylation events.

If significant ^{32}P -labeling of the desired protein cannot be easily demonstrated, yet another approach may be taken. Recent studies have utilized one or more phosphatases to reverse existing covalent modifications in proteins, resulting in changes in the function or activity of the substrate. *In vitro* dephosphorylation by one or more commercially available phosphatases has implicated phosphorylation as a regulatory mechanism in many physiological processes. These studies have been undertaken using cell extracts and subcellular fractions, as well as partially purified proteins, and do not require prior knowledge of the phosphorylation event. The methodologies discussed in this unit can be used to detect protein phosphorylation where actual incorporation of [^{32}P]phosphate into a specific polypeptide cannot be demonstrated.

The overall strategy is to first examine the functional effects elicited by nonspecific acid or alkaline phosphatases that dephosphorylate many phosphoproteins *in vitro* (Basic Protocol 1 and Alternate Protocol 1). Nonspecific phosphatases isolated from plant and animal tissues show significant activity against a wide variety of phosphoester-containing compounds, including many phosphoproteins. These enzymes reverse all phosphorylations whether they occur as phosphotyrosine, phosphothreonine, phosphoserine, or phosphohistidine so they can define the regulatory consequence of protein dephosphorylation

without necessarily identifying the specific phosphoamino acid. Protein phosphatases that selectively hydrolyze phosphoserine and phosphothreonine or phosphotyrosine residues can then be used to identify the functionally important covalent modification. Additional protocols describe digestion of phosphoproteins with a protein serine/threonine phosphatase (Basic Protocol 2) and protein tyrosine phosphatase (Alternate Protocol 2). A support protocol has been included to identify the radiolabel as $^{32}\text{P}_i$ based on its ability to form a complex with ammonium molybdate.

Protein dephosphorylation can be analyzed as the loss of [^{32}P]phosphate from metabolically labeled proteins following their separation by SDS-PAGE. Some phosphoproteins also show changes in their electrophoretic migration following the loss of covalently bound phosphate. This can provide an additional monitor of protein dephosphorylation that can be used even in the absence of metabolic labeling. Finally, measurements of protein function (e.g., opening or closing of ion channels, binding of nuclear factors to specific DNA elements, or altered enzyme activity) can define the consequences of dephosphorylation even when little information is available about the specific phosphopeptides involved.

BASIC PROTOCOL 1

DIGESTION OF PHOSPHOPROTEINS WITH NONSPECIFIC ACID PHOSPHATASES

Potato acid phosphatase shows a broad substrate specificity and hydrolyzes many metabolites containing phosphoester bonds. This enzyme shows comparatively low activity against phosphoproteins. Moreover, metabolites present in cell extracts or some subcellular fractions may inhibit its ability to dephosphorylate protein substrates. In this protocol, a sample containing a phosphoprotein is digested with potato acid phosphatase and analyzed for evidence of structural and functional changes.

Materials

Sample containing 100 to 200 μg total protein
50 mM piperazine-*N,N'*-bis(2-hydroxypropanesulfonic acid) (PIPES), pH 6.0
Sephadex G-25 column (optional)
PIPES/2-ME or PIPES/DTT buffer, pH 6.0: 50 mM PIPES containing 15 mM
2-mercaptoethanol or 1 mM dithiothreitol (prepare fresh)
Potato acid phosphatase
2 \times SDS-PAGE sample buffer: 50 mM Tris·Cl (pH 7.5; APPENDIX 2)/0.4 M glycine
(pH 8.3)/0.2% (w/v) SDS
100 mM sodium pyrophosphate or other general phosphatase inhibitor
90°C water bath or heating block
Additional reagents and equipment for electrophoresis (UNIT 10.2)

1. Prepare a protein sample containing 100 to 200 μg total protein. Remove inhibitory metabolites or particulate material.

If the substrate is particulate, soluble contaminants can be removed by washing 2 to 3 times with 50 mM PIPES, pH 6.0. Inhibitory metabolites can be removed by dialyzing against the same buffer, or if the substrate is a soluble protein, it can be desalted on a Sephadex G-25 column.

2. Incubate the sample in 100 μl PIPES/2-ME or PIPES/DTT, pH 6.0, for 10 min at 30°C.

The pH optimum for potato acid phosphatase hydrolysis is between pH 4.0 and 5.0. However, many phosphoprotein substrates may be irreversibly inactivated at low pH, so incubation at pH 6.0 is recommended.

3. Add 5 to 10 U potato acid phosphatase and incubate 15 min at 30°C.

If it is not possible to incorporate [³²P]phosphate into the substrate protein by metabolic labeling, control reactions should include a general phosphatase inhibitor—e.g., sodium vanadate, sodium pyrophosphate, sodium glycerophosphate, sodium orthophosphate, or p-nitrophenyl phosphate (PNPP) at a final concentration ≥10 mM—to distinguish the effects produced by protein dephosphorylation by potato acid phosphatase from those produced by contaminating proteases.

One unit of acid phosphatase hydrolyzes 1 nmol PNPP in 1 min at 30°C and pH 4.0.

4. Remove 10 µl of the sample and add an equal volume of 2× SDS-PAGE sample buffer. Heat 5 min at 90°C.
5. Electrophorese control and dephosphorylated material on an SDS polyacrylamide gel (UNIT 10.2). For a radiolabeled sample, analyze the loss of radiolabel in the substrate protein by autoradiography or phosphoimage analysis; for unlabeled sample, analyze the change in substrate mobility by immunoblot analysis.
6. Add 10 µl of 100 mM sodium pyrophosphate (10 mM final concentration) to the remaining dephosphorylated material to terminate the dephosphorylation reaction. Use an appropriate assay of protein function to characterize the changes that accompany substrate dephosphorylation.

DIGESTION OF PHOSPHOPROTEINS WITH NONSPECIFIC ALKALINE PHOSPHATASE

ALTERNATE PROTOCOL 1

Calf intestine alkaline phosphatase has been widely utilized to dephosphorylate both proteins and nucleic acids. With the widespread use of this enzyme in molecular biology most commercial preparations are essentially free of contaminating proteases. Alkaline phosphatase has a broad pH profile with an optimum between pH 8.0 and 8.5. In contrast to acid phosphatases, this enzyme can be utilized for in vitro dephosphorylation of proteins under conditions that do not denature the substrate proteins. Calf intestine alkaline phosphatase effectively dephosphorylates proteins containing phosphoserine and phosphothreonine residues, which together account for >97% of the protein-bound phosphate in eukaryotic cells. Under defined conditions, preferential dephosphorylation of phosphotyrosines by alkaline phosphatases has also been reported (Swarup et al., 1981). Alkaline phosphatase activity is stimulated by Mg²⁺ ions, although significant activity is seen even in the absence of divalent cations.

Additional Materials (also see Basic Protocol 1)

Tris/MgCl₂, pH 7.5 or HEPES/MgCl₂, pH 7.5 buffer: 50 mM Tris·Cl (pH 7.5; APPENDIX 2)/1 mM MgCl₂ or 50 mM N,-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES; pH 7.5)/1 mM MgCl₂

Calf intestine alkaline phosphatase (molecular biology grade)

1. Incubate the sample (containing 100 to 200 µg total protein in 100 µl Tris/MgCl₂ or HEPES/MgCl₂) for 10 min at 30°C.
2. Add 20 to 30 U calf intestine alkaline phosphatase and incubate 15 min at 30°C.

One unit of calf intestine alkaline phosphatase hydrolyzes 1 nmol p-nitrophenyl phosphate (PNPP) in 1 min at 30°C and pH 8.5.

3. Terminate the dephosphorylation reaction by adding an equal volume of 2× SDS-PAGE sample buffer or a general phosphatase inhibitor. Analyze changes in substrate mobility and function (see Basic Protocol 1).

Analysis of Protein Phosphorylation

18.5.3

DIGESTION OF PHOSPHOPROTEINS WITH PROTEIN SERINE/THREONINE PHOSPHATASES

Protein phosphatase 1, 2A, and 2B (PP1, PP2A, and PP2B, respectively) represent three major classes of protein serine/threonine phosphatases found in eukaryotic cells. These enzymes are currently available from several suppliers; they will retain full enzymatic activity for many months when stored below -20°C (see supplier's recommendations). This protocol describes the use of PP2A, a broad-specificity phosphatase, to dephosphorylate the phosphoproteins.

Materials

Sample containing 100 μg total protein
Tris/DTT/ MnCl_2 buffer, pH 7.5: 50 mM Tris-Cl (pH 7.5; *APPENDIX 2*)/
1 mM dithiothreitol (DTT)/1 mM MnCl_2 (prepare fresh)
Microcystin-LR
Protein phosphatase 2A (PP2A), catalytic subunit

1. Prepare the sample (containing 100 μg total protein) in 100 μl Tris/DTT/ MnCl_2 buffer, pH 7.5. Prepare a control reaction in the same buffer with 1 μM microcystin-LR. Incubate 10 min at 37°C .

Microcystin-LR is a potent inhibitor of PP1 and PP2A.

2. Add 0.2 to 0.5 U PP2A and incubate 10 to 30 min at 37°C .

One unit of PP2A or PP1 activity hydrolyzes 1 nmol phosphorylase A in 1 min at 30°C and pH 7.5.

3. Add microcystin-LR to 1 μM final concentration to terminate the dephosphorylation reaction.

Unlike the general phosphatases discussed above, protein phosphatases show some selectivity for the dephosphorylation of different sites in substrate phosphoproteins and can be used to gain insight into the functional role of individual protein-bound phosphates.

4. Analyze the dephosphorylated material by SDS-PAGE or functional assays (see Basic Protocol 1).

DIGESTION OF PHOSPHOPROTEINS WITH PROTEIN TYROSINE PHOSPHATASES

Transmembrane tyrosine phosphatases such as CD45 possess low in vitro activity against many substrates, leading to the suggestion that association with extracellular ligands activates these receptor phosphatases. In this regard, protein tyrosine phosphatase 1B (PTP-1B) and src homology domain-containing protein tyrosine phosphatases (SH-PTP1 or SH-PTP2) are highly active phosphotyrosine phosphatases that demonstrate no measurable activity against phosphoserine and phosphothreonine and may be the preferred reagents to investigate the regulatory role of tyrosine phosphorylation.

Materials

Sample containing 10 to 100 μg total protein
50 mM imidazole, pH 7.5
Protein tyrosine phosphatase (e.g., PTP-1B or SH-PTP)
2 \times SDS-PAGE sample buffer (see Basic Protocol 1) *or* 100 mM sodium vanadate

1. Incubate the sample (containing 10 to 100 μg total protein) in 50 mM imidazole, pH 7.5, for 10 min at 37°C.
2. Add 1 to 5 U protein tyrosine phosphatase and incubate 15 to 30 min at 37°C.
One unit of phosphatase activity hydrolyzes 1 nmol p-nitrophenyl phosphate (PNPP) in 1 min at 37°C and pH 7.0.
3. Terminate the dephosphorylation reaction by adding an equal volume of 2 \times SDS-PAGE sample buffer *or* 100 mM sodium vanadate to a final concentration of 0.1 mM.
Recombinant PTP-1B and SH-PTP1 are also available as GST fusion proteins that can be bound to glutathione-agarose and conveniently removed by centrifugation or filtration following dephosphorylation of the substrate.
4. Analyze digested material by gel electrophoresis, immunoblotting, or a functional assay (see Basic Protocol 1, steps 5 and 6).

MEASUREMENT AND IDENTIFICATION OF RELEASED ^{32}P

Time-dependent dephosphorylation of radiolabeled proteins is usually monitored by precipitating the protein substrate with 10% to 15% (w/v) trichloroacetic acid (TCA) at 4°C. Following removal of the TCA-denatured phosphoprotein by centrifugation, radioactivity that accumulates in the TCA-soluble fraction provides a monitor of [^{32}P]phosphate release. However, this procedure cannot distinguish between the release of orthophosphate and TCA-soluble phosphopeptides. To define a dephosphorylation event, the TCA-soluble radioactivity must be characterized as $^{32}\text{P}_i$. This procedure takes advantage of the unique ability of $^{32}\text{P}_i$ orthophosphate to form a complex with ammonium molybdate. The [^{32}P]phosphomolybdate complex is soluble in organic solvent and can be readily separated from ^{32}P -labeled phosphopeptides. Therefore, this assay specifically monitors protein dephosphorylation (Shenolikar and Ingebritsen, 1984).

Materials

Trichloroacetic acid
 Radiolabeled protein/phosphatase reaction mixture (see Basic Protocol 1)
 1.25 mM potassium phosphate (KH_2PO_4)/1 N H_2SO_4
 1:1 (v/v) isobutanol/toluene
 5% (w/v) ammonium molybdate
 Scintillation fluid
 Liquid scintillation counter

1. Add trichloroacetic acid (TCA) to dephosphorylated radiolabeled protein to give a final concentration of 10% to 15% (w/v). Incubate 10 min at 4°C.
2. Microcentrifuge 5 min at maximum speed. Remove 0.1 ml of the TCA supernatant and place in a microcentrifuge tube. Add 0.2 ml of 1.25 mM KH_2PO_4 /1 N H_2SO_4 and mix.
3. Add 0.5 ml of 1:1 isobutanol/toluene to the microcentrifuge tube and mix thoroughly.
4. Add 0.1 ml of 5% ammonium molybdate and mix.
5. Microcentrifuge 5 min at maximum speed to separate aqueous and organic phases.
6. Remove 0.3 ml of the upper (organic phase), mix with 1 ml scintillation fluid, and count in a liquid scintillation counter.

SUPPORT PROTOCOL

Analysis of Protein Phosphorylation

18.5.5

COMMENTARY

Background Information

A key feature of protein phosphorylation (as compared to other protein modifications, such as proteolysis) is its reversibility. The ability to phosphorylate a substrate *in vitro* requires that the kinase responsible for phosphorylation be known. However, many cellular protein kinases are themselves activated via protein phosphorylation, making it difficult to use them *in vitro* to phosphorylate the substrate. Establishing the physiological relevance of many *in vitro* phosphorylations is also made difficult because these studies often do not take account of the physiological concentrations of the kinase and its substrate. *In vitro* experiments also tend to ignore the importance of the subcellular localization of the substrate and the kinase, sometimes leading to modifications that do not occur *in vivo*. For these reasons, knowledge of the physiological stimuli that regulate the substrate's function can be used to promote substrate phosphorylation as well as to provide important clues in the identification of protein kinases that phosphorylate the substrate.

Most cellular phosphoproteins are subject to covalent modification at multiple sites by more than one protein kinase. Therefore, *in vitro* studies with purified protein kinases often fail to recreate the spectrum of phosphorylations seen in the intact cell, and this also makes it difficult to define the role of individual covalent modifications. Thus, a new strategy of analyzing the role of multisite phosphorylation has been developed using proteins that have been modified in the intact cell. However, it is particularly important to isolate such substrates in the presence of phosphatase inhibitors and to preserve the protein-bound phosphates during lengthy purification procedures.

Biochemical studies of protein phosphatases have established the *in vitro* substrate specificity of these enzymes, which distinguish between different phosphoamino acids (phosphoserine/phosphothreonine versus phosphotyrosine) and different phosphoprotein substrates. These enzymes can also show preferential dephosphorylation of specific sites (Shenolikar and Nairn, 1991; Charbonneau and Tonks, 1992; Shenolikar, 1994). *In vitro* dephosphorylation by selected phosphatases may not only define the functional role of selected covalent modifications but also identify "silent" or "structural" phosphorylations that do not directly regulate the protein function. These phosphorylations may play an in-

direct role in modulating protein phosphorylation or dephosphorylation of other sites.

This unit has focused on commercially available phosphatases that have been used to characterize the functional importance of protein phosphorylation. For example, several growth-associated kinases, including the mitogen-activated protein kinases (MAP kinases) and the cyclin-dependent kinases such as *cdc2*, are phosphorylated on adjacent threonine and tyrosine residues. Phosphorylation of these enzymes is controlled by kinases and phosphatases that are themselves highly regulated in the intact cell. *In vitro* dephosphorylation by serine/threonine-specific or tyrosine-specific phosphatases both established the functional importance for phosphorylations even prior to the identification of the kinases and phosphatases that regulate these proteins.

The most direct method for detecting protein phosphorylation is clearly metabolic labeling of cells with $^{32}\text{P}_i$ (see *UNIT 18.2*) and subsequent isolation of the ^{32}P -labeled substrate protein. However, it is often difficult to develop a rapid purification procedure for the specific protein of interest without selective reagents such as monospecific antibodies or other affinity ligands. Significant labeling of proteins is also a problem given the low abundance of many regulatory proteins and the slow turnover of their protein-bound phosphate under "basal" conditions. In cases where [^{32}P]phosphate can be readily incorporated into the protein, *in vitro* dephosphorylation by selected phosphatases can establish the functional importance of the modification. Ability to correlate loss of [^{32}P]phosphate from a specific polypeptide with a functional change provides the best evidence for the physiological importance of protein phosphorylation.

Initial experiments should use a general phosphatase such as potato acid phosphatase or calf intestine alkaline phosphatase which can successfully dephosphorylate a wide variety of phosphoproteins modified on several different amino acids. It should be noted that acid phosphatases from animal tissues (e.g., bone, prostate, liver, and heart) represent a class of low-molecular-weight (18,000- to 25,000-kDa) protein tyrosine phosphatases that selectively dephosphorylate phosphotyrosine residues. These enzymes were defined as acid phosphatases because they hydrolyzed *p*-nitrophenyl phosphate (PNPP) at a pH optimum between 4.0 and 5.0. However, at physiological pH,

these enzymes appear to specifically dephosphorylate proteins and peptides containing phosphotyrosine residues. The mammalian acid phosphatases show no significant activity against phosphoserine/phosphothreonine-containing proteins.

With phosphoprotein substrates, potato acid phosphatase shows a preference for dephosphorylating phosphotyrosine residues, followed by phosphothreonine residues. By comparison, this enzyme shows very low activity against phosphoserine-containing substrates. Wheat germ acid phosphatase can dephosphorylate phosphoserines but still shows significantly higher activity against phosphotyrosine and phosphothreonine (Van Etten and Waymack, 1991). In this regard, alkaline phosphatase is often preferred over potato or wheat germ acid phosphatase for dephosphorylation of phosphoserine, the predominant protein modification in eukaryotic cells.

When a general phosphatase, such as alkaline phosphatase, is used, effects independent of protein dephosphorylation must be considered. For instance, alkaline phosphatase hydrolyses ATP and inhibits ATP-dependent processes, such as protein kinases and ATP-dependent ion channels that are also inhibited by protein dephosphorylation (Berger et al., 1993). To distinguish between these differing effects, use of immobilized alkaline phosphatase is recommended. Agarose or dextran beads covalently linked to alkaline phosphatase should be washed extensively with the assay buffer to remove storage solutions and any unbound alkaline phosphatase. Following incubation with the substrate protein, immobilized alkaline phosphatase can be removed by centrifugation or filtration. Functional analysis of the substrate can then be undertaken without concern for the potential effects of the phosphatase on such analysis. However, if the substrate is present in a particulate fraction (e.g., in subcellular organelles), it cannot be easily separated from the beads by centrifugation or filtration. In that case, the phosphatase should be inhibited with a general inhibitor such as sodium pyrophosphate. In contrast to the general phosphatases, protein phosphatases are inefficient at hydrolyzing ATP and do not hinder analysis of ATP-dependent processes.

Once phosphorylation of a substrate is established using a general phosphatase, the next step is to use protein phosphatases that have much higher activities against phosphoprotein substrates than either acid or alkaline phosphatase and are highly selective for specific

phosphoamino acids. Protein phosphatases 1, 2A, and 2B (PP1, PP2A, and PP2B) represent three major classes of protein serine/threonine phosphatases in eukaryotic cells. These enzymes differ in their subunit structure, substrate specificity, and regulation by divalent cations. PP1 and PP2A account for >90% of the total protein serine/threonine phosphatase activity in many cell extracts (Shenolikar and Nairn, 1991) and demonstrate a broad *in vitro* substrate specificity. Therefore, PP1 and PP2A are the most commonly used reagents for *in vitro* dephosphorylation of phosphoserine- and phosphothreonine-containing proteins. PP1 and PP2A are inhibited by microcystin-LR as well as several other recently discovered inhibitors, including okadaic acid, calyculin A, and tautomycin, albeit with differing IC_{50} values.

Inhibitors, such as okadaic acid (with IC_{50} for PP2A of 0.1 to 1.0 nM and for PP1 of 10 to 100 nM), calyculin A (with an IC_{50} for PP1 of 1 nM and for PP2A of 10 nM), and microcystin-LR (with an IC_{50} for both PP1 and PP2A of 0.1 nM) are used to exclude nonspecific effects of PP1 and PP2A. These inhibitors represent important experimental tools for establishing the physiological importance of reversible protein phosphorylation.

PP2B, also called calcineurin, is a Ca^{2+} /calmodulin-dependent phosphatase and demonstrates a narrow *in vitro* substrate specificity compared to PP1 or PP2A. The enzyme purified from mammalian tissues consists of a catalytic subunit that is tightly associated with a calcium-binding regulatory subunit. PP2B has no activity in the absence of 1 μ M calmodulin and 1 mM $CaCl_2$ and can be activated by either Ca^{2+} /calmodulin or 1 mM $MnCl_2$. Many highly purified PP2B preparations show no activity in the presence of Ca^{2+} /calmodulin but are fully activated by Mn^{2+} . The immunosuppressive drugs cyclosporin A and FK506 selectively inhibit PP2B *in vivo* and *in vitro*.

PP2B in the presence of Ni^{2+} ions and PP2A in association with an endogenous regulator protein or viral antigens can dephosphorylate proteins and peptides containing phosphotyrosines. However, under the conditions described in Basic Protocol 2, PP1, PP2A, and PP2B are highly selective for dephosphorylation of phosphoserine and phosphothreonine residues. PP1 and PP2A represent the major phosphohistidine phosphatase activity measured in tissue extracts, but the regulatory importance of this modification has not yet been established.

Critical Parameters

Some commercial preparations of potato acid phosphatase contain contaminating protease activity. Because phosphorylation sites reside near the surface of the substrate protein, they are often accessible to proteases, so functional changes that result from limited proteolysis can be incorrectly attributed to dephosphorylation. To limit the effects of proteases, high enzyme concentrations or prolonged incubations with the general phosphatases should be avoided. Aside from including protease inhibitors in the reaction, two strategies should be considered to distinguish proteolysis from dephosphorylation. Formation of a complex between trichloroacetic acid-soluble [³²P]phosphate and ammonium molybdate (Support Protocol) is particularly useful in distinguishing [³²P]phosphate from ³²P-labeled phosphopeptides. The use of phosphatase inhibitors in control reactions also identifies those effects that can be attributed to reactions in which there are contaminating proteolytic enzymes.

Commercial preparations of PP2A and PP1 contain only the free catalytic subunits. In vivo these subunits associate with regulatory subunits, which modulate their substrate specificity. However, the catalytic subunits are the most readily purified to homogeneity and can be stored for prolonged periods without significant changes in their enzymatic properties. Both PP1 and PP2A catalytic subunits retain high activity in the absence of divalent cations; PP2A activity may be further stimulated by 1 mM Mn²⁺ in the enzyme reaction. Long-term storage of PP1 and PP2A results in an apparent loss of enzyme activity. However, these inactive enzymes can be fully reactivated by including 1 mM MnCl₂ in the assay. The Mn²⁺-dependent PP1 enzyme shows slightly altered substrate specificity when compared with PP1 purified from tissues. Moreover, PP1 is potentially inhibited by several endogenous inhibitors. Thus, PP2A may be the preferred reagent for in vitro dephosphorylation of substrates in many cell extracts. Recent studies show that some tissues may contain endogenous PP2A inhibitors (Li et al., 1995). These inhibitory proteins could hinder the ability of PP2A to dephosphorylate proteins in some tissue preparations.

Troubleshooting

The absence of a functional change following incubation of the substrate with one or more phosphatases may indicate either that the protein was not phosphorylated or that the dephosphorylation of existing phosphates has no effect

on protein function. It is also possible that components in the reaction mixture inhibited the phosphatases. The latter possibility can be readily established if the substrate protein has been metabolically labeled with [³²P]phosphate. SDS-PAGE followed by autoradiography or phosphoimage analysis can directly monitor the time-dependent loss of radiolabel from substrate protein. Coincidence between the removal of radiolabeled phosphate and change of function of the substrate protein can be used to distinguish between important regulatory modifications and “silent” phosphorylations. In analyses of unlabeled substrates, the reaction should include an internal standard or a known ³²P-labeled protein or peptide. Dephosphorylation of the radiolabeled marker in the presence or absence of the sample should establish the extent to which activity of the added phosphatase has been compromised by components in the sample. If several different phosphatases fail to elicit a change in protein function under conditions that dephosphorylate the marker, the substrate protein may contain no protein-bound phosphate or phosphorylation may not be functionally important for the protein.

Anticipated Results

Most phosphoproteins should be dephosphorylated by the general phosphatases, leading to complete removal of protein-bound phosphate and functional changes indicating that reversible phosphorylation controls the protein function. In a number of cases, metabolic labeling and phosphoamino acid analysis or the use of specific protein (phosphoserine/phosphothreonine or phosphotyrosine) phosphatases has successfully identified the amino acids modified. Such studies have then located the phosphorylated residues, especially in proteins whose primary structures have been determined by amino acid sequencing or cDNA cloning. A combination of biochemical studies and site-directed mutagenesis has then been used to establish the functional role of phosphorylation at individual sites. Increasing evidence points to the presence of both positive and negative regulatory phosphorylations in proteins. Thus, it is difficult to predict the functional outcome of complete in vitro dephosphorylation of many substrates.

Time Considerations

Approximately 1 hr is required to complete the dephosphorylation reaction. SDS-PAGE

and analysis of the gel require 1.5 hr. The time required for functional analysis depends on the particular assay used.

Production of Antibodies That Recognize Specific Tyrosine-Phosphorylated Peptides

It is possible to produce anti-phosphopeptide antibodies (i.e., antibodies recognizing phosphorylated peptides) that recognize a protein only in its phosphorylated state, and that do not cross-react with either the cognate unphosphorylated protein or other phosphoproteins. Because the state of phosphorylation is often indicative of a protein's functional state or activity, such antibodies provide a convenient probe of the functional state of a protein. Thus, unlike conventional antibodies, anti-phosphopeptide antibodies provide information regarding not only the abundance of a protein but also its activity. Unlike general anti-phosphoamino acid (e.g., anti-phosphotyrosine) antibodies, which have broad reactivity, anti-phosphopeptide antibodies may have unique specificity toward the cognate proteins. Such reagents not only facilitate conventional *in vitro* analysis of phosphoproteins, but also allow heretofore impossible applications—e.g., differential isolation of species of a particular protein that have been phosphorylated at individual phosphorylation sites, as well as analysis of the functional state of a protein *in situ* by immunohistochemical techniques.

Basic Protocol 1 describes the production of polyclonal anti-phosphopeptide antibodies and Basic Protocol 2 describes the production of monoclonal anti-phosphopeptide antibodies. Both of these procedures are based upon immunizing animals with oligopeptides that have been synthesized containing phosphorylated tyrosine; hence, a knowledge of the sequence and phosphorylation site of the protein of interest is a prerequisite for either protocol. Such an immunization will generate an immune response with at least four components: (1) anti-carrier protein reactivity, (2) general anti-phosphotyrosine reactivity, (3) phosphorylation-independent anti-peptide reactivity, and (4) phosphorylation-dependent anti-peptide reactivity. For the production of polyclonal antibodies (see Basic Protocol 1), a multiple-step affinity chromatographic purification with several negative-selection steps is carried out to produce a final antibody preparation having the desired reactivity. For production of monoclonal antibodies (see Basic Protocol 2), ELISAs are performed to screen candidate hybridoma supernatants against the cognate phosphopeptide, as well as against related phosphorylated and nonphosphorylated peptides, until one is found with the desired reactivity and specificity. Although monoclonal antibodies have a number of advantages, production of polyclonal antibodies is likely to be more predictable, as in the authors' experience a monoclonal hybridoma clone of stringent specificity may occur with very low frequency (see Critical Parameters). Production of monoclonal antibodies is also generally more time-consuming and expensive. The relative merits of monoclonal and polyclonal antibodies are discussed in the Chapter 11 introduction and in general antibody guides (see Key References). Support Protocols are provided for the coupling of peptides (Support Protocol 2) and phosphotyrosine (Support Protocol 3) to the affinity matrix (Affi-Gel 10); BSA-agarose affinity matrix is commercially available. General methods for the coupling of peptides to carrier proteins for use in immunization are described in *UNIT 11.16*.

This unit describes production of antibodies against tyrosine-phosphorylated peptides, with which the authors have the most expertise, but the principles discussed here also apply to peptides phosphorylated on serine and threonine (see Key References).

Strategic Planning

The first step of the planning phase is design and synthesis of the required peptides (see Support Protocol 1 and Background Information). The authors employ a peptide containing fifteen amino acids with the phosphorylation site Tyr in the center (residue 8). This peptide consists of fourteen amino acids from the actual sequence of the protein plus an N-terminal Lys to enhance coupling of the peptide to a carrier protein (BSA is used as a carrier in this protocol). The peptide, coupled to BSA, is then used to immunize rabbits. The cognate phosphopeptide is also immobilized on an affinity-chromatography column support (see Support Protocol 2); this affinity matrix will ultimately be used to purify the antibody from the rabbit serum. In addition, a series of negative-selection affinity-chromatography columns are used to adsorb antibodies from the serum that cross-react with epitopes other than the cognate phosphopeptide. These columns are composed of matrix coupled to various synthetic peptides—principally the cognate nonphosphorylated peptide (to remove phosphorylation-independent antibodies) and phosphotyrosine itself (to remove indiscriminant anti-phosphotyrosine reactivity; see Support Protocol 3 for preparation of phosphotyrosine affinity columns). Additional negative-selection steps may be used if needed, depending upon the particular target chosen, to remove antibodies that cross-react with phosphorylation sites of other proteins having known homology to the target site. This cross-reactivity occurs particularly when the target protein is a member of a family of homologous proteins—e.g., a subgroup of related receptor tyrosine protein kinases. If such cross-reactivity is anticipated, it is possible to synthesize not only the cognate phosphorylated and nonphosphorylated peptides, but also phosphopeptides based upon the related homologous sequences, to be used for negative selection. The authors also pass the serum over a column consisting of immobilized carrier protein (commercially available BSA-agarose) to remove the majority of the antibodies generated against the much larger carrier protein. Thus, a typical purification scheme might consist of the following:

Negative-selection affinity-purification columns

- BSA (carrier)
- phosphotyrosine
- cognate nonphosphopeptide
- homologous phosphopeptides (if desired)

Positive-selection affinity-purification column

- cognate phosphopeptide.

The second step in planning is to raise and test antisera in rabbits. To prepare the phosphopeptide-carrier conjugate for immunization of rabbits, the authors couple a 30-fold molar excess of phosphopeptide (14.4 mg dissolved in water and neutralized with 1 N NaOH) to BSA (20 mg dissolved in 0.4 M sodium phosphate buffer, pH 7.5), using glutaraldehyde as the cross-linking reagent as described in Doolittle (1986). The reaction is allowed to proceed 30 min at room temperature; the development of a yellow color in the coupling solution is an indication that the glutaraldehyde has reacted. General methods for coupling of peptides to carrier proteins for use in immunization are described in *UNIT 11.16*. Conjugation can be confirmed by performing an anti-phosphotyrosine immunoblot (*UNIT 18.4*) on a small test aliquot of the conjugate (although a smear should be expected on the blot, resulting from variation in the amount of peptide coupled per BSA molecule as well as from possible multimers of BSA). Guidelines for immunization of rabbits are provided in *UNIT 11.12*, and many institutions have core facilities for the immunization of

rabbits and production of antisera. The authors immunize with 1 mg of immunogen (the peptide-BSA conjugate prepared above, dissolved in PBS) in 1 ml of a 50% emulsion with complete Freund's adjuvant. This is administered subcutaneously at multiple sites, followed by four boosts at 2-week intervals using same quantity of immunogen in incomplete Freund's adjuvant. An adequate immune response can be seen as early as week 6.

The specificity of the final antibody is demonstrated most simply by immunoblot analysis (*UNIT 10.8*) using a panel of relevant phosphorylated and nonphosphorylated proteins. Electrophoresis is carried out with purified cognate protein in both its phosphorylated and unphosphorylated states, as well as with any proteins toward which there could conceivably be cross-reactivity. These are most easily isolated by immunoprecipitation using conventional antibodies. The blot is probed with the purified anti-phosphopeptide antibody to demonstrate appropriate reactivity. This immunoblot assay may also be used after each chromatographic step to monitor the success of the purification.

An assay also must be devised for estimating the titer of the immune response in the sera of the immunized rabbits. Convenient screening assays for this purpose include tests for the ability of crude sera to immunoprecipitate the target phosphoprotein from a cell lysate known to contain it, as well as immunoblotting of purified phosphorylated target protein with the crude serum.

The relationship among the above procedures is illustrated by the flow chart in Figure 18.6.1.

Purification Method

The purification of polyclonal antibodies consists of multiple affinity-chromatography steps for the negative and positive selection of antibodies of the appropriate reactivity (see Fig. 18.6.1). All of the following chromatographic steps may be carried out at room temperature, with the solutions applied to the columns by gravity.

Materials

- BSA-agarose affinity matrix (Sigma) packed (as in Support Protocol 2) in a 10-ml bed volume column
- Phosphotyrosine affinity matrix column (10-ml bed volume; see Support Protocol 3)
- Crude serum from rabbit immunized with phosphopeptide-BSA conjugate (refer to Strategic Planning, above)
- PBS/azide: PBS (*APPENDIX 2*) containing 0.02% (w/v) sodium azide (store indefinitely at 4°C or room temperature)
- Cognate nonphosphopeptide affinity matrix column (3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)
- 3 M NaSCN
- Homologous phosphopeptide affinity matrix columns (optional; 3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)
- Positive-selection phosphopeptide affinity matrix column (3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)
- 3.5 M and 4.5 M MgCl₂ (optional; see Critical Parameters)
- Spectrophotometer (optional)
- Dialysis tubing (MWCO 12,000 to 14,000; 10 mm width, 6.4 mm diameter; e.g., Spectra/Por 4 from Spectrum)
- Additional reagents and equipment for dialysis (*APPENDIX 3C*), protein quantitation (*UNIT 10.1*), and analysis of antibodies by ELISA (*UNIT 11.2*) or immunoblotting (*UNIT 10.8*)

Figure 18.6.1 Flow chart for production of polyclonal anti-phosphopeptide antibodies.

Deplete reactivity of serum toward phosphotyrosine and carrier protein

1. Connect the washed BSA-agarose and phosphotyrosine affinity matrix columns in series.
2. Pass ~15 ml crude serum through the two columns, allowing it to flow through by gravity. Wash with PBS/azide until all of the yellow color of the serum has passed through the columns (or monitor the A_{280} of the column effluent spectrophotometrically until baseline absorbance is reached), then wash with an additional 5 to 10 ml PBS/azide, collecting all washings in the flowthrough fraction, which will contain the antibody of interest.

Aliquots of the crude serum as well as this first flowthrough may be saved for subsequent analysis and comparison of individual purification fractions. The serum may be analyzed at this time for elimination of anti-phosphotyrosine reactivity by performing immunoblotting (UNIT 10.8) of samples containing a variety of phosphotyrosyl proteins; alternatively it is possible to save an aliquot for analysis and proceed to the next step (see Troubleshooting).

Expect that with each passage through a column, the volume of the serum will increase, which will prolong the amount of time needed for subsequent columns. Note that if flowthrough is monitored by the passage of the yellow color of the serum, this will become more difficult as the serum becomes more dilute.

After the serum passes through, regenerate the columns by washing with 10 bed volumes of 3 M NaSCN followed by 10 bed volumes of PBS/azide, and store at 4°C in PBS/azide for future use.

Deplete reactivity of serum toward cognate nonphosphopeptide

3. Pass the flowthrough serum through the nonphosphopeptide affinity matrix column by gravity as many times as necessary to deplete cross-reactivity, regenerating the column between passes by washing with 10 bed volumes of 3 M NaSCN followed by 10 bed volumes PBS/azide.

A 15-ml starting serum sample may have to be passed over this column several times to quantitatively deplete cross-reactivity (see Critical Parameters). The serum may be analyzed after each or several passes, or an aliquot can be saved for analysis at a later time.

4. If cross-reactivity with homologous phosphoprotein(s) is anticipated, pass the flowthrough serum through the homologous phosphopeptide affinity matrix column(s) using the methodology described in step 3.

Refer to Strategic Planning, above, for discussion of cross-reactivity with homologous phosphoproteins.

Purify antibodies by positive-selection affinity chromatography and dialysis

5. Hydrate and wash ~25-cm strips of dialysis tubing in advance for collection of fractions from the positive-selection affinity purification. Secure one end of each length of tubing with a dialysis clamp and check for leaks (APPENDIX 3C). Also prepare 6 liters PBS/azide and cool to 4°C in advance to use as the dialysis solution.

To minimize the time that the antibodies are exposed to the elution solution, fractions (~3 ml each) from the positive-selection affinity column will be collected directly into preprepared dialysis tubing.

6. Pass the flowthrough serum from the previous chromatography step through the positive-selection phosphopeptide affinity column three times, without washing between passes.

Three passes are performed to maximize the interaction of the antibody with the affinity matrix.

7. Collect the flowthrough serum from the final pass, then wash the column with 5 to 20 ml PBS/azide (depending upon the precolumn volume and column bed volume) and combine the washings with the flowthrough serum. Wash with an additional 20 ml PBS/azide, and collect the washings separately as the “wash” fraction.
8. Elute with chaotropic agent of choice: either 20 ml of 3 M NaSCN, or 10 ml of 3.5 M MgCl₂ followed by 10 ml of 4.5 M MgCl₂. Upon starting the elution, immediately begin collecting ~3-ml fractions directly into the dialysis bags prepared in step 5, securing the proximal end of the tubing with dialysis clamps and dropping the bag immediately into the PBS/azide dialysis solution. Collect at least six fractions.

Alternatively, ~3-ml fractions can be collected in tubes and the liquid immediately placed into dialysis tubing upon completion of each fraction. Most of the antibody will elute in the first three fractions from a column of 2- to 3-ml bed volume. Regenerate the column as in step 3.

See Critical Parameters for a discussion of the relative merits of NaSCN versus MgCl₂ as eluants.

9. Dialyze all fractions collected in step 8 exhaustively against PBS/azide at 4°C (APPENDIX 3C).

Analyze and store purified antibody

10. Determine protein concentration of dialyzed fractions by measuring absorbance at 280 nm or by a colorimetric protein assay (UNIT 10.1) and calculate yield.

The authors have generally recovered ≥1 mg of purified antibody from a 15-ml serum sample.

11. Store the antibody in aliquots at -70°C; store working aliquot at 4°C.
12. Assay the reactivity and cross-reactivity of the final samples, as well as any aliquots saved from previous steps, using ELISA (UNIT 11.2) or immunoblotting (UNIT 10.8).

BASIC PROTOCOL 2

PRODUCTION OF MONOCLONAL ANTI-PHOSHOPEPTIDE ANTIBODIES

Strategic Planning

As in the production of polyclonal anti-phosphopeptide antibodies (see Basic Protocol 1), the first step of the planning phase for anti-phosphopeptide monoclonal antibodies is the design and synthesis of the required peptides (see Support Protocol 1 and Background Information). Here too, the authors employ a peptide containing fifteen amino acids with the phosphorylation site Tyr in the center (residue 8), consisting of fourteen amino acids from the actual sequence of the protein plus an N-terminal Lys to enhance coupling to a carrier protein. A different carrier protein must be employed for immunization than will be used as substrate for the ELISA screen, to avoid detection of anti-carrier antibodies in the ELISA (see Purification Method, below). The authors use keyhole limpet hemocyanin (KLH) as the carrier for immunization and BSA as the carrier for the ELISA substrate. General methods for coupling of peptides to carrier proteins for use in immunization are described in UNIT 11.16. The cognate phosphopeptide can also be immobilized to an affinity-chromatographic column support (see Support Protocol 2) and used ultimately to affinity-purify the antibody produced by the desired hybridoma clone. A number of additional peptides must be produced for use in ELISA screening of candidate hybridoma supernatants, to screen both for the presence of the desired reactivity and the absence of undesired cross-reactivity. For ELISA screening, the peptides are coupled to a carrier protein different from the one used for immunization. Bovine serum albumin (BSA) is

Production of Antibodies That Recognize Phosphorylated Peptides

18.6.6

used for screening, because many of the clones are likely to react against the carrier used in the immunization of the mice (KLH) and because unconjugated peptides have not been found to function well as ELISA substrates (Doolittle, 1986). In addition, because antibodies may be generated against the cross-linking reagent, the method used for coupling the phosphopeptide to the BSA to produce the substrate for ELISAs should be different from that used to link peptides to the KLH carrier for immunization (Czernik et al., 1991; Doolittle, 1986).

The second step of planning is to raise antibodies in mice. General guidelines for the immunization of mice and the production of monoclonal antibodies are described in *UNITS 11.4-11.11*, and many institutions have core facilities that will perform that task. The authors have immunized BALB/c mice by intraperitoneal injection with 1 mg/ml of immunogen (dissolved in PBS) in a 50% emulsion with complete Freund's adjuvant on day 1 and boosted intraperitoneally on days 15 and 37 with immunogen in incomplete Freund's adjuvant. Test bleeds from day 47 were analyzed by ELISA. On day 57 the mouse with the best titer was boosted intravenously, and its spleen was harvested on day 60. Freshly harvested spleen cells were prepared for cell fusion to generate hybridoma lines, which were subsequently screened by ELISA (*UNIT 11.7*). The purpose of the ELISA screening is to identify clones that react with the cognate phosphopeptide and to eliminate clones that cross-react with other epitopes in addition to the cognate phosphopeptide. Epitopes screened by ELISA generally consist of the cognate nonphosphorylated peptide (to eliminate clones with phosphorylation-independent reactivities) and at least one unrelated phosphopeptide (to eliminate clones with indiscriminant anti-phosphotyrosine reactivity). In addition, depending upon the particular target chosen, it may be necessary to screen for reactivity with phosphopeptides from proteins of known homology. This occurs particularly when the target protein is a member of a family of homologous proteins—e.g., the subgroups of related receptor tyrosine protein kinases. If such cross-reactivity is anticipated, it is essential to synthesize not only the cognate phosphorylated and nonphosphorylated peptides and at least one unrelated phosphopeptide, but also phosphopeptides based upon the related homologous sequences. Thus, a typical ELISA screening scheme might consist of the following steps.

1. Screen for clones that exhibit reactivity against the cognate phosphopeptide. These clones, which will likely be <10% of all the clones, are potential candidates for the desired clones.
2. Screen for clones with reactivity against the cognate nonphosphopeptide. These clones, which are phosphorylation state-independent, are then eliminated.
3. Screen for clones with reactivity against at least one unrelated phosphopeptide. These clones, which are likely to represent indiscriminant anti-phosphotyrosine reactivity, are also eliminated.
4. Screen for and eliminate clones with reactivity against potential cross-reacting homologous peptides, if any are anticipated.

General guidelines for ELISA screening are described in *UNIT 11.2*. In the ELISAs performed in the authors' laboratory, 96-well polyvinyl chloride assay plates are generally used and bound monoclonal antibody is detected using biotinylated horse anti-mouse secondary antibody followed by horseradish peroxidase (HRPO)-conjugated Avidin D (Vector Labs) and 4-aminoantipyrine(Sigma)/H₂O₂ as the substrate. This gives a deep red color in positive wells and absence of color in negative wells, allowing easy visual scoring without the need for quantitative measurements. The clones that pass all the screening steps are candidates for desirable hybridoma cell lines. These are expanded, frozen down as a pool, subcloned by limiting dilution, then rescreened against cognate phosphopeptide

to ensure continued production of antibody through the early passages. Those continuing to produce are expanded further and a larger quantity of either culture supernatant or ascites fluid is screened in further immunoassays. Reactivity is demonstrated most simply by immunoblot analysis using a panel of relevant phosphorylated and nonphosphorylated proteins. Electrophoresis is carried out with purified (generally by immunoprecipitation using conventional antibodies) cognate protein in both its phosphorylated and unphosphorylated states, as well as with any proteins toward which there could conceivably be cross-reactivity. The blot is probed with the monoclonal antibody preparation to demonstrate appropriate reactivity. The antibody preparation can ultimately be purified on a cognate phosphopeptide affinity column.

The relationship among the above procedures is illustrated by the flow chart in Figure 18.6.2.

Purification Method

This protocol presents procedures for isolating hybridoma clones of the desired reactivity, starting from the point at which candidate hybridoma clones have been seeded in 96-well culture plates (see Fig. 18.6.2). Candidate hybridoma supernatants are screened in ELISA assays against a series of peptides (as described in Strategic Planning). Identified clones are expanded, subcloned by limiting dilution, and further purified.

Materials

- Candidate hybridoma cell lines from fusion (refer to Strategic Planning and *UNITS 11.4-11.11*)
- HT medium (*UNIT 11.7*)
- Screening diluent (see recipe)
- BSA-conjugated cognate phosphopeptide (for use as ELISA antigen; refer to Strategic Planning, Support Protocol 1, *UNIT 11.2* & *UNIT 11.15*)
- Negative control: preimmune serum from mouse used to produce hybridoma line (*UNIT 11.4*)
- Positive control: immune serum from mouse used to produce hybridoma line (*UNIT 11.4*)
- BSA-conjugated cognate nonphosphopeptide (for use as ELISA antigen; refer to Strategic Planning, Support Protocol 1, and *UNIT 11.2*)
- BSA-conjugated noncognate phosphotyrosyl peptide (for use as ELISA antigen; refer to Strategic Planning, Support Protocol 1, and *UNIT 11.2*)
- BSA-conjugated homologous phosphopeptides (optional, for use as ELISA antigens; refer to Strategic Planning, Support Protocol 1, and *UNIT 11.2*)
- 96-well polystyrene tissue culture plates
- Grid note sheets
- Additional reagents and equipment for cloning by limiting dilution (*UNIT 11.8*), ELISA (*UNIT 11.2*), and freezing and recovery of hybridoma cell lines (*UNIT 11.9*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

Identify and sample conditioned media from candidate hybridomas

1. Seed hybridoma cells from fusion at a low density (aiming for one cell per three wells) in multiple 96-well polystyrene tissue culture plates using HT medium (see *UNIT 11.7*). Examine at ~2 weeks and identify all single-colony hybridoma culture wells as potential candidates by recording the number of colonies per well on a 96-grid note sheet. Mark the underside of each well containing one colony for easy identification.

The supernatant fluid from wells possessing a single colony will be screened for reactivity.

- Using sterile technique, remove an aliquot of supernatant (e.g., 100 μ l from a 200- μ l culture) from each potential candidate well and transfer to a separate 96-well polystyrene plate (the “screen plate”). Record the original plate number and well position and the corresponding plate number and well position for the screen plate (e.g., on a grid sheet representing the screen plate, record the original plate number and well position from which the supernatant in each well was transferred). Replace the aliquot removed from each original well with 100 μ l 37°C fresh HT medium.

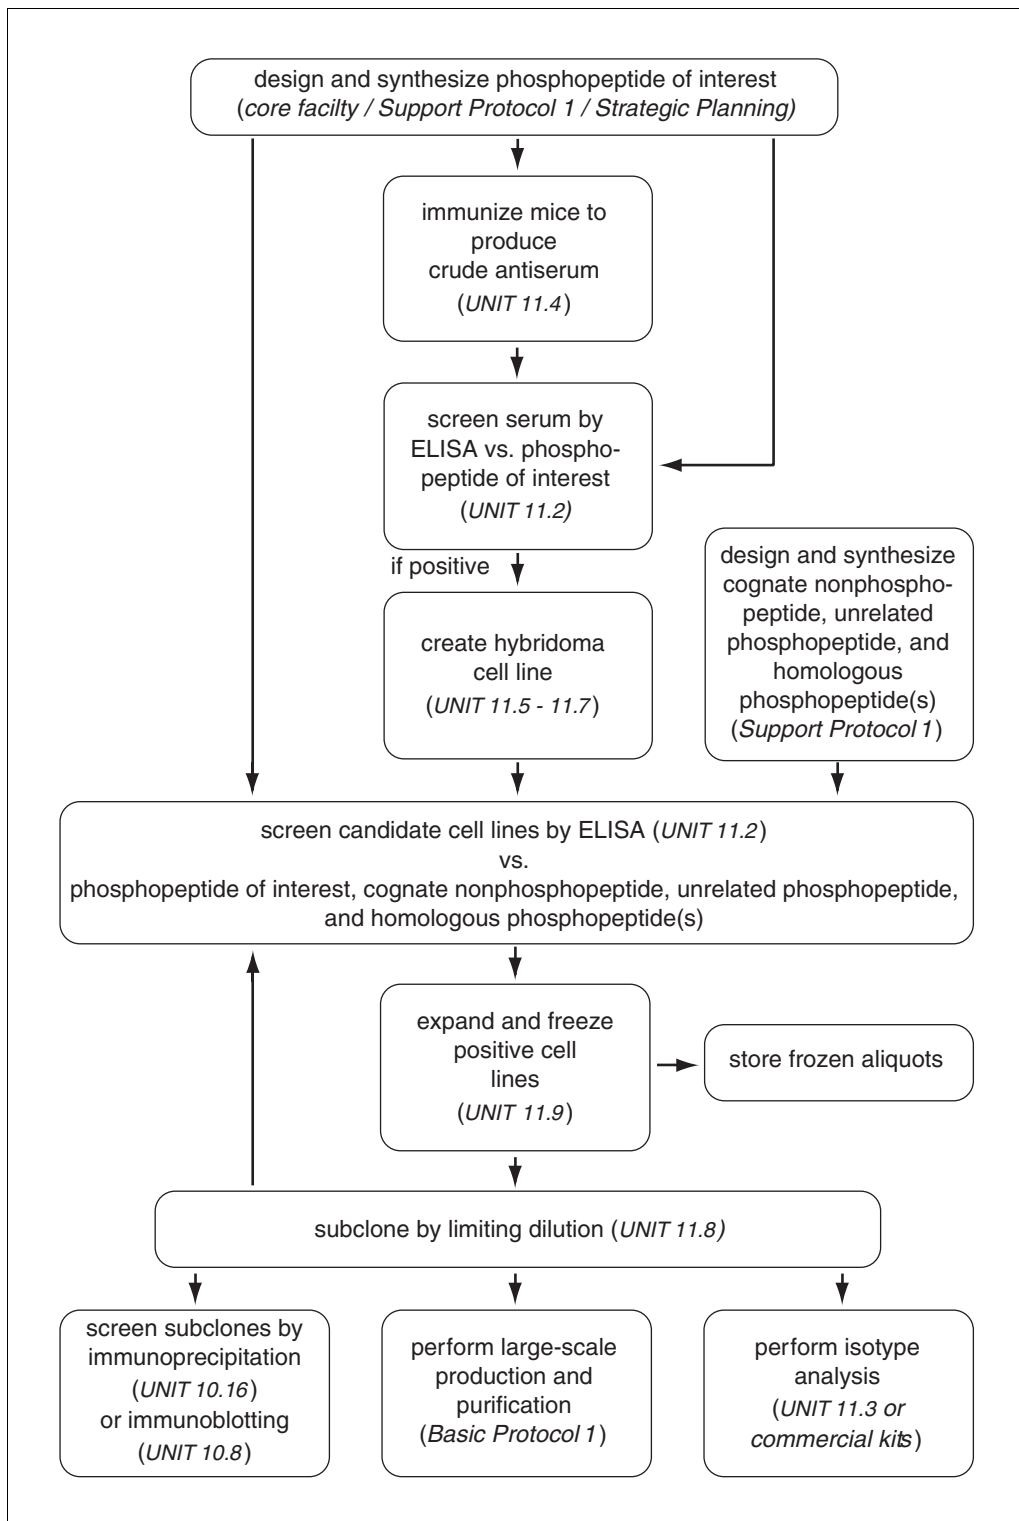

Figure 18.6.2 Flow chart for production of monoclonal anti-phosphopeptide antibodies.

A brightly colored dot sticker the size of one well, attached to the tissue culture hood surface, will help to keep the plate in register, as the plate may be moved one well at a time along the sticker. If the supernatants are not to be tested immediately, store the screen plates at 4°C, wrapped in plastic wrap.

3. To each supernatant in the screen plates, add 150 µl screening diluent

The components of the screening diluent prevent microbial contamination; this reagent also serves to expand the volume should multiple rounds of screening be required.

Screen candidate hybridomas by ELISA

4. Screen an aliquot (e.g., 50 µl) of each candidate hybridoma supernatant from the screen plate in an ELISA (see *UNIT 11.2* as a general guide) using the cognate phosphopeptide–BSA conjugate as antigen. Record the screen-plate number and well position and corresponding original culture plate number and well position for each positive sample. Also assay preimmune serum from the mouse used for fusion (negative control) and immune serum from the same mouse (positive control), each at a 1:100 dilution in a 1:1 mixture of HT medium and screening diluent. Include an ELISA with screening diluent only (additional negative control).

It is important to use a different carrier protein in the ELISAs (BSA) than that used for the immunizations (KLH), to avoid detecting reactivity against the carrier (refer to Strategic Planning, above).

5. Screen an aliquot of each positive sample from step 4 in an ELISA (*UNIT 11.2*) against the cognate nonphosphopeptide–BSA conjugate to eliminate clones with phosphorylation-independent reactivity, against the unrelated phosphotyrosylpeptide–BSA conjugate to eliminate clones with indiscriminant phosphotyrosine reactivity, and, if cross-reactivity with homologous phosphoprotein(s) is anticipated, against phosphopeptide-BSA conjugates corresponding to any potentially cross-reacting homologous phosphoproteins.

These screens may be done sequentially or, if the number of candidate hybridomas has diminished sufficiently, simultaneously. Isolation of clones with phosphorylation-independent cognate peptide specificity may also be useful.

6. Expand clones that satisfy all screening requirements and freeze aliquots (*UNIT 11.9*) as backup; use remainder for subcloning by limiting dilution (*UNIT 11.8*).
7. Screen culture supernatants from subclones as in steps 4 and 5 to check for continued production and specificity of the antibody.

Keep representative independent subclones from each original parental colony, as it cannot be predicted whether each parental monoclonal antibody will recognize the cognate holophosphoprotein or function in all types of immunoassays desired in the future. Candidate subclones should then also be expanded and frozen. It is a good idea to continue to check for production of the appropriate antibody after several rounds of serial passaging and after freezing, thawing, and reexpansion.

8. To characterize the subclones further and identify the most useful clones, assay the culture supernatants for reactivity with cognate holophosphoprotein in individual immunoassays (e.g., immunoprecipitations, as described in *UNIT 10.16*, or immunoblot analyses, as described in *UNIT 10.8*).

*Antibody from the desired clones can be produced on a large scale by harvesting large volumes of culture supernatant and performing affinity purification (see Basic Protocol 1), or by producing ascites fluid (*UNIT 11.10*), which can be purified by ammonium sulfate precipitation followed by affinity purification. Isotype analysis can be performed as described in *UNIT 11.3* or by using commercially available kits (Pierce or Sigma).*

SYNTHESIS OF PEPTIDES

Many institutions have core facilities for synthesis of peptides using automated solid-phase peptide synthesizers. For phosphotyrosine-containing peptides, the authors originally used standard Merrifield solid-phase procedures with *t*-butyloxycarbonyl (Boc) amino acids and Boc-*O*-(dibenzylphosphono)-L-tyrosine as the phosphorylated residue (Barany and Merrifield, 1979). For cleavage of phosphopeptide from the resin, 1 g of phosphopeptide resin was stirred 10 min at 0°C with 2 ml dimethyl sulfide; then an ice-cold mixture of 4 ml trifluoromethanesulfonic acid (TFMSA) and 10 ml of trifluoroacetic acid was added slowly with stirring. The resulting reaction mixture was stirred under a nitrogen atmosphere 4 hr at 0°C and the cleaved phosphopeptide precipitated with methyl *t*-butyl ether at -30°C. The precipitate was dissolved in 40% acetic acid and lyophilized several times from water. This original method suffers from low yields. Currently, most phosphotyrosyl-containing peptides are synthesized with 9-fluorenylmethyloxycarbonyl (Fmoc) phosphotyrosine. The lack of a side chain protecting group on the phosphotyrosine (Kitas et al., 1994) allows standard Fmoc synthesis and cleavage procedures to be employed (Chang and Meienhofer, 1978). However, a higher molar excess of activated Fmoc amino acids than that used in standard procedures may be required for efficient coupling of amino acids after unprotected phosphotyrosine has been added. In some circumstances, a double coupling procedure may be employed to add the few amino acids following phosphotyrosine to the growing peptide chain. This alternative requires the sequential, repeated addition of the next particular amino acid to be added to the peptide. A support protocol for the coupling of peptides to an affinity matrix is provided (see Support Protocol 2); general methods for coupling peptides to carrier proteins are described in *UNIT 11.16*.

COUPLING OF PEPTIDES TO AFFI-GEL 10 AFFINITY MATRIX

This protocol describes coupling of phosphopeptides or nonphosphopeptides to Affi-Gel 10 affinity matrix for use in affinity column chromatographic purification of antibodies. Anhydrous coupling, detailed here, is the most efficient coupling method for peptides. The steps here result in production of 3 ml final bed volume of affinity resin; 3 μmol of peptide is coupled per milliliter Affi-Gel 10. According to the manufacturer's specifications, Affi-Gel 10 resin contains ~15 μmol of active ester per milliliter of gel, and the gel has a capacity for 35 mg of protein or 15 to 20 μmol of a low-molecular-weight ligand per milliliter of gel. Note that these capacities are dependent upon the molecular weight and nature of the protein. After coupling, the matrix may be poured into columns of the appropriate size.

Materials

Synthetic oligopeptide for coupling (see Support Protocol 1)
Dimethyl sulfoxide (DMSO)
N-methylmorpholine (99% purity; Acros Organics)
Affi-Gel 10 (Bio-Rad) or equivalent activated support matrix
Ethanolamine
0.1 M ethanolamine·HCl, pH 8.0
High-salt/high-pH solution: 0.5 M NaCl/0.4% (w/v) sodium bicarbonate
High-salt/low-pH solution: 0.5 M NaCl/100 mM sodium acetate, pH 4.2
PBS/azide: PBS (*APPENDIX 2*) containing 0.02% (w/v) sodium azide
0.5 M NaCl
3 M NaSCN

Polypropylene screw-cap centrifuge tubes (do not use polystyrene tubes with DMSO)

Analysis of Protein Phosphorylation

18.6.11

End-over-end rotator
IEC Clinical centrifuge (or equivalent)
Vacuum aspirator
Glass chromatography columns, ≥ 5 -ml capacity

Prepare peptide solution

1. Dissolve peptide in DMSO at a volume ~ 0.5 to 4 times the desired bed volume.

For a 3-ml bed volume, dissolve a total of 9 μmol peptide, which for an average 15-mer peptide of mol. wt. ~ 1700 would be 15.3 mg.

2. Neutralize the peptide solution by titration as follows: add peptide synthesis-grade *N*-methylmorpholine (full-strength or diluted to 1:1 to 1:9 in DMSO) in 1 to 2 μl increments, remove a 2 to 3 μl aliquot after each addition, dilute this with 50 μl water, then spot it onto a strip of pH paper. Repeat this process until a pH in the range of 7 to 8 is reached.

*IMPORTANT NOTE: Titrate carefully, as it is very easy to overshoot the desired pH. Typically 7 to 8 μl of *N*-methylmorpholine is required per 3 μmol peptide, although the precise amount will depend greatly upon the particular amino acid sequence. The aliquots must be mixed with water because pH is a measure of hydrogen ion concentration, and hence the pH of a nonaqueous solution cannot be measured.*

Add peptide to Affi-Gel 10

3. Mix contents of the bottle of Affi-Gel 10 matrix well to resuspend the resin, then transfer the required amount of resin to a screw-cap polypropylene centrifuge tube and wash three times in DMSO, each time by centrifuging 5 min at $700 \times g$ (2000 rpm in an IEC Clinical centrifuge, setting 5), room temperature, aspirating the supernatant, resuspending the resin in 5 vol DMSO, then centrifuging again at $700 \times g$.

IMPORTANT NOTE: Be sure to take at least twice as much Affi-Gel 10 as ultimately will be needed, as the volume will shrink. The resin is supplied as a 50% slurry; therefore, it is necessary to take at least four times the required bed volume. Avoid centrifugation at higher than recommended speed as this may result in collapse of the resin.

4. Aspirate the excess DMSO from the resin and add the peptide solution prepared in step 2. Incubate overnight at room temperature with end-over-end rotation.

Quench and wash the resin

5. Add 2 μl pure ethanolamine per ml resin and incubate 2 hr at room temperature with end-over-end rotation.

Ethanolamine is added directly to the coupling reaction to quench unreacted ester groups.

6. Wash twice in DMSO as in step 3.
7. Wash twice in 0.1 M ethanolamine-HCl, pH 8.0, as in step 3 (performing the first wash on ice as a great deal of heat will be generated). Remove the 0.1 M ethanolamine-HCl from the second wash and replace with fresh, incubate tube overnight at 4°C with end-over-end rotation, then centrifuge at low speed and aspirate the supernatant.
8. Wash three times with high-salt/high-pH solution using the technique described in step 3.

9. Wash three times with high-salt/low-pH solution using the technique described in step 3.
10. Wash three times with PBS/azide using the technique described in step 3 and store washed resin at 4°C until ready to pack in column.
11. Mix matrix into a slurry with 0.5 M NaCl and pour into glass chromatography columns.
Commercially available glass chromatography columns can be used; alternatively, 5-ml plastic syringes with 1-cc plugs of silanized glass wool (UNIT 5.6) in the bottom may function as columns.
12. Wash each column with 10 column volumes 3 M NaSCN followed by 10 column volumes PBS/azide.

COUPLING OF PHOSPHOTYROSINE TO AFFI-GEL 10 AFFINITY MATRIX

SUPPORT PROTOCOL 3

This protocol describes coupling of phosphotyrosine to Affi-Gel 10 affinity matrix for use in affinity column chromatographic purification of antibodies. Phosphotyrosine is insoluble under the anhydrous conditions used for coupling peptides (see Support Protocol 2); thus coupling is done under aqueous conditions. The steps here result in production of 10 ml final bed volume of affinity resin; as for peptides, 3 μmol phosphotyrosine is coupled per milliliter of Affi-Gel 10. According to the manufacturer's specifications, Affi-Gel 10 resin contains ~ 15 μmol of active ester per ml of gel, and the gel has a capacity for 35 mg of protein per ml gel or 15 to 20 μmol of a low-molecular-weight ligand per ml gel. Note that these capacities may vary depending upon the molecular weight and nature of the protein. Phosphotyrosine-agarose affinity matrix is now also available commercially from Sigma.

Materials

- Phosphotyrosine
- 1 M NaOH (optional)
- 0.4% (w/v) sodium bicarbonate
- Fritted-glass funnel and vacuum aspirator
- Glass chromatography column, ≥ 14 -ml capacity
- Additional reagents and equipment for coupling peptides to Affi-Gel 10 affinity matrix (see Support Protocol 2)

Prepare phosphotyrosine solution

1. Dissolve phosphotyrosine in 0.4% sodium bicarbonate at a volume ~ 0.5 to 4 times the desired bed volume.
For a 10-ml bed volume, dissolve a total of 30 μmol phosphotyrosine. Based on its molecular weight of 261, this amounts to 7.8 mg, although it is acceptable (and may be easier) to use an excess, as phosphotyrosine is relatively inexpensive.
2. Check that the pH is in the range of 7 to 8 using pH paper. If adjustment is necessary, neutralize the solution by titration—i.e., adding small amounts of 1 M NaOH, removing a 2- to 3- μl aliquot after each addition, then spotting the aliquots onto a strip of pH paper. Repeat this process until a pH in the range of 7 to 8 is reached.

Add phosphotyrosine to Affi-Gel 10

3. Mix contents of the bottle of Affi-Gel 10 matrix well to resuspend resin, then transfer the required amount of resin to a fritted-glass funnel attached to a vacuum aspirator.

Analysis of Protein Phosphorylation

18.6.13

Wash three times, each time by pouring cold distilled water over the resin in the funnel and aspirating, then perform one final wash in the same manner using ice-cold 0.4% sodium bicarbonate.

IMPORTANT NOTE: *Be sure to take at least twice as much Affi-Gel 10 as ultimately will be needed, as the volume will shrink. The resin is supplied as a 50% slurry; therefore, it is necessary to take at least four times the required bed volume. Do not allow >20 min to elapse from the time the resin is removed from the bottle to the time it is mixed with the phosphotyrosine solution.*

4. Remove most of the excess liquid from the gel by vacuum aspiration without letting it dry completely, transfer it to a screw-cap centrifuge tube, and add the phosphotyrosine solution from step 2.
5. Incubate overnight at 4°C with end-over-end rotation.

Quench and wash resin

6. Add 2 µl pure ethanolamine per ml resin and incubate 2 hr at room temperature with end-over-end rotation.

Ethanolamine is added directly to the coupling reaction to quench unreacted ester groups.

7. Wash resin twice, each time by centrifuging at low speed (see Support Protocol 2, step 3), aspirating the supernatant, resuspending the resin in 5 vol of 0.4% sodium bicarbonate, then centrifuging again at low speed.
8. Wash resin twice with 0.1 M ethanolamine-HCl, pH 8.0, as in step 7. Remove the 0.1 M ethanolamine from the second wash and replace with fresh, incubate tube overnight at 4°C with end-over-end rotation, then centrifuge at low speed and aspirate the supernatant.
9. Wash, store, and pack resin in columns (see Support Protocol 2, steps 8 to 12).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Screening diluent

- 6.18 g boric acid (100 mM final)
- 9.54 g sodium borate (47 mM final)
- 4.38 g NaCl (75 mM final)
- 10 g bovine serum albumin (BSA; 1% w/v final)
- 1 g sodium azide (1% w/v final)
- H₂O to 1 liter

The pH of the solution will be 8.4 to 8.5.

COMMENTARY

Background Information

Conventional antibodies have proven to be invaluable tools in numerous techniques for the biochemical analysis of proteins. In the past antibodies with specificity toward the phosphorylated forms of proteins were produced serendipitously. Using techniques such as those described in this unit, such antibodies may now be produced by design. Whereas

phosphorylated holoproteins might in general be poor candidates for immunogens in the production of such antibodies as a result of their susceptibility to dephosphorylation, it has been suggested that short phosphopeptides are relatively resistant to phosphatases (Czernik et al., 1991), thereby providing a better chance of success.

A dramatic advance in the analysis of pro-

tein tyrosine phosphorylation and the regulation of signal transduction pathways by such phosphorylation occurred with the production of polyclonal and monoclonal anti-phosphotyrosine antibodies (Frackelton et al., 1983; Ross et al., 1981; reviewed in Stern, 1991). These antibodies proved capable of recognizing phosphorylated tyrosine residues in the context of virtually any flanking peptide sequence, and were shown to be exquisitely specific in the requirement for a phosphorylated tyrosine yet at the same time remarkably promiscuous in their acceptance of any peptide sequence. Techniques using polyclonal and monoclonal anti-phosphotyrosine antibodies have supplanted the standard methodology of metabolically labeling proteins with $^{32}\text{P}_i$, which was cumbersome, time-consuming, hazardous, and of relatively lower sensitivity.

Antibodies that recognize a specific tyrosyl-phosphorylated peptide as described in this unit represent a marriage of anti-phosphotyrosine technology with the stringent sequence-dependent specificity of conventional antibodies (Bangalore et al., 1992; DiGiovanna and Stern, 1995; Epstein et al., 1992; Roussel, 1990). Conceptually, they may be thought of either as anti-phosphotyrosine antibodies that have strict sequence specificity, or as conventional antibodies possessing the additional specificity of phosphorylation dependence.

Anti-phosphotyrosine antibodies have been most useful in the analysis of tyrosine phosphorylation of proteins in a technique using a combination of immunoprecipitation and immunoblotting (known as the "IP-western" method). In this procedure, a protein typically is immunoprecipitated either with conventional anti-protein antibody or with anti-phosphotyrosine antibody, then immunoblotted with whichever of these two antibodies was not used for the immunoprecipitation. Because anti-phosphopeptide antibodies recognize the cognate protein, but only when it is phosphorylated, they are capable of performing both functions in a single step—i.e., either an immunoprecipitation alone or an immunoblot alone is sufficient to supply the desired information.

The most useful functions for such antibodies are likely to be those that in fact are not possible using traditional reagents. For example, using anti-phosphopeptide antibodies, it is possible to identify and isolate distinct phosphorylated species of a phosphoprotein containing multiple phosphorylation sites. Thus, phosphorylation at each site can be examined

independently, and a preparative separation of individual phosphospecies of a holoprotein can be achieved. Another unique application is analysis of the abundance and phosphorylation state of individual proteins *in situ* in preparations of cells or tissues. Because phosphorylation is a major mode of regulation of protein function, the phosphorylation state is often an indicator of the functional status of a protein. The mere identification of a protein in a cell or tissue specimen gives no indication of its functional status. The ability of anti-phosphopeptide antibodies to demonstrate the phosphorylation state, and by extrapolation the functional state, of a single protein with high specificity places these reagents in a unique class. Hence, identity and functional status may be probed simultaneously using one simple assay. In tissue sections, one may probe to determine whether a particular protein is present, and, if present, in what functional state it is found. The authors have employed this strategy in immunohistochemical staining of formalin-fixed, paraffin-embedded human breast tumors using antibody to the phosphorylated form of the receptor tyrosine kinase Neu (DiGiovanna and Stern, 1995), and were able to demonstrate that Neu is phosphorylated, and therefore functionally active, in only a subset of the tumors that overexpress this protein.

Anti-phosphopeptide antibodies possess unique properties that render them capable of performing functions not possible with conventional reagents. From the technical considerations regarding their production, it would follow that antibodies with specificity for the non-phosphorylated state should also be achievable, and the production of such antibodies has also been reported (Czernik et al., 1991; Epstein, 1995; Kawakatsu et al., 1996; Nairn et al., 1982; Roussel, 1990; Tzartos et al., 1995).

Critical Parameters

In the production of polyclonal anti-phosphopeptide antibodies, a major challenge is the depletion of cross-reactivity. The first consideration in achieving this is the anticipation of potential cross-reacting proteins in the planning phase of the procedure. Cross-reactivity is most likely to occur when the target protein is a member of a family of closely related homologous proteins—e.g., of the subfamilies of tyrosine protein kinases. The authors have produced a monoclonal anti-phosphopeptide antibody with specificity for the Tyr-1248 autophosphorylation site of Neu (DiGiovanna and Stern, 1995). A homologous site exists in

the epidermal growth factor receptor (EGFR). The antibody produced in the authors' laboratory does not cross-react with the homologous EGFR site in spite of having identical residues in seven of the 14 amino acids of the peptide sequence (five of which are N-terminal to the phosphotyrosine, one C-terminal, and the phosphotyrosine itself). Thus, specificity is achievable even with at least up to 50% identity. Nevertheless, such a close relationship among the phosphorylation sites of different proteins highlights the importance of considering all known related proteins.

The second consideration in depleting cross-reactivity is the quantity of cross-reactive antibodies in a given aliquot to be purified relative to the capacity of the peptide columns used for the negative selection. Because of the expense of the peptides, the authors have generally prepared small columns (with 2- to 3-ml bed volumes) and passed the sera over the columns multiple times, empirically determining the number of passes necessary to quantitatively deplete cross-reacting material. In these columns, 3 μmol of ligand is coupled per milliliter of Affi-Gel 10. The manufacturer states that the resin contains $\sim 15 \mu\text{mol}$ of active ester per milliliter of gel, and that the gel has a capacity for 35 mg of protein or 15 to 20 μmol of a low-molecular-weight ligand per milliliter of gel. The BSA and phosphotyrosine columns are relatively inexpensive to produce; thus, a single large column of each is practical and sufficient.

Because the authors elute the antibodies from the positive-selection affinity column in strongly chaotropic solutions that are potentially deleterious to the stability of the antibody (3 M NaSCN or 3.5 M followed by 4.5 M MgCl_2), care is taken to collect the fractions in preprepared dialysis tubing so that they may be immediately placed into the PBS dialysate, thus minimizing the time that the antibodies are exposed to the eluting solutions. Although MgCl_2 is thought to be "gentler," the authors have found that gravity-driven flow rates from phosphopeptide columns eluted with this salt quickly become extremely slow, possibly because of precipitation of the salt in the column or an interaction of the Mg^{2+} ion with the phosphate groups. Thus use of NaSCN is preferred, and this salt appears to permit recovery of comparable activity.

In the production of monoclonal anti-phosphotyrosyl peptide antibody, which the authors have carried out once, a major technical hurdle was the low frequency with which clones of the

desired specificity were produced (DiGiovanna and Stern, 1995). In that work, in which antibody was produced to the phosphorylated form of the receptor tyrosine kinase Neu, >1200 hybridomas (obtained from a single fusion) were screened to obtain a single clone that satisfied all requirements. The authors found 68 candidate clones that recognized the cognate phosphopeptide, of which only 20 were unreactive toward the cognate nonphosphopeptide. Of those, seven cross-reacted with an unrelated phosphopeptide (i.e., exhibited indiscriminant phosphotyrosine activity), and of the remainder three cross-reacted with the homologous EGFR. The remaining ten were subcloned by limiting dilution, after which only five continued to produce antibody. Of these five, only one reliably detected the phosphorylated holoprotein in immunoblots and immunoprecipitations. Thus, the "hit rate" for an antibody that satisfied all requirements was <1 in 1000 clones. As this is the only monoclonal anti-phosphotyrosyl peptide antibody produced by the authors to date, it is impossible to be sure whether this low frequency will be a general phenomenon. It is crucial to devise a convenient and reliable ELISA assay for such extensive screening. Other assays may require extensive optimization. For example, the monoclonal antibody produced in the above project performed poorly in immunoblotting when any detection system other than a very sensitive chemiluminescence-based assay was used. This was possibly due to a low affinity of the antibody for the cognate protein. In addition, extensive optimization, particularly aimed toward enhancing the strength of the signal, was required for use of the antibody in immunohistochemistry. Finally, it is important to use different carrier proteins for the immunizing conjugate and the ELISA conjugate, so that antibodies to the carrier used for the immunization will not give positive reactions in the ELISA. Some authorities also advocate using different cross-linking agents, as antibodies against the cross-linker itself could theoretically be generated as well (Czernik et al., 1991; Doolittle, 1986).

Troubleshooting

In the production of polyclonal anti-phosphopeptide antibodies, the most common unfavorable outcomes are persistence of cross-reactivity, loss of specific reactivity, and poor yield. Although it may be tempting, in the interest of saving time, to perform the entire purification and postpone all analyses until the

end (a reasonable course of action once a scheme is known to work), it may be prudent, especially with a new protocol, to analyze the serum at each step. For example, the authors have produced antibody to phosphorylated EGFR (M. Digiovanna, M.A. Lerman, and D. Stern, unpub. observ.). The crude antiserum cross-reacted with the related receptors Neu and HER-4, which had been anticipated. The purification was monitored by probing, after each column, an immunoblot consisting of four lanes containing lysates from cells overexpressing (1) phosphorylated EGFR, (2) non-phosphorylated EGFR, (3) phosphorylated Neu, and (4) phosphorylated HER-4. In following the depletion of cross-reactivity, such stepwise analysis demonstrates whether undesired cross-reactivity has been eliminated or whether further passes through a particular negative-selection column are necessary.

If loss of specific reactivity is also a problem, stepwise analyses can also demonstrate where the loss is occurring. Loss of specific reactivity can occur for three major reasons. The first possible reason is that the antibody is not stable over the course of the purification, which may be the case if the procedure is very prolonged. If this is suspected, the pace of the purification may be hastened or the procedure may be carried out at 4°C instead of room temperature. With prolonged purifications, it is especially important to include sodium azide in the PBS used to dilute the serum, to prevent microbial growth. Activity may also be lost nonspecifically as a result of the multiple manipulations in a protocol requiring multiple columns and/or multiple passes through each column. In this case, fraction analysis may indicate which columns are absolutely essential, and also indicate the minimum necessary number of passes through each column. Also, creating larger columns with greater capacity should reduce the number of times the serum will need to be passed over each to deplete cross-reactivity. Finally, specific activity may be lost as a result of the presence in one of the negative-selection columns of a cross-reacting peptide that is so similar to the peptide of interest that essentially any antibody that recognizes the cognate phosphopeptide will recognize this phosphopeptide as well. In this last theoretical scenario, ultimate unique specificity may not be achievable.

The columns used in the purifications can be regenerated and used repeatedly if stored at 4°C in sodium azide-containing buffer to prevent microbial contamination and consequent damage to the matrix. A theoretical considera-

tion is that with repeated use, phosphatases in serum may eventually cleave enough phosphate groups from the peptide moieties on the column to render it ineffective as a phosphopeptide column. Thus, it may be prudent to periodically prepare fresh columns. An alternative would be to add phosphatase inhibitors to the serum prior to purification. Similarly, proteases in serum may eventually cleave peptides from the resin, and this may be prevented by adding protease inhibitors to the serum.

As discussed in Critical Parameters, the main technical hurdle in the production of monoclonal antibodies appears to be the large number of clones that it may be necessary to screen to find one with the desired reactivity. Here, time and persistence are the primary defenses. Another obstacle may be the failure of hybridoma cells to continue to produce antibody upon subcloning, which is likely due to the continuing genetic instability of hybridomas at early passage. If the parental hybridoma colony has been expanded and frozen prior to subcloning, this will serve as a potential source for additional subclones, although it is possible that these additional daughter clones may also be nonproducing. The use of the final monoclonal antibody in a variety of immunoassays is more likely to require potentially extensive optimization of protocols and higher concentrations (because of lower affinities) than the use of polyclonal antibodies.

Anticipated Results

In the production of polyclonal antibodies, the authors have obtained yields of ~1 mg of purified anti-phosphopeptide antibody from a single 15-ml serum sample (M. Digiovanna, M.A. Lerman, and D. Stern, unpub. observ.). These antibodies have been used in the immunoprecipitation of phosphoproteins from both denaturing and nondenaturing solutions. They have also been used in immunoblotting, in immunofluorescence on fixed cultured cells, and in immunohistochemistry on formalin-fixed, paraffin-embedded tissue sections. Specificity can be demonstrated when such assays are inhibited by cognate phosphopeptide but not by cognate nonphosphopeptide or unrelated phosphopeptides.

Through the production of monoclonal antibodies a permanent supply of a uniform reagent is ensured. Many milligrams can be obtained from the ascites produced by a single mouse. The authors have used such an antibody in all of the same assays as described above for polyclonal antibodies. More extensive optimi-

zation of protocols is likely to be required with monoclonal antibodies, and these may be expected to have a lower affinity than typical polyclonal antibodies. Isotype analysis can easily be performed as described in *UNIT 11.3* or by use of commercially available kits (Pierce or Sigma).

Time Considerations

For both protocols, the principal time-consuming step is the production of an immune response in the immunized animals. For the production of polyclonal antibodies, the authors have obtained high titers of reactive sera as early as 6 to 8 weeks in animals that have been boosted every 2 weeks. Later bleeds with continued boosts have yielded even higher titers. Once adequate bleeds have been obtained and the necessary affinity columns prepared, purification can generally be carried out within 1 week, with the exact length of time depending upon the number of columns and the necessity of analyzing the product after each step.

In the production of monoclonal antibodies, the authors have harvested splenocytes at ~2 months from the initial immunization, with several boosts in between. The screening of hybridoma supernatants can take 1 to 2 weeks, and their expansion and subcloning several weeks more.

Assays of Protein Kinases Using Exogenous Substrates

In studies of the regulation of specific biochemical events by reversible phosphorylation, assaying the protein kinases themselves can often lead to significant progress in understanding the mechanistic details of a system under study. This unit describes assays for a variety of protein kinases that require different conditions to detect and measure their activities: cyclic nucleotide-dependent kinases (see Basic Protocol 1), protein kinase C and isoforms (see Basic Protocol 2), casein kinases (see Basic Protocol 3 and Alternate Protocol), Ca²⁺/calmodulin-dependent kinases (see Basic Protocol 4), and tyrosine kinase (see Basic Protocol 5). The unit is not meant to be a catalog of individual protein kinase assays; however, the general principles of these assays should apply to most if not all known protein kinases. It is also possible to perform in-gel assays for specific kinase activity (see Basic Protocol 6).

To assay the phosphotransfer reactions catalyzed by protein kinases, it is necessary first to identify a target substrate for the transfer reaction. Essentially this means a substrate that is quite specific—i.e., is not phosphorylated very well or at all by other protein kinases under the appropriate assay conditions (see Strategic Planning). The source of the enzyme activity can be crude cell lysate (see Support Protocol 1), a cellular fraction, an immunoprecipitate, a partially purified protein, or a purified enzyme. The results of the assay can be evaluated using trichloroacetic acid (TCA) precipitation to measure incorporation of radioactivity (see Support Protocol 2), adsorption of the labeled material onto P81 phosphocellulose paper (see Support Protocol 3), or electrophoretic separation and autoradiography (see Support Protocol 4).

STRATEGIC PLANNING

The basic strategy for protein kinase assays involves the use of a labeled donor substrate so that when phosphotransferase activity is present in the enzyme sample, accumulation of the label in the protein or peptide acceptor substrate can be easily detected. The most often used protocol requires [γ -³²P]ATP as the donor substrate and a specific protein or peptide as the acceptor substrate. Phosphotransfer is detected as the accumulation of [³²P]-labeled protein or peptide. The main problem with this assay is that it requires ³²P, a high-energy β emitter. There are a few examples of kinase assays that do not require [γ -³²P]ATP, but they are far more specialized and generally not as widely applicable. Hopefully, further development of nonradioactive kinase assays will provide good alternatives and reduce the use of radioisotopes.

Enzyme Sources

Of all the choices to be made in designing protein kinase assays, of paramount importance is the source of enzyme activity: very crude sources such as whole-cell lysates (see Support Protocol 1 and UNIT 18.2), immunoprecipitates, partially purified preparations, and homogeneous purified protein can be the source of the enzyme activity. The first requirement is that the kinase activity be relatively stable under both the conditions used to prepare the enzyme and those used for the assay. Often enzymes are unstable in whole-cell lysates or homogenates and become very stable after only an initial purification step. Protein kinases commonly exist in intact cells as phosphoproteins themselves, and the phosphorylation state is often important for activity. Thus, it is essential to attempt to preserve the phosphorylation state, e.g., by inhibiting protein phosphatases. Including specific kinase inhibitors in the lysis or homogenation buffer is a common procedure to inhibit serine/threonine kinases (sodium fluoride, β -glycerophosphate, okadaic acid) or

tyrosine kinases (sodium vanadate, phenylarsinine oxide). Other common inclusions in lysis buffer are chelating agents and protease inhibitors. Many enzymes, including kinases, are sensitive to limited proteolysis. Chelators, such as EDTA and EGTA, act to chelate calcium and reduce the activity of calcium-activated proteases. The most commonly used protease inhibitors include phenylmethylsulfonyl fluoride (PMSF), leupeptin, pepstatin A, antipain, and benzamidine. It is always a good idea to add these inhibitors to the lysis buffer just before it is used to lyse cells, especially in the early stages of a new project; the need for specific inhibitors should be investigated at a later time. The oxidation state of cysteines and the state of disulfide linkages may influence enzyme activity, so inclusion of a reducing agent—e.g., 2-mercaptoethanol (2-ME) or dithiothreitol (DTT)—is sometimes essential to preserve enzyme activity. Low concentrations of a detergent such as Brij35, at or just above the critical micelle concentration, may also stabilize enzyme activity.

Choice of Substrate

Selecting a substrate normally depends on the type of experiment and the enzyme preparation, i.e., whether there are any contaminating kinases in the enzyme sample that phosphorylate the same or similar substrates. The type of experiment may range from following a particular activity through purification to determining substrate specificity or kinetics for the kinase-catalyzed reaction. Most often specific substrate information is available from previously published work or from initial experiments to identify a suitable substrate. It is always helpful to evaluate the suitability of several substrates in parallel experiments in order to identify the best substrate.

For crude extracts, the best substrate will be one that is phosphorylated by the kinase of interest and by no other kinase. In practice this is rarely the case, so a compromise must be reached. If an antibody that recognizes the kinase is available, it is easier to use that antibody to immunoprecipitate the protein and use the immunoprecipitate as the source of enzyme activity. Immunoprecipitation is useful because it provides a quick one-step partial purification of the kinase that also concentrates the activity. With a partially purified enzyme, it may be easier to select an appropriate specific substrate.

Histones are very basic proteins found complexed with DNA in the nucleus of the cell. They have been used for many years as protein kinase substrates because of their relative abundance, ease of purification, and ability to function as very good substrates for a large number of protein kinases. Distinct fractions of mixed histones and purified histones are available commercially from a wide variety of sources. Different kinases have different specificities with respect to phosphorylation of histones, hence the type of histone preparation that should be used depends on the type of kinase to be assayed. Histones have been used to assay many protein kinases and may be used for cAMP- and cGMP-dependent protein kinases. However, phosphorylation of histone substrates is generally not enzyme specific—e.g., histone H1 is phosphorylated by cAMP-dependent protein kinases, most cyclin/cdk complexes, and some protein kinase Cs albeit on different sites, and histone 2B is phosphorylated by both cAMP- and cGMP-dependent protein kinases and protein kinase B—so more specific substrates are generally preferred.

Initially, it is much easier to use intact proteins as substrates for kinase assays. However, once a substrate is identified, specific determinant(s) within the protein that allow phosphorylation and specific primary sequence requirements can be identified, and the appropriate peptide sequences modeled on the phosphorylation site can be synthesized and used as substrate.

When synthetic peptide substrates are used to assay protein kinase activity, it is possible to study the specificity of different kinases. Synthetic peptide substrates are available from

a number of suppliers, e.g., Peninsula Labs, Bachem Biosciences, and Calbiochem-Novabiochem. Peptides are easy to use: they are potentially available in large quantities as chemically defined molecules, their purification is usually straightforward, and they provide a single phosphorylation site. In addition, it is relatively simple to synthesize a series of peptides with single amino acid changes to further define the specificity of an enzyme. However, peptides do have their disadvantages. They are expensive, \$10 to \$20 per residue. The kinase may not recognize the disordered structure usually adopted by small peptides in solution, or it may promiscuously phosphorylate the peptide. Finally, it is very difficult to use peptides to model reactions in which prior derivitization (i.e., phosphorylation) is required for specific kinase activity.

Table 18.7.1 summarizes the sequence specificity of a number of protein serine/threonine kinases, and Table 18.7.2 provides similar information for protein tyrosine kinases.

Table 18.7.1 Substrate Specificities of Some Protein Serine/Threonine Kinases

Enzyme	Consensus sequence ^{a,b}
cAMP-dependent protein kinase	XArgArgX <u>Ser</u> Φ
cGMP-dependent protein kinase	XArg/LysX <u>Ser</u> Φ
Protein kinase Cα	XLys/ArgXX <u>Ser</u> X
Cyclin B/cdc2	X <u>Ser</u> ProXLys/ArgX
Casein kinase I	Glu/Ser(P) XX <u>Ser</u>
Ca ²⁺ /calmodulin-dependent protein kinase type II	XArgXX <u>Ser</u> X
MAP kinase	XPro <u>Ser</u> XX
Casein kinase II	X <u>Ser</u> XGluGlu/AspX

^aSee Table A.1C.1 for amino acid codes. X indicates any amino acid, Φ indicates a hydrophobic residue, underlining indicates the sites of phosphorylation (which, although marked Ser in each case, may be either Ser or Thr residues), and (P) indicates a phosphorylated residue.

^bSequence information based on Pearson and Kemp (1991).

Table 18.7.2 Substrate Specificities of Some Protein Tyrosine Kinases

Enzyme	Optimal sequence ^{a,b}
MT/c-src	GluGluIle <u>Tyr</u> GlyGluPheGlu
c-abl	AlaGluValIle <u>Tyr</u> AlaAlaProPhe
c-fps/fes	GluGluGluIle <u>Tyr</u> GluGluIleGlu
lck	XGluXIle <u>Tyr</u> GlyValLeuPhe
EGF receptor	GluGluGluGlu <u>Tyr</u> PheGluLeuVal
PDGF receptor	GluGluGluGlu <u>Tyr</u> ValPheIleGlu
Insulin receptor	XGluGluGlu <u>Tyr</u> MetMetMetMet

^aThese sequences were determined through the use of peptide libraries (Songyang et al., 1995), and their relevance to in vivo phosphorylation specificities is unclear.

^bSee Table A.1C.1 for amino acid codes. X indicates any amino acid; underlining indicates the site of phosphorylation.

Assay Conditions

The assay conditions can have profound effects on any enzyme activity: if pepsin is assayed at pH 7, it is essentially inactive, but at pH 3, it has good protease activity. Similarly T4 DNA ligase is inhibited by salt concentrations >150 mM. For kinases, it is a good idea to use preliminary experiments to identify the effects of pH, salt concentration, concentrations of cations such as Mg^{2+} or Mn^{2+} , and temperature to optimize the assay conditions for the kinase of interest. It is often advantageous to perform kinase assays at 30°C rather than 37°C because the lower temperature makes it easier to stay within the linear range of the kinase, thus providing more control of the assay.

Another factor to be considered when optimizing an assay for a newly identified kinase is the concentration of ATP in the reaction mixture. In these protocols and in general, detection of kinase activity is based on the transfer of radiolabeled phosphate from ATP to the substrate, so the concentration of ATP can be varied only a little. Also, the specific activity of the $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ must be known in order to actually measure phosphotransfer. Most kinases have a K_m for ATP of 1 to 100 μM . If there is too much ATP in the reaction mixture, it will be difficult to measure phosphotransfer. An ATP concentration of 50 to 100 μM tends to work well. At that concentration, the enzyme should be working at $\geq 50\%$ of maximum, depending on its apparent K_m for ATP, and addition of sufficient $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ to measure phosphotransfer is not prohibitively expensive. Usually the substrate concentration is high so that the enzyme is working at or close to V_{\max} .

Controls

Including the correct controls for a kinase assay is critical to the success of the assay, especially when the enzyme source is a cell or tissue extract. The appropriate controls should always include a no substrate control, a no enzyme source control, a heat-denatured enzyme control, and, for enzymes that require an activator or cofactor, controls that use irrelevant activator or cofactor and controls without activator or cofactor.

CAUTION: These assays use $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ which should be handled and disposed of according to safety regulations. See *APPENDIX 1F* and the institutional Radiation Safety Office for guidelines for proper handling and disposal of ^{32}P .

ASSAY FOR CYCLIC NUCLEOTIDE-DEPENDENT PROTEIN KINASES

Cyclic adenosine monophosphate (cAMP)-and cyclic guanosine monophosphate (cGMP)-dependent protein kinases (PrKs) are quite similar in structure and require similar assay conditions. cAMP-PrK is a heterotetramer consisting of two regulatory (R) subunits and two catalytic (C) subunits, R_2C_2 . In each case the regulatory subunits have binding sites for two molecules of cAMP. When the cAMP concentration is elevated in cells after activation of receptor-linked adenylyl cyclases, cAMP binds to the R subunits, causing the affinity of the C subunits for R subunits to drop by about four orders of magnitude. The formation of $R_2\text{cAMP}_4$ dimers and free C-subunits is favored, and the C-subunits are now active.

The case of cGMP-PrK is slightly different in that there are no free catalytic subunits released. cGMP-PrK is composed of two identical subunits. Each subunit has a regulatory domain and a catalytic domain, which are homologous to the R and C subunits of cAMP-PrK. On binding four molecules of cGMP the enzyme is activated, presumably by a conformational change.

The assay procedures for these two kinases are very similar and the same protein substrate can be used for each one as detailed below. More recently, both of these kinases have been assayed using peptide substrates.

BASIC PROTOCOL 1

Assays of Protein Kinases Using Exogenous Substrates

18.7.4

Materials

5× cyclic nucleotide–dependent kinase reaction buffer (see recipe)
10 mg/ml histone 2B in H₂O
[γ-³²P]ATP solution (see recipe)
20× cyclic nucleotide solution: 20 μM cyclic AMP in H₂O/20 μM cyclic GMP in H₂O
Enzyme sample containing cyclic nucleotide–dependent kinase activity (see Support Protocol 1), kept on ice until use
30° water bath

Additional reagents and equipment for TCA precipitation (see Support Protocol 2), adsorption onto P81 phosphocellulose paper (see Support Protocol 3), or electrophoretic analysis (see Support Protocol 4)

1. For each assay reaction, add the following to a 1.5-ml microcentrifuge tube kept on ice:

4 μl 5× cyclic nucleotide–dependent kinase reaction buffer
1 μl of 10 mg/ml histone 2B
1 μl [γ-³²P]ATP solution (to give 5 μCi/μl and 5 μM ATP final)
1 μl 20× cyclic nucleotide solution
0 to 13 μl H₂O.

Cap tube and warm the mixture in a 30°C water bath.

Perform each assay in triplicate and include no substrate, no enzyme, and no cyclic nucleotide controls.

The total reaction mix volume is 20 μl per reaction. The amount of water required depends on how much enzyme sample is used in step 2.

Sufficient reaction mix can be prepared in a single tube for all the reactions by multiplying the quantities for a single reaction by the total number of reactions + 1. Then the total amount of reaction mixture (minus enzyme) for one reaction can be added to each tube. This is often very convenient and reduces the potential for pipetting errors.

2. Start the reaction by adding 1 to 14 μl ice-cold enzyme sample containing cyclic nucleotide–dependent kinase activity.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μl: add 75 μl reaction mix to 25 μl immunoprecipitate bound to beads.

3. Incubate 10 min in a 30°C water bath.
4. Stop the reaction using the reagent appropriate for the analytic method to be used—20 μl ice-cold 10% TCA for TCA precipitation (see Support Protocol 2), or 10 μl or 20 μl ice-cold 2× SDS-PAGE sample buffer for electrophoretic analysis (see Support Protocol 4). Use 10 μl of the reaction mix for adsorption to P81 phosphocellulose paper (see Support Protocol 3). Proceed with analysis by one of those methods.

ASSAY FOR PROTEIN KINASE C ISOFORMS

There are presently at least ten members of the protein kinase C (PKC) family of kinases. Protein kinase C was originally identified as a kinase activity that was reversibly activated by calcium (Ca^{2+}), phospholipid (usually phosphatidylserine), and the neutral lipid diacylglycerol (DAG; Takai et al., 1979). Subsequently, these kinases were shown to be the sites of action for the tumor-promoting phorbol esters, which bind to some PKC isoforms and activate the kinase activity by substituting for DAG.

The initial isoforms of PKC that were purified were called α , β , and γ , and it is these forms that are the most clearly regulated by Ca^{2+} , phospholipid, and DAG or phorbol esters. They are termed the “conventional” subfamily of PKCs (cPKCs). Another subfamily contains δ , ϵ , ν , and θ , the “novel” PKCs (nPKCs); these kinases are not regulated by Ca^{2+} but are activated by phorbol esters and phospholipids. A third subfamily, the “atypical” PKCs (aPKCs), consist of ζ , λ , and τ ; these are not regulated by Ca^{2+} nor do they bind phorbol esters or DAG, but there is still a requirement for phospholipids. When the isoforms are analyzed, the reaction buffer must include the appropriate activating cofactors.

Materials

- 5 \times PKC reaction buffer (see recipe)
- 10 mg/ml histone H1 in H_2O
- $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ solution (see recipe)
- Enzyme sample containing PKC activity (see Support Protocol 1)
- 30 $^\circ\text{C}$ water bath

Additional reagents and equipment for TCA precipitation (see Support Protocol 2), adsorption onto P81 phosphocellulose paper (see Support Protocol 3), or electrophoretic analysis (see Support Protocol 4)

1. For each assay reaction, add the following to a 1.5-ml microcentrifuge tube:

- 4 μl 5 \times PKC reaction buffer
- 1 μl 10 mg/ml histone H1
- 1 μl $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ solution (to give 5 $\mu\text{Ci}/\mu\text{l}$ and 5 μM ATP final)
- 0 to 14 μl H_2O .

Cap tube and warm the mixture 10 min in a 30 $^\circ\text{C}$ water bath.

Perform each assay in triplicate and include no substrate and no enzyme controls.

The total reaction mix volume is 20 μl per reaction. The amount of water required depends on how much enzyme sample is used in step 2.

Sufficient reaction mix can be prepared in a single tube for all the reactions by multiplying the quantities for a single reaction by the total number of reactions + 1. Then the total amount of reaction mixture (minus enzyme) for one reaction can be added to each tube. This is often very convenient and reduces the potential for pipetting errors.

2. Start reaction by adding 1 to 14 μl enzyme sample containing PKC activity to the warmed reaction mixture.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μl : add 75 μl reaction mix to 25 μl immunoprecipitate bound to beads.

3. Incubate 10 min in a 30°C water bath.
4. Stop the reaction using the reagent appropriate for the analytic method to be used—20 μ l ice-cold 10% TCA for TCA precipitation (see Support Protocol 2), 10 μ l, or 20 μ l ice-cold 2 \times SDS-PAGE sample buffer for electrophoretic analysis (see Support Protocol 4). Use 10 μ l of the reaction mix for adsorption to P81 phosphocellulose paper (see Support Protocol 3). Proceed with analysis by one of those methods.

ASSAY FOR CASEIN KINASES USING β -CASEIN

Casein is a very acidic milk protein available in reasonable purity and quantity. Casein kinases were named for their ability to phosphorylate casein rather than other substrates available at the time. Because of its acidic nature, the use of casein as a substrate presents a number of problems, one of which is the fact that it does not carry a net positive charge at low pH and thus does not bind to P81 phosphocellulose paper. In recent years this problem has been circumvented by using short acidic peptides engineered to bind to P81 paper as substrates for the casein kinases (see Alternate Protocol).

There are currently two known mammalian casein kinases, casein kinase I and casein kinase II, named for their order of elution from anion-exchange chromatography columns. Casein kinases show a marked preference for substrates containing acidic residues close to the serine or threonine to be phosphorylated.

Casein kinase I is a 37-kDa monomer that phosphorylates serine and threonine residues (see Table 18.7.1) and utilizes ATP only as phosphoryl group donor. The basic phosphorylation consensus sequence is Glu/Ser(P)XXSer (where the underlined residue is the phosphate acceptor, and may be either Ser or Thr).

Mammalian casein kinase II is a tetramer of $\alpha_2\beta_2$ structure: the α -subunit is 24 to 28 kDa and the β -subunit is 37 to 44 kDa. Its preferred substrate has aspartate or glutamate residues C-terminal to the phosphorylation site serine or threonine and a consensus of SerGluGlu/Asp. Casein kinase II is unusual in that it can utilize both ATP and GTP as phosphoryl group donor with similar K_m values, $\sim 10 \mu\text{M}$ for ATP and $\sim 30 \mu\text{M}$ for GTP. Mammalian casein kinase II is also inhibited by heparin, whereas casein kinase I is not. The IC_{50} for the inhibition of casein kinase II by heparin is in the 10 to 20 nM range and at these concentrations casein kinase I is not inhibited.

Assays of either casein kinase I or II can be performed using casein as substrate. When isolated from milk, casein is a phosphoprotein. However, it is preferable to use dephosphorylated casein as substrate; this is commercially available in a relatively pure state as either the α or β isoform.

Materials

- 5 \times casein kinase reaction buffer (see recipe)
- 10 mg/ml β -casein in H_2O
- $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ solution (see recipe)
- Enzyme sample containing casein kinase activity (see Support Protocol 1), kept on ice
- 30°C water bath
- Additional reagents and equipment for TCA precipitation (see Support Protocol 2) or electrophoretic analysis (see Support Protocol 4)

1. For each assay reaction, add the following to a 1.5-ml microcentrifuge tube kept on ice:

4 μ l 5 \times casein kinase reaction buffer
1 μ l 10 mg/ml β -casein
1 μ l [γ - 32 P]ATP solution (to give 5 μ Ci/ μ l and 5 μ M ATP final)
1 to 14 μ l H₂O.

Cap tube and warm the mixture 10 min in a 30°C water bath.

This reaction mix can also be used for α -casein.

The total reaction mix volume is 20 μ l per reaction. The amount of water required depends on how much enzyme sample is used in step 2.

Sufficient reaction mix can be prepared in a single tube for all the reactions by multiplying the quantities for a single reaction by the total number of reactions + 1. Then the total amount of reaction mixture (minus enzyme) for one reaction can be added to each tube. This is often very convenient and reduces the potential for pipetting errors.

2. Start the reaction by adding 1 to 14 μ l enzyme sample containing casein kinase activity.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μ l: add 75 μ l reaction mix to 25 μ l immunoprecipitate bound to beads.

3. Incubate 10 min in a 30°C water bath.
4. Stop the reaction using the reagent appropriate for the analytic method to be used—20 μ l ice-cold 10% TCA for TCA precipitation (see Support Protocol 2), or 10 μ l or 20 μ l ice-cold 2 \times SDS-PAGE sample buffer for electrophoretic analysis (see Support Protocol 4). Proceed with analysis by one of those methods.

ALTERNATE PROTOCOL

ASSAY FOR CASEIN KINASES USING A PEPTIDE SUBSTRATE

Casein kinase I can be assayed with the peptide AspAspAspGluGluSerIleThrArgArg. Casein kinase II has most recently been assayed using specific peptide substrates, e.g., ArgArgArgGluGluGluThrGluGluGlu (where the underlined residue is the phosphate acceptor). In both cases the arginine residues allow binding to P81 phosphocellulose paper. The first peptide is relatively specific for casein kinase I, but the kinetics of its phosphorylation are not ideal; the K_m is in the millimolar range. Thus, it is preferable to use this assay for casein kinase I only if the kinase is highly purified.

Additional Materials (also see Basic Protocol 3)

10 mM synthetic peptide substrate solution (see recipe) for casein kinase: e.g.,
AspAspAspGluGluSerIleThrArgArg (for casein kinase I) or
ArgArgArgGluGluGluThrGluGluGlu (for casein kinase II)

Additional reagents and equipment for TCA precipitation (see Support Protocol 2), adsorption onto P81 phosphocellulose paper (see Support Protocol 3), or electrophoretic analysis (see Support Protocol 4)

1. For each assay, add the following to a microcentrifuge tube:

10 μ l 5 \times casein kinase reaction buffer
5 μ l 10 mM synthetic peptide substrate solution for casein kinase
5 μ l [γ - 32 P]ATP solution (to give 5 μ Ci/ μ l and 5 μ M ATP final)
0 to 30 μ l H₂O.

Cap the tube and warm 10 min in a 30°C water bath.

The total reaction mix volume is 50 μ l per reaction. The amount of water required depends on how much enzyme sample is based.

Sufficient reaction mix can be prepared in a single tube for all the reactions by multiplying the quantities for a single reaction by the total number of reactions + 1. Then the total amount of reaction mix minus enzyme for one reaction can be added to each tube. This is often very convenient and reduces the potential for pipetting errors.

2. Start the reaction by adding 1 to 30 μ l enzyme sample containing casein kinase activity.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μ l: add 75 μ l reaction mix to 25 μ l immunoprecipitate bound to beads.

3. Incubate 10 min in a 30°C water bath.
4. Stop the reaction using the reagent appropriate for the analytic method to be used—20 μ l ice-cold 10% TCA for TCA precipitation (see Support Protocol 2), or 10 μ l or 20 μ l ice-cold 2 \times SDS-PAGE sample buffer for electrophoretic analysis (see Support Protocol 4). Use 10 μ l of the reaction mix for adsorption to P81 phosphocellulose paper (see Support Protocol 3). Proceed with analysis by one of those methods.

ASSAY FOR Ca²⁺/CALMODULIN-DEPENDENT KINASES

As the name implies, Ca²⁺/calmodulin-dependent kinases are dependent on Ca²⁺ and calmodulin for their activity. Ca²⁺/calmodulin-dependent kinase I (CaM kinase I) is a monomeric protein of ~40 kDa. Ca²⁺/calmodulin-dependent kinase II (CaM kinase II) is composed of the products of four distinct genes for α , β , γ , and δ subunits. In its native form, CaM kinase II is an oligomer of M_r ~500,000 to 600,000. As its name suggests, both Ca²⁺ and calmodulin are required for activity.

Little is known of the physiological function of CaM kinase I. Activity can be assayed using the protein synapsin 1 as substrate, but both CaM kinase I and CaM kinase II phosphorylate full-length synapsin 1. This problem can be overcome by using synthetic peptide substrates that include the specific phosphorylation site for the enzyme being assayed. CaM kinase I can be assayed using a peptide containing site 1 of synapsin I, TyrLeuArgArgArgLeuSerAspSerAsnPhe (where the underlined residue is the phosphate acceptor). CaM kinase II can be assayed using autocalmodulin, LysLysAlaLeuArgGlnGlu-ThrValAspAlaLeu (Hanson et al., 1989), which is modeled on the autophosphorylation site of the kinase itself.

BASIC PROTOCOL 4

Analysis of Protein Phosphorylation

18.7.9

Materials

- 5× CaM kinase reaction buffer (see recipe)
- 10 mM synthetic peptide substrate solution (see recipe): e.g.,
 - TyrLeuArgArgArgLeuSerAspSerAsnPhe (for CaM kinase I) or
 - LysLysAlaLeuArgGlnGluThrValAspAlaLeu (autocamtide for CaM kinase II)
- [γ -³²P]ATP solution (see recipe)
- 1 mg/ml calmodulin in Milli-Q-purified water (store small aliquots at -70°C)
- Enzyme sample containing CaM kinase activity (see Support Protocol 1), kept on ice
- 30°C water bath
- Additional reagents and equipment for adsorption onto P81 phosphocellulose paper (see Support Protocol 3)

1. Set up and label duplicate 1.5-ml microcentrifuge tubes. For each reaction, prepare a mixture containing:

- 5 μ l 5× CaM kinase reaction buffer
- 5 μ l 10 mM synthetic peptide substrate solution
- 5 μ l [γ -³²P]ATP solution (to give 5 μ Ci/ μ l and 5 μ M ATP final)
- 5 μ l 1 mg/ml calmodulin *or* 5 μ l H₂O
- 0 to 30 μ l H₂O.

Cap tube and warm the mixture 10 min in a 30°C water bath.

The reaction mix is described for 50 μ l per reaction, but it can be carried out in volumes of 25 to 100 μ l by adjusting the amounts of the ingredients proportionally.

Control reactions should include one reaction without calmodulin so that any background phosphotransfer reactions can be accounted for and only calcium²⁺/calmodulin-dependent phosphotransfer is measured.

2. Start each set of reactions sequentially every 30 sec by adding 1 to 25 μ l enzyme sample containing CaM kinase activity to one of the tubes.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μ l: add 75 μ l reaction mixture to 25 μ l immunoprecipitate bound to beads.

3. Incubate for 10 min in a 30°C water bath.
4. Once the desired incubation time has elapsed, pipet 30 μ l of the contents of the tube quickly onto the surface of prepared P81 paper squares (see Support Protocol 3).

Only adsorption onto P81 phosphocellulose (see Support Protocol 3) is used to measure CaM kinase-mediated transfer because peptides are not efficiently precipitated by TCA, and they require specialized techniques for analysis by PAGE.

ASSAY FOR TYROSINE KINASES

Acid-denatured rabbit muscle enolase was first used as an exogenous tyrosine kinase substrate in the early 1980s, and it is still a useful substrate in a number of experimental situations. Usually enolase is used as a substrate for cytosolic tyrosine kinases such as pp60^{c-src}. Once the reaction is complete, phosphorylation of enolase is detected by separating proteins in the reaction mixture by SDS-PAGE (UNIT 10.2).

The following method is optimized for pp60^{c-src}, but may be applied to other tyrosine kinases. It is also useful as a framework for the assay of any tyrosine kinase, but optimization of the immunoprecipitation and assay buffers is required for the tyrosine kinase of interest.

Materials

- Rabbit muscle enolase (enolase EC 4.2.1.11; ammonium sulfate precipitate or suspension purified from rabbit muscle)
- 1 mM DTT/50 mM HEPES, pH 7.0
- Glycerol
- 100 mM acetic acid
- 5× tyrosine kinase reaction buffer (see recipe)
- [γ -³²P]ATP solution (see recipe)
- Enzyme sample containing tyrosine kinase activity (see Support Protocol 1), kept on ice
- 2× SDS-PAGE sample buffer (UNIT 10.2), ice-cold
- 30°C and boiling water bath

- Additional reagents and equipment for immunoprecipitation (UNIT 10.16) or SDS-PAGE (see Support Protocol 4 and UNIT 10.2)

1. Microcentrifuge the equivalent of 100 μ g rabbit muscle enolase 5 min at maximum speed, 4°C. Discard the supernatant.
2. Add 10 μ l of 1 mM DTT/50 mM HEPES, pH 7.0, to the pellet, mix thoroughly, and incubate 30 to 60 min on ice.
3. Add 10 μ l glycerol, mix, and then keep on ice if assays are to be performed the same day.

This preparation can also be stored at -70°C until required.

4. Immediately prior to assay, add 20 μ l of 100 mM acetic acid to the enolase solution and mix thoroughly. Incubate this mixture 5 min in a 30°C water bath, and then keep on ice until the reaction mixture is prepared.

Do not store acid-denatured enolase on ice in this state for >1 hr.

5. For each reaction, add the following to a 1.5-ml microcentrifuge tube:

- 4 μ l 5× tyrosine kinase reaction buffer
- 1 μ l acid-denatured enolase (step 4; 2.5 μ g enolase total)
- 1 μ l [γ -³²P]ATP (to give 5 μ Ci/ μ l and 5 μ M ATP final)
- 0 to 14 μ l H₂O.

Cap the tube and warm the mixture 10 min in a 30°C water bath.

The amount of water required depends on the amount of enzyme sample to be added; the total reaction volume should be 20 μ l.

Sufficient reaction mix can be prepared in a single tube for all the reactions by multiplying the quantities for a single reaction by the total number of reactions + 1. Then the total amount of reaction mix minus enzyme for one reaction can be added to each tube. This is often very convenient and reduces the potential for pipetting errors.

6. Start the reactions by adding 1 to 14 μl enzyme sample containing tyrosine kinase activity.

The volume of enzyme used depends on the amount of activity in the enzyme sample. In a preliminary experiment, the maximum indicated amount can be used to gauge the extent of the phosphotransfer reaction. The volume can be reduced as appropriate in order to allow for linear incorporation of phosphate into the substrate during the assay.

For enzyme samples that are immunoprecipitates adsorbed onto Sepharose beads (UNIT 10.16), prepare the reaction mix minus enzyme source first, warm it, then dispense it into the immunoprecipitate. For immunoprecipitates, it is advisable to scale up the reaction for a total volume of 100 μl : add 75 μl reaction mixture to 25 μl immunoprecipitate bound to beads.

7. Incubate the tube 10 min in a 30°C water bath.
8. Stop the reaction by adding 20 μl ice-cold 2 \times SDS-PAGE sample buffer. Mix thoroughly and heat the tube 3 min in a boiling water bath. Analyze 20 μl of the reaction by SDS-PAGE (UNIT 10.2).

Most tyrosine kinases autophosphorylate on a number of tyrosine residues and in in vitro assays are promiscuous with respect to substrate. Backgrounds are often very high so TCA precipitation and adsorption to P81 phosphocellulose paper are not very useful for analysis of results. SDS-PAGE (see Support Protocol 4) gives more specific and cleaner results.

BASIC PROTOCOL 6

IN-GEL PROTEIN KINASE ASSAYS

In-gel protein kinase assays (Kameshita and Fujisawa, 1989) involve the copolymerization of a kinase substrate in the separating gel layer of an SDS-PAGE gel. Protein samples are run on the modified gel as usual (UNIT 10.2). After electrophoresis is complete, the separated proteins are allowed to refold by various gel treatments. The gel is then incubated with [γ - ^{32}P]ATP at 30°C for enough time to allow the ATP to penetrate the entire gel. After further washes to remove unincorporated [γ - ^{32}P]ATP, the gel is stained and fixed as normal. ^{32}P -containing proteins are revealed by autoradiography (APPENDIX 3A). Although in general these assays are not particularly sensitive, they are sometimes very useful for identifying kinases in complex mixtures.

Materials

- 10 mg/ml kinase substrate: e.g., myelin basic protein
- Enzyme sample containing kinase activity (see Support Protocol 1), kept on ice
- 20% (v/v) 2-propanol/50 mM Tris·Cl (pH 8.0 at room temperature; APPENDIX 2)
- 1 mM DTT/50 mM Tris·Cl (pH 8.0 at room temperature)
- 6 M guanidine-HCl/1 mM DTT/50 mM Tris·Cl (pH 8.0 at room temperature) *or* 8 M urea/1 mM DTT/50 mM Tris·Cl (pH 8.0 at room temperature)
- 1 mM DTT/0.05% (v/v) Tween 20/50 mM Tris·Cl (pH 8.0 at 4°C)
- Appropriate kinase reaction buffer (see recipes)
- 10 mM Mg/ATP solution (see recipe)
- 10 mCi/ml [γ - ^{32}P]ATP (3000 Ci/mmol; Amersham, DuPont NEN, or ICN Biomedicals)
- 5% (w/v) trichloroacetic acid (TCA)
- 1% (w/v) sodium pyrophosphate/5% (w/v) TCA
- Container for radioactive incubation: e.g., small tray with tight cover, or heat-sealable polyethylene bag (Seal-a-Meal)
- Seal-a-Meal apparatus (optional)

Additional reagents and equipment for SDS-PAGE (UNIT 10.2) and autoradiography (APPENDIX 3A)

CAUTION: Because the samples are radioactive, great care should be exercised in sample preparation and loading. Perform the reactions and subsequent manipulations in screw-cap microcentrifuge tubes to minimize the risk of ^{32}P contamination. Run gels until the dye front passes out of the gel, as all residual $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ will migrate with the dye front. This means that the SDS-PAGE running buffer will be contaminated with ^{32}P , and it should be disposed of as radioactive waste according to safety regulations. See *APPENDIX 1F* for proper handling and disposal.

Separate proteins on modified gel

1. Prepare the mixture for a polyacrylamide gel of the appropriate %T (see *UNIT 10.2*). Add 10 mg/ml kinase substrate to give a final concentration of 1 mg/ml in the gel mixture. Polymerize as usual in a cassette prepared for casting the gel.

Myelin basic protein has been used with some success for assays of the MAP kinase family of enzymes. However, any protein is suitable if it is a substrate for the kinase of interest. This assay can also be used to identify potential substrates.

2. Prepare the enzyme samples containing kinase activity for SDS-PAGE in the usual way and carry out electrophoresis (see *UNIT 10.2*).
3. Once separation is complete, place the gel in 200 ml of 20% 2-propanol/50 mM Tris·Cl, pH 8.0. Wash the gel for 20 min, change to fresh buffer, and repeat twice for a total of three 20-min washes.

Washing with propanol removes SDS from the gel.

4. Wash the gel with 200 ml of 1 mM DTT/50 mM Tris·Cl (pH 8.0) three times, 20 min each.
5. Wash the gel with 250 ml of either 6 M guanidine·HCl/1 mM DTT/50 mM Tris·Cl (pH 8.0), or 8 M urea/1 mM DTT/50 mM Tris·Cl (pH 8.0) twice, 30 min each.

Either guanidine-HCl or urea can be used to denature the proteins. Depending on the kinase, one or the other may be more successful; guanidine-HCl should be tried first, because it seems to work best for most kinases.

6. Wash the gel eight to ten times at 4°C over a period of 18 hr with 250 ml of 1 mM DTT/0.05% Tween 20/50 mM Tris·Cl (pH 8.0), to renature proteins.

Assay for kinase activity

7. Incubate the gel with 250 ml of an appropriate kinase reaction buffer containing 10 mM MgCl_2 , for 20 min at 30°C.
8. Remove all traces of buffer and place the gel in a small tray or a Seal-a-Meal bag (the container is to be used for radioactive incubation). Add as small an amount of kinase reaction buffer as possible to just cover the gel. Add 1/4 of the reaction buffer volume of 10 mM Mg/ATP solution to give a final concentration of 50 μM ATP. Add 20 $\mu\text{Ci/ml}$ $[\gamma\text{-}^{32}\text{P}]\text{ATP}$.
9. Incubate 1 hr at 30°C.

The duration of this incubation can be adjusted after viewing the results of the initial experiment.

10. Incubate the gel in 250 ml 5% TCA twice, 15 min each. Wash 10 min in 500 ml of 1% sodium pyrophosphate/5% TCA. Repeat this wash until the solution contains little or no radioactivity.
11. Dry the gel onto filter paper and autoradiograph (*APPENDIX 3A*).

PREPARING A CELL LYSATE FOR KINASE ASSAYS

This protocol describes a method for detergent-induced cell lysis to prepare a crude extract containing kinase enzyme activity. Other methods of cell lysis may be appropriate (see *UNIT 12.1*). Hypotonic lysis and isolation of P100 and S100 fractions can also provide useful data on the recovery of a protein kinase as a soluble or membrane-bound activity.

Materials

Cultured cells: adherent cells at ~70% confluence in 100-mm tissue culture dishes or suspension cells at 10^6 cells/ml
PBS (*APPENDIX 2*), ice-cold
Lysis buffer (see recipe)
Protease inhibitor stock solutions (see recipe)
Microcentrifuge, 4°C

1. Wash the cultured cells twice in ice-cold PBS. Completely aspirate the final wash solution.
2. Add 0.75 ml lysis buffer to $\sim 2 \times 10^7$ cells; for adherent cells check that the monolayer is completely covered. Add protease inhibitors from stock solutions to the appropriate final concentration: 1 mM PMSF, 100 μ M benzamidine, 5 μ g/ml leupeptin, 5 μ g/ml pepstatin A, and 5 μ g/ml antipain.

A 0.75- μ l lysate should provide sufficient material for immunoprecipitation (use 25% to 50% of the lysate for an initial experiment and scale up or down depending on the results) or simple purification. If the purification procedure involves more than one chromatography step, prepare a larger lysate because only 10% to 20% of the activity is recovered from each chromatography step.

3. Incubate the cells 10 min at 4°C. Scrape the cells from the dish and transfer the lysate to a labeled microcentrifuge tube.
4. Microcentrifuge the lysate 10 min at maximum speed, 4°C. Carefully remove the supernatant and transfer it to a clean microcentrifuge tube.

Lysates should be used immediately until proper storage conditions (e.g., -70°C, liquid nitrogen) can be determined experimentally. For some kinases, it may not be possible to store the lysate at all.

TCA PRECIPITATION TO DETERMINE INCORPORATION OF RADIOACTIVITY

One of the classical methods for separating a reaction product from the reactants is differential precipitation. In the case of protein kinase assays using a protein substrate and [γ - 32 P]ATP, it is very easy to precipitate the protein and leave the [γ - 32 P]ATP in the soluble fraction. Most proteins are quantitatively precipitated by trichloroacetic acid (TCA), so TCA can be used to precipitate proteins phosphorylated during a kinase assay. Protein precipitate can be captured by filtration and the filter can be washed with TCA. TCA precipitation is a quick and reproducible way to determine the extent of [32 P]phosphate transfer to protein substrates. However, peptides are not precipitated by TCA, so adsorption of labeled peptides to P81 phosphocellulose paper (see Support Protocol 3) is a more suitable method for analyzing the results of kinase assays that use a peptide as substrate.

Materials

Assay samples (see Basic Protocols 1 to 5 and Alternate Protocol)
5% and 10% (w/v) trichloroacetic acid (TCA), ice-cold
95% ethanol
Diethyl ether

Whatman GF-C glass-fiber filters
Vacuum manifold (e.g., Fisher)
20-ml scintillation vials
Scintillation counter

1. Stop the reaction by adding 20 μ l ice-cold 10% TCA. Mix thoroughly and incubate 10 min on ice to precipitate protein.
2. Pipet sample onto Whatman GF-C glass-fiber filter held in a vacuum manifold. Allow the sample to pass through the filter. Rinse the tube with 500 μ l ice-cold 5% TCA. Add this wash to the appropriate filter.
3. Wash each filter with 5 ml ice-cold 5% TCA solution four times. Wash once with 10 ml of 95% ethanol, then three times with 10 ml diethyl ether. Allow each filter to dry for a few minutes.

CAUTION: Diethyl ether is extremely flammable and washes should be performed in a fume hood away from any flame or heat source. Ether washes should be disposed of in an appropriate manner.

4. Place the dry filters in a 20-ml scintillation vial and count in a scintillation counter by detection of Cerenkov radiation.

Alternatively, if dpm quantitation is desired, place dry filter in 10 ml scintillation fluid and count.

The filter can also be counted by Cerenkov radiation after the washes with 95% ethanol. If the filters are to be counted in scintillant, however, the diethyl ether washes are essential, because TCA (which is removed by the ether) causes significant chemiluminescence when placed in scintillation fluid, making the counts produced by the scintillation counter meaningless.

ADSORPTION ONTO P81 PHOSPHOCELLULOSE PAPER

One of the main methods to separate [32 P]-labeled proteins or peptides from [γ - 32 P]ATP after a protein kinase assay reaction is by adsorbing the protein or peptide to P81 phosphocellulose paper. P81 paper is an ion-exchange matrix with net negative charge at most pHs. At low pH (such as in 75 mM orthophosphoric acid, which is used to wash the paper in this protocol), the excess [γ - 32 P]ATP left after a kinase assay will not bind. Under the same conditions, however, the phosphorylated peptide will bind to the P81 paper if it carries a net positive charge at low pH. In practice, this is usually achieved by tagging a peptide with two or three arginine or lysine residues at the N- or C-terminus. At the pH of 75 mM orthophosphoric acid the arginyl or lysyl side chains are positively charged and will bind to P81 paper. It is necessary, of course, that the activity of the kinase in question is not affected by the addition of basic residues to the substrate. Usually five or more residues are placed between the hydroxy-amino acid phosphorylation site and the basic residues required for binding to P81 paper.

When proteins are used as substrates for kinases, the net charge of the protein is also a consideration for adsorption to P81 paper. As for peptides, adsorption to P81 paper is more suitable for basic proteins than for acidic proteins. Under the conditions described in this protocol, histones bind very well to P81 paper because they are highly basic, but casein binds very poorly or not at all because it is a very acidic protein.

SUPPORT PROTOCOL 3

Analysis of Protein Phosphorylation

18.7.15

Figure 18.7.1 Addition of sample to P81 phosphocellulose paper. The 2×2 -cm squares of P81 paper are labeled using a pencil (ink is dissolved by the acetone wash), and 50% to 75% of the reaction product is applied to the paper.

Materials

Assay samples (see Basic Protocols 1 to 5 and Alternate Protocol)
 75 mM orthophosphoric acid (stored up to 6 months at room temperature)
 Acetone
 2×2 -cm squares of P81 phosphocellulose paper (Whatman)
 500-ml plastic beaker with the bottom replaced with solvent-resistant plastic or wire mesh (see Fig. 18.7.2)
 20-ml scintillation vial
 Scintillation counter

1. Cut 2×2 -cm squares of P81 paper, fold the end over, and label the folded end with pencil as shown in Figure 18.7.1. Place each square on a large piece of nonabsorbent material, such as plastic or acrylic sheeting or an aluminum foil-covered fiberboard.

Use a soft pencil to label the squares of P81 paper, as the final acetone wash will remove or destroy ink labels.

2. Pipet 15 or 30 μ l of the contents of each assay tube quickly onto the surface of the prepared P81 paper squares. Immediately place the paper squares in a 500-ml plastic beaker with the bottom replaced with solvent-resistant plastic or wire mesh (Fig. 18.7.2).

Usually 50% to 75% of the final reaction mixture is spotted onto P81 paper to ensure that there is sufficient signal to be detected.

Figure 18.7.2 Setup for washing P81 phosphocellulose paper with reaction samples. The paper squares are washed five times for 5 min each in 75 mM orthophosphoric acid and once in acetone. They are then air dried and counted in a scintillation counter.

If the plastic mesh used in the beaker is not solvent-resistant, the final acetone washes will dissolve it!

3. Place this beaker into a larger beaker containing 75 mM orthophosphoric acid and incubate 5 min with stirring.
4. Pour the used orthophosphoric acid wash into a container suitable for ^{32}P -containing liquid waste. Refill the large beaker with 75 mM orthophosphoric acid and incubate 5 min more. Repeat for a total of five 5-min washes.
5. Fill the large beaker with acetone and wash the P81 papers for 5 min. Discard the acetone and allow the papers to dry.
6. Place each square of P81 paper in a 20-ml scintillation vial and count by detection of Cerenkov radiation.

Alternatively, if the absolute dpm value is desired and a ^{32}P quenching curve is available for the scintillation counter, add scintillation fluid to the vials and count.

ELECTROPHORETIC ANALYSIS OF PHOSPHORYLATION

Electrophoretic analysis of phosphorylation allows a more specific determination of protein substrate phosphorylation, because other phosphoproteins are separated by electrophoresis. It is advantageous to use the resolving power of SDS-PAGE to assay relatively crude enzyme samples; this method of analysis may also give useful information on kinase autophosphorylation.

Stop the reaction (see Basic Protocols 1 to 5 or Alternate Protocol) by adding 20 μl ice-cold $2\times$ SDS-PAGE sample buffer (UNIT 10.2). Mix thoroughly, heat the sample 3 min in a boiling water bath, then analyze by SDS-PAGE (UNIT 10.2). Stain, fix, dry, and autoradiograph (APPENDIX 3A) the gel.

SUPPORT PROTOCOL 4

Analysis of Protein Phosphorylation

18.7.17

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **APPENDIX 4**.

[γ -³²P]ATP solution

Dilute 10 mM Mg/ATP solution (see recipe) 1/10 in water to give a 1 mM solution. For the assay, add 10 μ l of 1 mM Mg/ATP to 80 μ l water and then add 10 μ l of 10 mCi/ml [γ -³²P]ATP (3.3 pmol ATP).

The final ATP concentration is \sim 100 μ M (plus 33 nM from the [γ -³²P]ATP, which is negligible), and the 100 μ Ci (\sim 2.2 \times 10⁸ dpm) in 100 μ l gives a specific activity of 1 μ Ci/ μ l or \sim 2.2 \times 10⁷ dpm/nmol.

Suppliers for [γ -³²P]ATP include Amersham, NEN, and ICN; it is usually available at a variety of specific activities. A good specific activity to use is 3000 Ci/mmol, normally provided by the manufacturer at a concentration of 10 mCi/ml. Amersham's Redivue is a convenient [γ -³²P]ATP solution to use as it is stored at 4°C instead of -20° C.

As 1 Ci is \cong 2.2 \times 10¹² dpm, then for a specific activity of 3000 Ci/mmol

$$\begin{aligned} &= 3 \text{ Ci}/\mu\text{mol} \\ &= 6.6 \times 10^{12} \text{ dpm}/\mu\text{mol} \\ &= 6.6 \times 10^6 \text{ dpm}/\text{pmol} \\ &= 2.2 \times 10^6 \text{ dpm} \cong 1 \mu\text{Ci} \cong 0.33 \text{ pmol}. \end{aligned}$$

The stock Mg/ATP solution prepared earlier can be diluted to a working ATP solution of the desired concentration (in this example, 0.1 mM).

CaM kinase reaction buffer, 5 \times

100 mM Tris·Cl, pH 7.5 (**APPENDIX 2**)
25 mM MgCl₂
1 mM CaCl₂
Store up to 6 months at -20° C

Casein kinase reaction buffer, 5 \times

100 mM Tris·Cl, pH 7.5 at 30°C (**APPENDIX 2**)
25 mM MgCl₂
2.5 mM DTT
750 mM KCl
Store up to 6 months at -20° C

Cyclic nucleotide-dependent protein kinase reaction buffer, 5 \times

250 mM Tris·Cl, pH 7.5 at 30°C (**APPENDIX 2**)
25 mM MgCl₂
Store up to 6 months at -20° C

Lysis buffer

50 mM HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid), pH 7.4
100 mM NaCl
50 mM sodium fluoride
5 mM β -glycerophosphate
2 mM EDTA
2 mM EGTA
1 mM sodium vanadate (Na₃VO₄)
1% (v/v) Nonidet P-40 (NP-40) or Triton X-100
Store up to 6 months at -20° C

To stabilize kinase activity, specific kinase inhibitors, protease inhibitors, and reducing agents may be added to the lysis buffer (see *Strategic Planning, Enzyme Sources*).

Mg/ATP solution, 10 mM

Stock solutions:

20 mM MgCl₂ or MgSO₄

20 mM Na₂ATP

Working solution: Mix equal volumes of the two stock solutions and measure the pH. Adjust the pH slowly to pH 7.4 with 100 mM HCl or 100 mM NaOH. Store up to 1 year in small aliquots at –20°C.

If a precipitate forms, the solution should be stirred continually and the pH maintained at 7.4.

Adenosine triphosphate is normally purchased as a sodium salt. Most kinases require ATP to be complexed with magnesium for its efficient utilization as a substrate. In some cases manganese can substitute for Mg²⁺.

PKC reaction buffer, 5×

Solvent:

100 mM Tris·Cl, pH 7.5 at 30°C (APPENDIX 2)

25 mM MgCl₂

1 mM CaCl₂

Store up to 6 months at –20°C

Lipids:

Just before the buffer is to be used, transfer enough 5 µg/ml phosphatidylserine stock solution in chloroform to provide 100 µg phosphatidylserine/ml buffer (final concentration) to a clean tube. Add sufficient 0.5 µg/ml Diolein stock solution (Sigma) in chloroform to provide 10 µg Diolein/ml buffer (final concentration) to the same tube and mix. Dry the lipids under a stream of nitrogen.

Working solution:

Add the required volume solvent (see above) and place on ice for 10 min. Sonicate the mixture at medium power for 1 min while the sample is on ice. Let the sample sit on ice 2 min. Repeat sonication 4 more times for a total of 5 min. Discard any unused buffer.

Diolein is the old name for various preparations that contain mixed isomers of diacylglycerol, the cofactor for PKC. Diolein is a suitable source for the cofactor in these assays, and it is less expensive than pure preparations of 1,2-diacylglycerol.

Protease inhibitor stock solutions

100 mM phenylmethylsulfonyl fluoride (PMSF) in 100% ethanol

100 mM benzamidine

1 mg/ml leupeptin

1 mg/ml pepstatin A

1 mg/ml antipain

Store up to 6 months at –20°C

Synthetic peptide substrate solution

Prepare 10 mM solutions of each peptide (highest quality available) in Milli-Q water and adjust pH to 7.4 before storage at –70°C or use.

If the peptide is insoluble, check the sequence—a peptide with a high proportion of acidic residues may be more soluble at alkaline pH, and one with a high proportion of basic residues may be more soluble at acidic pH. Hydrophobic peptides may be solubilized by adding up to 20% (v/v) acetonitrile. Whatever is added must not compromise the assay conditions: e.g., if a peptide must be dissolved at pH 10, adding the solution to the reaction mix must not change the pH of the reaction.

Most synthetic peptides are quite stable when stored at –70°C; the stability of individual peptide substrates should be determined for the storage conditions used, however. If peptides are custom synthesized they should ideally be purified by HPLC before use.

Tyrosine kinase reaction buffer, 5×

100 mM HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid), pH 7.4

5 mM MnCl₂

5 mM DTT

500 μM sodium vanadate (Na₃VO₄)

Store up to 6 months at -20°C

COMMENTARY

Background Information

In recent years there has been an explosion of interest in protein kinases. It is now obvious that this class of enzyme plays many essential roles in a large array of biological processes, including the cellular responses to hormones, control of most stages of the cell cycle, and development of the nervous system in systems as diverse as fruit fly and man. Because of this interest, a very large number of protein kinase and protein phosphatase genes have been identified; current estimates are that there are well over 2000 genes encoding these enzymes in mammalian genomes. Obviously the study of protein kinases and phosphatases can provide fundamental information regarding the regulation of many diverse systems; the protocols provided in this unit include enough information to enable researchers new to this type of experiment to embark on the study of protein kinases.

Protein kinases can be assayed using two types of substrate, intact proteins or synthetic peptides, and there are advantages and disadvantages to the use of each. A number of intact proteins may be used as general protein kinase substrates, and those in common use are available in relatively pure form from a number of manufacturers at reasonable prices. The main disadvantage to the use of proteins as substrates is the lack of specificity, sometimes making interpretation of experimental data difficult. Intact proteins such as myelin basic protein (MBP) contain many different phosphorylation sites. MBP can be phosphorylated by MAP kinase, some protein kinase C isoforms, and Ca²⁺/calmodulin kinase II, each at one or more sites. Hence, it is often impossible to differentiate which kinase is responsible for phosphorylating MBP in a complex mixture like a whole cell lysate. Some proteins cause headaches because they cannot be used with simple experimental protocols, e.g., casein.

The use of synthetic peptides improves the specificity of the reaction by providing a single, well-defined phosphorylation site. They also allow experiments to define the consensus se-

quence for phosphorylation by a particular protein kinase and make it possible to design a substrate that has excellent kinetic properties for the kinase of interest. Peptides are often easier to use than their protein counterparts as in the case of casein kinases, where peptides can be designed that allow the use of phosphocellulose paper rather than other more involved methods for assessment of experimental results. Use of peptides is not without disadvantages though, the most significant being the cost of producing reasonable quantities of large numbers of peptides. When this is coupled with the observation that sometimes peptides are not recognized by the kinase because some structural element is missing, using peptide substrates can be a frustrating and expensive business. However, this is the exception rather than the rule, and the use of specific peptides to assay protein kinases is ultimately the best choice.

One unit of kinase activity is usually defined as the amount of enzyme required to transfer 1 μmol of phosphate to a substrate from ATP per minute. From the following example it is possible to calculate a number of the reaction parameters:

For this example, 1 mg protein (based on protein assay; see *UNIT 10.1A*) was used for the assay. The [γ-³²P]ATP in the assay mixture had a specific activity of 10⁶ dpm/nmol. After the 10-min reaction the ³²P-labeled product had a specific activity of 10⁵ dpm; therefore, there were (10⁵/10⁶) nmol of ³²P-labeled product, and the concentration was 10⁻¹ nmol or 100 pmol. Hence, the enzyme transferred 10 pmol of phosphate per minute, and represents 0.01 U of enzyme activity when measured with this substrate. Put another way, this represents an enzyme specific activity of 10 pmol/min/mg of protein. This latter expression of enzyme activity is a useful measure when comparing different preparations of a kinase or, during purification of a kinase, as a measure of the extent of purification through different steps.

Critical Parameters

Although it may seem obvious, the most critical element in performing kinase assays is using the correct controls. This is especially true when performing assays on tissue samples or cell extracts. Controls should always include addition of no substrate, addition of no enzyme source, addition of heat-denatured enzyme source, and, for reactions that require activator or cofactor, addition of any activator or cofactor and addition of no activator or cofactor.

Another important aspect is the concentration of ATP in the assay. The ATP concentration can vary depending on the type of experiment to be performed. For derivation of kinetic data, the concentrations of both ATP and peptide or protein substrate are critical. If kinase detection during purification is required, assay linearity is not as important as long as the right controls are present. For mapping *in vitro* phosphorylation sites on a kinase substrate, very often the ATP concentration is kept extremely low but the specific activity very high.

When designing potential peptide substrates for individual protein kinases, there are a number of considerations to remember. For example, phosphorylated peptide will bind to the P81 phosphocellulose paper. To be able to analyze the assay with this paper, it is necessary that the peptide carry a net positive charge at low pH. In practice this is usually achieved by tagging a peptide with two or three arginine or lysine residues at the N- or C-terminus. At the pH of 75 mM orthophosphoric acid, the arginyl or lysyl side chains are positively charged and will bind to the P81 paper. It is important to determine that the activity of the kinase of interest is relatively unaffected by the addition of basic residues to its peptide substrates in this way. To help ensure this is the case, it is a good idea to place five or more residues between the hydroxy-amino acid to be phosphorylated and the basic residues required for binding to P81 paper.

Net charge considerations also pertain to some extent to proteins used as substrates for protein kinases. Under the conditions described in Support Protocol 3, histones will bind very well to P81 paper, because they are highly basic, but casein, which is very acidic, binds very poorly or not at all. In these cases, the P81 paper assay is very good when histones are used to assay kinase activity, but worthless when casein is used.

When crude enzyme sources, such as cell lysates, are analyzed, many other proteins are present and phosphorylation of multiple proteins in the crude mixture is possible, as is

autophosphorylation of the protein kinase. Because many proteins will be precipitated by trichloroacetic acid (TCA) or will bind to P81 paper, there can be elevated backgrounds and severe overestimates of peptide phosphorylation when Support Protocols 2 and 3 are used. When performing kinetic studies, this overestimation of phosphorylation can be very misleading, as substrates other than the peptide under study will undoubtedly be phosphorylated and with different kinetics.

Troubleshooting

Any troubleshooting of kinase assay procedures should be very straightforward. If the assay does not work, verify that both the [γ - 32 P]ATP and the peptide or protein substrate have been added at the correct concentrations. It is also very important to keep the enzyme source on ice before use and to store it appropriately between experiments. Very often when this type of experiment does not work it is because of a labile enzyme, poor storage of the enzyme, or a combination. It is important to know how long a particular enzyme is stable under the conditions used and the rate of inactivation or denaturation, if relevant. It is also essential to know if the enzyme activity is comparable between different preparations, especially for purified proteins.

Anticipated Results

Depending on the requirements, information can be obtained about the specific activity of a particular enzyme preparation, kinetic parameters for the reaction catalyzed, or whether a particular kinase has been identified or substantially purified.

Time Considerations

Kinase assays are quite simple to set up and perform. If the samples for assay are available, it is a matter of only ~3 to 4 hr to go from assay set up to data interpretation when either TCA precipitation (Support Protocol 2) or adsorption to phosphocellulose paper (Support Protocol 3) is used to separate phosphorylated protein from contaminating [γ - 32 P]ATP. With SDS-PAGE analysis (Support Protocol 4), the assays can be set up, performed, and the samples run on a SDS-PAGE gel in ~4 to 5 hr. Gel drying and autoradiography can take from 2 hr to a number of days depending on the level of protein phosphorylation. In general, if individual protein bands have ~20,000 cpm of 32 P associated with them, they will be visible with 1 hr of autoradiography.

Permeabilization Strategies to Study Protein Phosphorylation

This unit deals with the use of nucleotide triphosphates to label proteins in vitro in permeabilized cells and isolated cellular fractions. These experiments generally utilize $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ as an exogenously added phosphate donor, although $[\gamma\text{-}^{32}\text{P}]\text{GTP}$ can be used in specific cases. The method is very straightforward, although numerous considerations must be made before applying it to each new system.

UNIT 18.2 describes labeling of phosphoproteins in intact cells with ^{32}P -labeled inorganic phosphate ($^{32}\text{P}_i$). After ascertaining that the protein of interest is a phosphoprotein using the protocols detailed in that unit, the phosphorylation event itself may be studied either in cell-free systems or in a more intact cellular system. In vitro, most protein kinases are capable of phosphorylating many substrates in addition to those phosphorylated in vivo, thus making it desirable to identify and study a protein kinase-catalyzed phosphorylation reaction in a more intact system than a cell lysate or homogenate. Permeabilization of intact cells provides a powerful experimental approach for accomplishing this. Brief permeabilization of cells is possible using a variety of agents. This procedure gives access to the intracellular milieu but still allows signal transduction events to be initiated by hormone stimulation of the cells via cell-surface receptors.

Brief chemical permeabilization of cells allows the introduction of cell-impermeable reagents into the intracellular compartment in order to study particular signal-transduction processes. In this type of experiment, relatively large molecules such as the Fab' fragments of specific antibodies may be introduced into the permeabilized cell, although the kinetics of entry may be too slow for the study of some processes. This technique is often more useful when introducing relatively small molecules into the permeabilized cell, for example non-cell-permeable activators (e.g., hydrophilic or lipophobic small molecules that cannot partition into the membrane) or inhibitors of protein kinases or phosphatases (see, e.g., Calbiochem catalog). The kinetics of entry into permeabilized cells for small molecules such as $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ are fast, and the system equilibrates the cellular ATP and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ with intracellular processes within 2 to 3 min. Figure 18.8.1 shows the

Figure 18.8.1 Equilibration of the monoester phosphates of the lipid phosphatidylinositol-4,5-bisphosphate with the ATP pool after permeabilization of human platelets. The letter A marks the point of addition of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$.

equilibration of the monoester phosphates of the lipid phosphatidylinositol-4,5-bisphosphate with the ATP pool after permeabilization of human platelets. As these monoester phosphates are known to equilibrate with the ATP pool extremely quickly, this experiment provides a good indication of the speed of equilibration of cellular ATP pools with intracellular processes after addition of [γ - ^{32}P]ATP to permeabilized cells.

Procedures are outlined for performing a protein phosphorylation experiment using permeabilized cells (see Basic Protocol 1) and isolated intracellular organelles (see Basic Protocol 2). Both of these procedures result in lysates from which the protein of interest may be easily immunoprecipitated; however alternative techniques are described for preparing the final lysate from either Basic Protocol 1 or Basic Protocol 2 for electrophoretic analysis (see Alternate Protocols 1, 2, 3, and 4). A related procedure that does not involve permeabilization is outlined for direct analysis of cytosolic or membrane-bound kinases (see Alternate Protocol 5). Two different methods for determining the specific radioactivity of ^{32}P -containing compounds are also included (see Support Protocols 1 and 2).

CAUTION: It cannot be emphasized enough that each investigator should be fully familiarized with their local regulations regarding the safe handling and disposal of ^{32}P and also have the appropriate equipment for dealing with the containment of ^{32}P . See *APPENDIX 1F* for more information on the safe use of radioisotopes.

NOTE: Milli-Q purified water or its equivalent should be used to prepare all solutions used throughout this unit.

BASIC PROTOCOL 1

ANALYSIS OF PROTEIN PHOSPHORYLATION IN PERMEABILIZED CELLS

When setting out to study a protein phosphorylation event via a permeabilization protocol, the general procedure is as follows. First, cells are incubated in a buffer which has been designed to mimic the composition of the intracellular compartment and which contains a permeabilizing agent. The preferred permeabilization agent of choice is streptolysin O, as this agent allows many signal-transduction systems to remain intact for a number of minutes after its addition (Stephens et al., 1994). This is certainly not true of all permeabilization agents or protocols; if another agent (e.g., saponin) is to be tried, the methods detailed below should be used as a general guideline only. Depending on the experiment to be performed, the permeabilization buffer may also contain [γ - ^{32}P]ATP and the particular reagents under study. The [$^{32}\gamma$ -P]ATP provides the “hot” phosphate, and will equilibrate with the intracellular processes utilizing ATP within 2 to 3 min (A.N. Carter, unpub. observ.). After a brief time the experimental reagents, such as inhibitors, can be introduced into the permeabilization medium and hence into the inside of the cell. At this point the cells may be stimulated with the appropriate agent in the same way as for intact cell preparations. The phosphorylation of the protein under study is initially investigated by immunoprecipitation as described in *UNIT 10.16* and *UNIT 18.2*, followed by phosphopeptide mapping as described in *UNIT 18.3*.

Materials

- Cell culture to be labeled
- Cell culture medium appropriate for cells being studied, buffered with 20 mM HEPES, pH 7.2, prewarmed to 37°C
- Cells under study (normally cultured cell lines or isolated primary cells in culture)
- Extracellular buffer (see recipe), 37°C
- Permeabilization buffer (see recipe), 37°C
- 60 U/ml streptolysin O working solution (see recipe), freshly prepared
- 10 mM cold ATP stock solution (see recipe)
- 10 mCi/ml [γ - ^{32}P]ATP (3000 Ci/mmol; e.g., DuPont NEN)

Permeabilization Strategies to Study Protein Phosphorylation

18.8.2

Pharmacological agents, peptides, or Fab' fragments to be studied
Appropriate receptor agonists
2× lysis buffer for immunoprecipitation (see recipe), ice-cold
Protease inhibitor stock solutions (in absolute ethanol; store up to 6 months at
–20°C):
100 mM phenylmethylsulfonyl fluoride (PMSF)
100 mM benzamidine
1 mg/ml pepstatin A
1 mg/ml leupeptin
1 mg/ml antipain
100 mM DTT
Dry ice/ethanol bath
Noncirculating 37°C water bath containing a flat shelf (preferably made of wire
mesh) with space for the number of cell plates in the experiment
50-ml centrifuge tubes
Tabletop centrifuge
Cell scrapers
Screw-cap microcentrifuge tubes

Permeabilize cells

For monolayer cultures

- 1a. Approximately 1 hr before starting the experiment, change the medium in the cell culture plates to be labeled to equivalent medium containing 20 mM HEPES. Return cells to incubator and allow the cells to equilibrate with the new medium before use.

The number of cells used for any experiment of this type is totally dependent on how easy it is to detect the end product being studied. In some cases, a 60-mm dish of cells that has just reached confluency, with $\sim 1 \times 10^6$ cells, is adequate; in others a 100-mm dish of cells with $\sim 1 \times 10^7$ cells is required. It is advisable to start with $\sim 1 \times 10^6$ cells and see if the signal is detectable. Use of a 60-mm dish allows a smaller volume of permeabilization medium (normally of the order of 0.5 to 2 ml) to be used.

Standard cell culture medium is buffered by bicarbonate ions in the medium and the CO₂ in the atmosphere of the incubator. Outside the incubator this buffering system is ineffective and the pH will quickly rise if the culture is left in the normal atmosphere. The pH of HEPES buffers are minimally affected by temperature (unlike Tris buffers), hence they provide good pH control for cell culture medium. One drawback is that HEPES may be toxic to some cells above a concentration of ~ 20 mM, so it is important to check possible cellular toxicity before the use of HEPES-buffered culture media.

- 2a. Place the required number of plates containing cells in the 37°C water bath and allow 10 min for the medium to reequilibrate.

The cells are stable in this state for an hour or so, depending on the rate of evaporation of the culture medium.

- 3a. Aspirate the culture medium from each plate and quickly rinse the cells twice, each time with 10 ml of 37°C extracellular buffer. Aspirate the extracellular buffer, then add 0.5 to 2 ml permeabilization buffer to each plate.

Be careful when rinsing, as some cell lines are less adherent than others. Usually, most epithelial or mesenchymal lines adhere well and will not slough off the dish unless extreme force is used. Transformed cells usually adhere poorly and can easily be rinsed off the dish if care is not taken.

- 4a. Add streptolysin O (from the 60 U/ml working solution) to each plate to a final concentration of 0.6 U/ml. Add cold ATP (from the 10 mM stock solution) to a final concentration of 100 μ M.

For suspension cultures

- 1b. Approximately 1 hr before starting the experiment, transfer cells to sterile 50-ml centrifuge tubes and centrifuge 5 min at $1000 \times g$, room temperature. Remove the supernatant, then rinse cells twice, each time by adding ~40 ml of 37°C extracellular buffer, centrifuging 5 min at $1000 \times g$, room temperature, and removing the supernatant.

The cell suspension may be split into aliquots, if desired, after the addition of the final rinse of extracellular medium. To do this, add the final (40-ml) rinse of extracellular medium, resuspend cells gently, and dispense aliquots into fresh tubes. Centrifuge the aliquots and remove the supernatants to complete the final rinse before proceeding to step 2b.

- 2b. Resuspend the cells in 37°C extracellular buffer at a density of 1×10^7 cells/ml. Allow the cells to equilibrate 15 to 30 min at 37°C with gentle swirling.

This step may have to be modified if a cell is used that could be activated by this procedure, (e.g., platelets). If a sensitive cell is used, equilibration time may be kept down to 5 to 10 min and the agitation may be omitted.

- 3b. Centrifuge cells again for 5 min at $1000 \times g$, room temperature, and aspirate the buffer.
- 4b. Add streptolysin O (from the 60 U/ml working solution) to fresh 37°C permeabilization buffer to a final concentration of 0.6 U/ml. Add cold ATP (from the 10 mM stock solution) to a final concentration of 100 μ M. Add this permeabilization solution containing streptolysin O and ATP to the cells and mix gently but thoroughly.

Addition of cold ATP at the same time as streptolysin O allows cellular ATP levels to be maintained and will therefore preserve cell viability. One important consideration is whether the cells under study possess cell-surface receptors for ATP. The ATP acts as a full agonist for some types of purinergic receptors, and this can obviously cause confusion when analyzing signal-transduction mechanisms. Prior to performing permeabilization studies, one should first determine, using intact cells, whether extracellular ATP activates signal-transduction mechanisms that interfere with the system under investigation. Stephens et al. (1994) have developed a way of inactivating extracellular receptors for ATP in neutrophils prior to permeabilization. The utility of this method for other cell types is not known to date, although it may be used as a guideline if required. Readers are referred to the original paper for full discussions of this method.

Permeabilize and label cells

5. Permeabilize cells by incubating 1 to 5 min at 37°C.

The time of incubation depends very much on the particular system under study and the cell type, and must be determined empirically. Permeabilization for >5 min usually reduces hormone responsiveness of cells dramatically. This is probably due to a number of processes, including the loss of cytosolic components into the extracellular permeabilization buffer and physical uncoupling of receptors from signal-transduction processes.

6. Add 10 mCi/ml [γ - 32 P]ATP to a final concentration of 50 to 500 μ Ci/ml.

[γ - 32 P]ATP is usually purchased at a specific activity of ~3000 Ci/mmol, and a concentration of 10 mCi/ml. Hence 5 μ l of the stock is 50 μ Ci [γ - 32 P]ATP. The label may be used at this concentration. If the stock [γ - 32 P]ATP is to be diluted into another solution it is better to do this directly before use.

The criterion for the amount of radiolabeled ATP to add (between 50 and 500 μ Ci/ml) is the detection limit. Initial experiments must be performed to see how much label must be added.

The alternative to this separate labeling step is to add the [γ - 32 P]ATP at the same time as the streptolysin O and cold ATP in step 4a or b. The type of experiment to be performed will determine at which point the [γ - 32 P]ATP is added to the cells.

7. Add the pharmacological agents, peptides, or Fab' fragments under study and allow time for their action as required.

Many pharmacological agents amenable to testing by this protocol are listed in the Calbiochem catalog. For example, a peptide containing residues 280 to 305 of the CaM kinase II α subunit can be a potent inhibitor of CaM kinase II and is non-cell-permeable. There are other peptides modeled on pseudosubstrate inhibitors of a variety of protein kinases that can be used as specific inhibitors, all of which are non-cell-permeable. Any Fab' fragment may be tested by this protocol as long as it has an effect on enzyme activity, either positive or negative. Similarly, if an antibody stops an enzyme from reaching its site of action, it may also be tested via this procedure.

The time for a particular agent to act as required should be determined experimentally as part of the initial experimental protocols. As with the [γ - 32 P]ATP addition, these agents may also be added at the same time as streptolysin O and cold ATP.

8. Add receptor agonists as required.

The same considerations are true for receptor agonist additions as for inhibitor and [γ - 32 P]ATP additions to the cells. One must perform preliminary experiments to empirically determine the timings for these additions for each cell type under study.

The remaining steps of this protocol are to prepare the cells for analysis by immunoprecipitation. If electrophoretic analysis is to be performed, see Alternate Protocols 1 and 2.

Prepare cell lysates for immunoprecipitation

- 9a. *For monolayer cultures:* Stop the reactions by rapidly aspirating the permeabilization buffer and adding 0.75 ml ice-cold 2 \times lysis buffer for immunoprecipitation to each plate. Add protease inhibitors and DTT (as stock solutions) to the following final concentrations:

PMSF to 1 mM final
Benzamidine to 1 mM
Pepstatin A to 5 μ g/ml final
Leupeptin to 5 μ g/ml final
Antipain to 5 μ g/ml final
DTT to 1 mM final.

Place plates on ice for 10 min, then scrape the cell debris from the bottoms of the plates into the buffer using a separate cell scraper for each plate.

- 9b. *For suspension cultures:* Stop the reactions by adding an equal volume of ice-cold 2 \times lysis buffer for immunoprecipitation. Add protease inhibitors and DTT to the final concentrations in step 9a, then place the tubes of cells on ice for 10 min.
10. Transfer lysates to screw-cap microcentrifuge tubes (one plate or cell aliquot/tube). Microcentrifuge lysates at maximum speed, 4 $^{\circ}$ C, then transfer the supernatants to fresh screw-cap microcentrifuge tubes and freeze immediately in a dry ice/ethanol bath. Store at -70° C until needed.

The lysates are now ready for immunoprecipitation (UNIT 10.16).

CAUTION: *The permeabilization buffer in the latter steps of this protocol contains [γ - 32 P]ATP, and great care should be taken to remove the medium safely and dispose of it correctly as liquid radioactive waste. The lysates and cell scrapers are also very radioactive at this point. Screw-cap tubes should be used at all subsequent stages of processing the cell lysates as these provide the best containment of the 32 P-containing samples. The same microcentrifuge should be used for all centrifugation steps; after use it will undoubtedly be contaminated with 32 P. It can then be set aside for future use with 32 P-containing samples with the appropriate safety precautions.*

INTACT CELL SAMPLE PREPARATION FOR ELECTROPHORETIC ANALYSIS OF PROTEIN PHOSPHORYLATION

The preceding protocol (see Basic Protocol 1) is set up to allow immunoprecipitation of specific proteins after the permeabilization experiment. Two alternatives to this approach, described below, involve using the separating power of polyacrylamide gel electrophoresis (PAGE) to fractionate proteins, instead of immunoprecipitation. Fractionation can be either by one-dimensional SDS-PAGE (UNIT 10.2), or by two-dimensional PAGE in which isoelectric focusing is performed as the first dimension, followed by SDS-PAGE (UNIT 10.3). In each case, sample loading must be optimized so that best resolution of the protein of interest is achieved.

These protocols are written for both monolayer cells and suspension cells. To perform the procedure with suspension cells, the cells must be centrifuged down as quickly as possible after reacting with the appropriate pharmacological agents/receptor agonists, then treated as described for monolayer cultures. Obviously, the timing of the reactions is less precise this way, but experiments can be done successfully and reproducibly if reaction and centrifugation times are kept exactly the same.

CAUTION: Samples for SDS-PAGE or isoelectric focusing will still contain a great deal of ^{32}P at the latter stages of the protocol. Great care should be exercised in sample preparation. In particular do not use a probe sonicator to shear DNA, as ^{32}P -containing aerosols will be produced. In the case of SDS-PAGE, the gels should be run until the dye front passes out of the gel. This means that the SDS-PAGE running buffer will be also be contaminated with ^{32}P . In the case of isoelectric focusing the ^{32}P will focus out of the gel during electrophoresis; hence the running buffer will be contaminated with ^{32}P . These solutions should be disposed of as radioactive waste as local regulations dictate.

ALTERNATE PROTOCOL 1

Intact Cell Sample Preparation for SDS-PAGE

Additional Materials (also see Basic Protocol 1)

2× SDS-PAGE sample buffer (see recipe), 4°C

Bath sonicator

Boiling water bath

1. Prepare cells and perform permeabilization and labeling (see Basic Protocol 1, steps 1 through 8).
- 2a. *For monolayer cultures:* Stop the reactions by rapidly aspirating the permeabilization buffer and adding 100 to 250 μl of 4°C 2× SDS-PAGE sample buffer to each plate. Quickly scrape the cells into the buffer using a separate cell scraper for each plate and quantitatively transfer the sample to a screw-cap microcentrifuge tube.
- 2b. *For suspension cultures:* Microcentrifuge the reaction tubes 1 min at maximum speed, room temperature. Quickly aspirate the supernatants, taking care not to disturb the cell pellets. Add 100 to 250 μl of 2× SDS-PAGE sample buffer to each tube and vortex thoroughly.

When performing this step for suspension cultures it is very important to use exactly the same times for centrifugations if reproducible data are to be obtained.

3. If samples are very viscous as a result of DNA being released from cell nuclei, shear the DNA by placing the capped sample tubes in a bath sonicator filled with ice water and sonicating 5 min.
4. Boil samples 3 min in a boiling water bath.

To perform the analysis, carefully apply up to 50 μl of the samples to the sample wells of a precast SDS-PAGE gel. Proceed as described in UNIT 10.2.

Intact Cell Sample Preparation for Isoelectric Focusing

ALTERNATE
PROTOCOL 2

Additional Materials (also see Basic Protocol 1)

Two-dimensional-PAGE lysis buffer (see recipe), 4°C

Two-dimensional-PAGE sample buffer (see recipe)

Bath sonicator

Dry ice/ethanol bath

Lyophilizer

1. Prepare cells and perform permeabilization and labeling (see Basic Protocol 1, steps 1 through 8).
- 2a. *For monolayer cultures:* Stop the reactions by rapidly aspirating the permeabilization buffer and adding 100 to 250 μ l of 4°C two-dimensional-PAGE lysis buffer. Scrape the cells into the buffer using a separate cell scraper for each plate and transfer the sample to a screw-cap microcentrifuge tube.
- 2b. *For suspension cultures:* Microcentrifuge the reaction tubes 1 min at maximum speed, room temperature. Quickly aspirate the supernatants, taking care not to disturb the cell pellets. Add 100 to 250 μ l of two-dimensional PAGE lysis buffer to each tube and vortex thoroughly.

When performing this step for suspension cultures it is very important to use exactly the same times for centrifugations if reproducible data are to be obtained.

3. If samples are very viscous as a result of DNA being released from cell nuclei, shear the DNA by placing the samples in a bath sonicator filled with ice-water and sonicating 5 min. Freeze samples in a dry ice/ethanol bath, then lyophilize.
4. Redissolve the lyophilized samples in 50 to 100 ml of two-dimensional-PAGE sample buffer. Warm the samples to 37°C for 3 to 5 min.

To perform the analysis, apply 10 to 20 μ l of each sample to a prepared isoelectric focusing gel of the required pH gradient (see UNIT 10.3). Samples for isoelectric focusing must have a low salt concentration because a high salt concentration often causes band broadening during isoelectric focusing.

ANALYSIS OF PROTEIN PHOSPHORYLATION USING ISOLATED SUBCELLULAR FRACTIONS

BASIC
PROTOCOL 2

When the protein under study exists in a particular organelle and is phosphorylated in intact cells, one consideration when studying the phosphorylation event *in vitro* in isolated organelles is whether the protein is accessible to exogenously added kinases or phosphatases, or whether it is accessible to endogenous kinases or phosphatases. For instance, if it is a protein of the endoplasmic reticulum, is its location transmembrane or intraluminal? If transmembrane, is it normally phosphorylated on the cytosolic side or luminal side of the membrane?

Permeabilization protocols can also be used with intact intracellular organelles as well as intact cells. This is obviously an important consideration when dealing with proteins found inside the organelle in question. Another consideration here is whether the organelle can be isolated in an intact condition, or whether its contents will be partially or completely lost during purification. In the case of mitochondria this does not pose a problem, but for more fragile organelles such as the Golgi apparatus this may be more problematic.

The study of protein phosphorylation in isolated organelles (see Castle, 1995 for isolation procedures) can be a straightforward extension of the permeabilization protocols de-

Analysis of
Protein
Phosphorylation

18.8.7

scribed above (see Basic Protocol 1 and Alternate Protocols 1 and 2). The isolated organelle is treated in the same way as one would treat cultured cells in suspension. However, as there is little or no requirement for the maintenance of signal-transduction mechanisms in isolated organelles, the permeabilization procedure can be more prolonged than for intact cells. This allows the introduction of larger molecules such as purified protein kinases into the organelles under study.

Materials

Suspension of isolated intracellular organelles
Intracellular buffer (see recipe), 4°C
Permeabilization buffer (see recipe), 37°C
60 U/ml streptolysin O working solution (see recipe)
10 mM cold ATP stock solution (see recipe)
10 mCi/ml [γ -³²P]ATP (3000 Ci/mmol; e.g., DuPont NEN)
Reagents under study: e.g., kinase/phosphatase inhibitors, protein kinases, or phosphatases
2× lysis buffer for immunoprecipitation (see recipe), 4°C

Screw-cap microcentrifuge tubes
Benchtop ultracentrifuge (e.g., Beckman TL-100 or Airfuge)
37°C circulating water bath

1. Wash the organelle preparation three times with 4°C intracellular buffer, each time by ultracentrifuging 10 min at $\geq 100,000 \times g$. Transfer the equivalent of 1 mg of protein to individual screw-cap microcentrifuge tubes and keep on ice.

The best way to wash the organelle preparations is to use a Beckman TL-100 benchtop ultracentrifuge or the older Beckman Airfuge. Both of these instruments will produce g-forces $> 100,000 \times g$. Because of the difficulty in centrifuging some organelles (e.g., plasma membrane preparations) it is essential to use ultracentrifugation for all organelles except nuclei, which can be recovered by microcentrifuging 30 sec at maximum speed. See Castle (1995) for details of organelle isolation.

2. Ultracentrifuge the organelle preparation 10 min at $\geq 100,000 \times g$, 4°C, and aspirate the supernatant. Add 200 ml 37°C permeabilization buffer, mix gently, and transfer to the 37°C circulating water bath.

Work quickly at this point to minimize any proteolytic and other unwanted side reactions.

3. Add streptolysin O (from the 60 U/ml working solution) to each tube to a final concentration of 0.6 U/ml. Add cold ATP (from the 10 mM stock solution) to a final concentration of 100 μ M.

Exactly the same considerations apply when performing permeabilization of organelles as when performing permeabilization of intact cells (see Basic Protocol 1). However, because there is no intact signal-transduction machinery in isolated organelle preparations, the range of possible experiments is fewer, so the system is usually more robust than for intact-cell experiments.

4. Add 10 mCi/ml [γ -³²P]ATP to a final concentration of 50 to 500 μ Ci/ml.

The criterion for the amount of radiolabeled ATP to add (between 50 and 500 μ Ci/ml) is the detection limit. Initial experiments must be performed to see how much label must be added.

5. Add the reagents under study—e.g., kinase/phosphatase inhibitors, protein kinases, or phosphatases.

6. Add 200 ml of 4°C 2× lysis buffer to each tube to lyse the organelles. Mix well and place on ice for 5 min.
7. Microcentrifuge the samples 10 min at maximum speed, 4°C. Store lysates at –70°C.

The lysates are now ready for immunoprecipitation (UNIT 10.16).

ORGANELLE SAMPLE PREPARATION FOR ELECTROPHORETIC ANALYSIS OF PROTEIN PHOSPHORYLATION

Exactly the same considerations apply to the electrophoretic analysis of protein phosphorylation in isolated organelles as apply to permeabilized cells (see Alternate Protocols 1 and 2). Organelle preparations must first be ultracentrifuged and the supernatant removed before adding the appropriate buffer for electrophoresis. For this, the use of a Beckman TL-100 benchtop ultracentrifuge, which can provide g -forces $>300,000 \times g$, is recommended. Complete removal of the supernatant is especially important if two-dimensional-PAGE (Alternate Protocol 4) is used, as the salt concentration must be kept low.

CAUTION: Samples for SDS-PAGE or isoelectric focusing will contain a great deal ^{32}P at the latter stages of the protocol. Great care should be exercised in sample preparation. In the case of SDS-PAGE, the gels should be run until the dye front passes out of the gel. This means that the SDS-PAGE running buffer will be also be contaminated with ^{32}P . In the case of isoelectric focusing, the ^{32}P will focus out of the gel during electrophoresis; hence the running buffer will be contaminated with ^{32}P . These solutions should be disposed of as radioactive waste as local regulations dictate.

Organelle Sample Preparation for SDS-PAGE

Additional Materials (also see Basic Protocol 2)

2× SDS-PAGE sample buffer (see recipe)
Boiling water bath

1. Prepare organelles and perform permeabilization and labeling (see Basic Protocol 2, steps 1 through 5).
2. Ultracentrifuge samples 10 min at $100,000 \times g$, 4°C, and aspirate the supernatant. Add 50 μl of 2× SDS-PAGE sample buffer and mix well.
3. Boil the samples 3 min in a boiling water bath.

The samples are now ready for analysis by SDS-PAGE (UNIT 10.2).

Organelle Sample Preparation for Isoelectric Focusing

Additional Materials (also see Basic Protocol 2)

Two-dimensional-PAGE lysis buffer (see recipe)
Lyophilizer

1. Prepare organelles and perform permeabilization and labeling (see Basic Protocol 2, steps 1 through 5).
2. Ultracentrifuge samples 10 min at $>100,000 \times g$, 4°C, and aspirate the supernatant. Add 200 μl of two-dimensional-PAGE lysis buffer and mix well.
3. Lyophilize the samples overnight.

The samples are now ready for analysis by isoelectric focusing (UNIT 10.3). Samples for isoelectric focusing must have a low salt concentration because a high salt concentration often causes band broadening during the isoelectric focusing dimension.

**ALTERNATE
PROTOCOL 3**

**ALTERNATE
PROTOCOL 4**

**Analysis of
Protein
Phosphorylation**

18.8.9

DIRECT ANALYSIS OF CYTOSOLIC OR MEMBRANE-BOUND KINASES

This protocol utilizes isolated subcellular fractions in straightforward kinase assays by adding exogenous, purified protein kinases to the reaction mixture containing the organelle in question. This works only if the protein under study is phosphorylated by a cytosolic or membrane-bound kinase and its substrate is on the cytosolic face of the organelle. One can then determine the phosphorylation of proteins by analyzing the reaction mixture by SDS-PAGE. It is a good idea to perform the reactions and subsequent manipulations in screw-cap microcentrifuge tubes to minimize the risk of [^{32}P] contamination.

This protocol may be used to extend findings based on the use of the permeabilization strategies and assays with isolated organelles detailed elsewhere in this unit. Hence, if a protein of interest is phosphorylated, it can be useful to determine the subcellular localizations of the kinase(s) responsible, as this may make it possible to infer clues as to the identity of the kinase(s).

Materials

Appropriate kinase assay buffer (UNIT 18.7), 4°C
[γ - ^{32}P]ATP solution (see recipe in UNIT 18.7)
Suspension of isolated intracellular organelles, 4°C
Purified protein kinase of interest (keep on ice)
2× SDS-PAGE sample buffer (see recipe), ice-cold

Screw-cap microcentrifuge tubes
30°C and boiling water baths

1. Prepare the following reaction mixture in a screw-cap microcentrifuge tube at 4°C:

10 μl 5× kinase assay buffer
5 μl [γ - ^{32}P]ATP solution (5 μCi /5 μM ATP final)
1 to 35 μl organelle suspension (i.e., volume equivalent to 1 mg protein)
 H_2O to 50 to 100 μl .

After reaction mix has been assembled, warm to 30°C for 5 min.

2. Start reaction by addition of the purified protein kinase of interest. Incubate 15 min at 30°C.

In the case of immunoprecipitated enzymes adsorbed onto beads, the assay mix minus the enzyme source can be made up complete first. This can then be dispensed, prewarmed, onto the immunoprecipitates.

Incubation time can be adjusted as necessary depending on the extent of protein phosphorylation observed and the linearity of the reaction.

3. Stop the reactions by the addition of 100 μl of ice-cold 2× SDS-PAGE sample buffer. After thorough mixing, heat the samples 3 min in a boiling water bath.

The samples are then ready for resolution by SDS-PAGE (UNIT 10.2).

Samples for SDS-PAGE contain all the ^{32}P originally in the assays. Great care should be exercised in sample preparation and loading. The gels should be run until the dye front passes out of the gel. This means that the SDS-PAGE running buffer will be contaminated with ^{32}P , and this should be disposed of as radioactive waste as local regulations dictate.

DETERMINATION OF SPECIFIC RADIOACTIVITY

The specific radioactivity (specific activity) of any radioactive compound is defined as the number of atoms of the radioactive isotope in a molecule as a proportion of the total number of atoms of the same type. The structure of ATP is shown in Figure 18.8.2, and the form used in the study of protein kinases is $[\gamma\text{-}^{32}\text{P}]\text{ATP}$, indicating that only the γ phosphate group has the radioactive ^{32}P atom. There are, however, two other atoms of ^{31}P . Hence, to attain the maximum possible specific activity, one should replace 100% of all phosphorus atoms with the ^{32}P isotope. This is obviously not necessary in the case of kinase phosphotransfer reactions, as only the γ phosphate is transferred to a substrate; therefore in practice it is irrelevant whether the α and β phosphate groups have the ^{32}P label. The units used by vendors of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ are curies per mole (Ci/mol), even though the curie is no longer the international unit of radioactivity.

Figure 18.8.2 Structure of ATP highlighting the α , β , and γ phosphates/phosphorus atoms.

It is important to know the specific radioactivity of the ATP in a kinase assay, as important data can be derived from this information. Consequently this can be determined as required, although one can make assumptions based on the volume of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ added to cold ATP prior to the assay. Obviously, the specific activity of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ cannot be assumed when adding $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ to permeabilized cells or after labeling intact cells with $^{32}\text{P}_i$. In these cases, one can determine the specific activity experimentally as described below.

The specific radioactivity of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ can be determined by a number of methods, but the following are reliable and relatively simple. Methodologies for the extraction of ATP from either $^{32}\text{P}_i$ -labeled cells or from cell lysates are detailed below (Stephens and Downes, 1990). The basis for the extraction is the same in each case, but slightly different alternative steps are required. Protein or cell debris is first precipitated with perchloric acid and removed by centrifugation. The supernatants are then neutralized with a mixture of tri-*n*-octylamine and 1,1,2-trichlorotrifluoroethane (Freon). The aqueous phase from this step can then be directly analyzed for ATP concentration and ^{32}P content. ATP may be quantified using anion-exchange HPLC to separate nucleotides and a UV detector to detect nucleotides via UV absorption at 254 nm. The peak areas associated with injection of different amounts of ATP onto the column are then calculated and a standard curve constructed. The radioactivity associated with the ATP peak is easily determined by scintillation counting.

Materials

- ³²P-labeled cells or cell lysates
- Phosphate-buffered saline (PBS; APPENDIX 2)
- Standard ATP samples of known concentration in 4% perchloric acid 4% or 8% (v/v) perchloric acid, ice-cold
- Tri-*n*-octylamine (Sigma)
- 1,1,2-trichlorotrifluoroethane (Freon; e.g., Aldrich, Sigma)
- Linear gradient consisting of:
 - Solution A: Milli-Q water filtered through 0.2-mm filter
 - Solution B: 1.25 M NH₄H₂PO₄, pH 3.8 (adjust pH with H₃PO₄; filter through 0.2-mm filter)
- Nucleotide standard mix: e.g., 1 mM each of AMP, ADP, ATP, GMP, GDP, and GTP

- Cell scrapers
- Polypropylene screw-cap microcentrifuge tubes or 5-ml polypropylene tubes with very tight-fitting caps
- Tabletop centrifuge
- HPLC system consisting of:
 - Whatman Partisphere SAX HPLC column and guard column
 - Apparatus for producing linear gradient
 - UV detector set at 254 nm
 - Fraction collector
- Whatman low-dead-volume 0.2-mm syringe filters

- Additional reagents and equipment for HPLC (UNITS 10.12-10.14)

Extract ATP from cells or cell lysates

For labeled cells

- 1a. Aspirate the medium from the labeled cells and rinse twice with PBS. Aspirate the final wash thoroughly and place the cells on ice. Quickly add 0.5 ml of ice-cold 4% perchloric acid and mix gently to lyse the cells. Incubate 5 min on ice.
- 2a. Scrape the cells into the acid solution using a cell scraper and quantitatively transfer the lysate to a screw-cap microcentrifuge tube. Microcentrifuge 5 min at maximum speed, 4°C, to bring down the cell debris.
- 3a. Transfer the supernatant to a fresh tube and keep on ice. Freshly prepare a mixture of 1.2 parts tri-*n*-octylamine to 1 part Freon (on a v/v basis) and mix well. Add 0.6 ml of this mixture to the perchloric acid supernatants, cap the tubes tightly, and vortex for at least 1 min. Extract four to six standard ATP samples of known concentration in parallel with the test supernatants.

It is very important that the samples be mixed extremely thoroughly at this point to ensure complete neutralization.

For labeled cell lysates

- 1b. In a 5-ml polypropylene tube add an equal volume of ice-cold 8% perchloric to the amount of labeled cell lysate required and place on ice. Mix thoroughly and incubate 5 min on ice.
- 2b. Centrifuge 5 min (or until protein is completely pelleted) at 3800 × *g*, 4°C.
- 3b. Transfer the supernatant to a fresh tube and keep on ice. Freshly prepare a mixture of 1.2 parts tri-*n*-octylamine to 1 part Freon (on a v/v basis) and mix well. Add 1.2 vol of this mixture to the volume of sample remaining after protein precipitation and

vortex extremely well. Extract four to six standard ATP samples of known concentration in parallel with the test supernatants.

It is very important that the samples be mixed extremely thoroughly at this point to ensure complete neutralization.

Recover neutralized aqueous sample

4. After complete mixing, centrifuge 5 min at $3800 \times g$, room temperature.

*Three layers should be evident following centrifugation. The bottom layer is excess tri-*n*-octylamine/Freon, the central layer is octylamine perchlorate (which is often yellow in color), and the upper layer is the neutralized aqueous sample.*

5. Transfer the upper layer to a fresh tube and measure the pH using pH paper.

*The pH should be pH 6 to 7. If the pH of the sample is <6 , repeat the treatment with tri-*n*-octylamine/Freon, although this is rarely necessary.*

Quantitate ATP concentration

6. Equilibrate the SAX column in water for 30 min at 1 ml/min flow rate.

As an alternative to this step and subsequent steps it is possible to quantitate ATP using a luminescent assay. A very easy, sensitive and convenient assay for ATP is available from Sigma and is based on using the enzyme luciferase, which produces light from luciferin and ATP. Hence, at constant luciferin/luciferase concentrations, standard curves can be constructed for the quantum light yield at different ATP concentrations. Unknown samples derived from cell lysates can thus be easily quantitated. If, however, one needs to determine the specific radioactivity of the γ phosphate of ATP (as for $^{32}\text{P}_i$ -labeled cells), proceed as described in this protocol.

7. Subject the column to a blank gradient run—i.e., run the linear gradient to be used (from 100% solution A to 100% solution B) through the column but do not inject the sample.

A typical simple gradient is shown in Table 18.8.1. The initial 5 min allows the contents of the injection loop to be cleared and passed onto the column, assuming use of up to a 5-ml-volume loop. It is very important that the ionic strength of the sample be <200 mM for the inorganic phosphate to bind to the column. In practice, sample loops of up to 5-ml volume can be used successfully, allowing 0.5-ml samples to be diluted 10-fold with water before analysis.

Table 18.8.1 Gradient Profile for the Separation of Nucleotides by HPLC and Approximate Retention Times for Selected Nucleotides^{a,b}

Time (min)	%A	%B	Approximate retention time (min)		
			AMP/GMP	ADP/GDP	ATP/GTP
0	100	0			
5	100	0			
70	40	60	30/35	45/52	75/85
85	40	60			
90	0	100			
120	0	100			
125	0	0			

^aA = Milli-Q water; B = 1.25 M $\text{NH}_4\text{H}_2\text{PO}_4$ buffer, pH 3.8.

^bColumn = Whatman Partisphere SAX, 25 cm \times 4.6-mm i.d. The retention times for the nucleotides are approximate, as different HPLC systems produce slight differences in gradient delivery and different HPLC columns give different separations.

8. Filter standard mixture of nucleotides through a low-dead-volume syringe filter, then run on the SAX column.

A good mix to use is AMP, ADP, ATP, GMP, GDP, and GTP, all at a concentration of 1mg/ml. A 10-ml injection will result in easily detected peaks at 254 nm using the UV detector. Once consistent separation of the required standard nucleotides is made, the samples can be analyzed.

9. Filter the four to six ATP samples of known concentration (from step 5) through a low-dead-volume syringe filter and inject them into the SAX column. Construct a standard curve.

The unknown samples should fall around the center of the curve. In practice, this can be estimated according to the fact that the intracellular concentration of ATP is normally ~1 mM, so the starting cell volume can be used to roughly estimate the ATP concentration in the cell lysates.

10. Filter the unknown samples (from step 5) through a low-dead-volume syringe filter, then run them on the SAX column and collect the ATP peak (which absorbs at 254 nm) using a fraction collector connected in series after the UV monitor.

The concentration of ATP is then calculated.

11. Transfer an aliquot of the ATP peak to a scintillation vial and determine cpm.

The amount of [γ - ^{32}P]ATP is then calculated from the amount of ^{32}P associated with the peak absorbing at 254 nm.

SUPPORT PROTOCOL 2

DETERMINATION OF THE SPECIFIC ACTIVITY OF THE γ -PHOSPHATE OF [^{32}P]ATP

The above technique (see Support Protocol 1) details methods for the determination of the total ATP concentration and the amount of ^{32}P associated with that concentration. For the case of permeabilized cells where [γ - ^{32}P]ATP has been introduced specifically as the phosphate donor, the amount of radioactivity associated with ATP will give the specific activity of the γ phosphate. However, when cells are labeled with [^{32}P]inorganic phosphate ($^{32}\text{P}_i$) as in UNIT 18.2, the ^{32}P will be distributed between all of the phosphorus atoms in ATP and hence the total radioactivity will not give a meaningful result regarding the specific activity of the γ phosphate of ATP. Also, in permeabilization studies such as the ones described in this unit, it is good to know the final specific activity of the ATP because the [γ - ^{32}P]ATP is diluted with the ATP contained within the cells. A good method for obtaining this specific activity information is the one developed by Hawkins et al. (1983), which uses cyclic AMP-dependent protein kinase (cA-PrK) to phosphorylate the substrate histone 2A under conditions where the purified [^{32}P]ATP is the sole ATP in the assay. The ^{32}P -labeled ATP is completely used up during the phosphorylation of histone. Phosphorylated histone is easily separated from other ^{32}P -containing metabolites; hence the amount of ^{32}P associated with the γ phosphate of the labeled ATP is easily determined. The method detailed below is a slight modification of the Hawkins method and uses a peptide substrate in place of histone to allow greater specificity. This procedure is the basis for many protein kinase assays and is described in greater detail in UNIT 18.7. The details of assays for cA-PrK are dealt with in detail in that unit, along with specifics about assay buffers and substrate preparation.

Materials

- Cell lysates containing unknown [^{32}P]ATP concentrations
- cA-PrK (purified subunit from bovine heart; Calbiochem) and 10 \times cA-PrK assay buffer (see recipe)
- 0.5 mM cyclic AMP (cAMP; Calbiochem)

10 mg/ml kemptide (Sigma)
1 M DTT (store at -20°C)
0.5 M MgCl_2
75 mM orthophosphoric acid
Acetone

Screw-cap microcentrifuge tubes

P 81 phosphocellulose paper, precut and labeled (Support Protocol 3 in *UNIT 18.7*)

30°C circulating water bath

Additional reagents and equipment for precipitating ^{32}P -labeled peptide on P 81 paper (Support Protocol 3 in *UNIT 18.7*)

1. For each lysate to be assayed, prepare the following reaction mixture in a screw-cap microcentrifuge tube on ice:

25 μl [γ - ^{32}P]ATP-containing lysate
5 μl $10\times$ cA-Prk assay buffer
1 μl 0.5 mM cAMP
5 μl 10 mg/ml kemptide
1 μl 1 M DTT
1 μl 0.5 M MgCl_2
2 μl H_2O .

Once all assay tubes have been set up and labeled, cap tubes and keep on ice.

2. Start one reaction every 30 sec by directly adding 15 U cA-PrK to the reaction mixture and transferring the tube to a 30°C water bath. Incubate for the optimal period of time.

Because the objective is to transfer all of the γ -phosphate of ATP if possible, a relatively large amount of cA-PrK is required. Initially, 15 U per tube can be used; this can be adjusted for later experiments.

The optimal assay time must be determined empirically by performing a time course. Times of 60, 120, 180, and 240 min should be tried; the time chosen should be one after the incorporation of ^{32}P into kemptide has reached a plateau.

3. Pipet 30 μl of the contents of each tube onto the surface of prepared P 81 paper squares (see *UNIT 18.7*, Support Protocol 1). Immediately place the squares in a beaker of 75 mM orthophosphoric acid.
4. Once all the assay tubes have been treated as in step 3, wash the P 81 paper squares five times with 75 mM orthophosphoric acid as described in *UNIT 18.7*, Support Protocol 1.
5. Fill the beaker with acetone and wash the papers an additional 5 min as described in *UNIT 18.7*, Support Protocol 1. Discard the acetone and allow the papers to dry at room temperature.
6. Place each square of P 81 paper in a separate 20-ml scintillation vial and determine the associated radioactivity using a scintillation counter.

Once the number of dpm of ^{32}P transferred is known, it is a simple task to calculate the specific activity of the ATP input into the experiment. For example—if the amount of total ATP has been determined to be 10 μmol , the radioactivity associated with ATP is 220,000 dpm, the amount of ^{32}P transferred to kemptide is 110,000 dpm, and the amount of ^{32}P remaining is 110,000 dpm—then there are 125,000 dpm of ^{32}P in the γ -phosphate of ATP as there are $\sim 2.2 \times 10^6$ dpm per μCi . Hence, 110,000 dpm is equivalent to 0.05 μCi , so the specific activity of the γ -phosphate of ATP is 0.5 mCi/mmol.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

ca-PrK assay buffer, 10×

500 mM Tris·Cl, pH 7.5 at 30°C (APPENDIX 2)

50 mM MgCl₂

Store up to 6 months at -20°C

Cold ATP stock solution, 10 mM

Mix equal volumes of 20 mM MgCl₂ and 20 mM disodium ATP. Slowly raise the pH of the solution to 7.4 with 1 M NaOH using constant stirring. Filter sterilize and store in small aliquots up to 1 year at -20°C.

Extracellular buffer

110 mM NaCl

10 mM KCl

1 mM MgCl₂

1.5 mM CaCl₂

30 mM HEPES

10 mM glucose

Filter sterilize and store up to 1 month at 4°C

Intracellular buffer

25 mM NaHCO₃

120 mM KCl

1 mM KH₂PO₄

10 mM MgCl₂

20 mM HEPES

10 mM glucose

Filter sterilize and store up to 1 month at 4°C

Lysis buffer for immunoprecipitation, 2×

100 mM HEPES

200 mM NaCl

40 mM EDTA

4 mM EGTA

100 mM NaF

20 mM β-glycerophosphate

2 mM Na₃VO₄

2% (v/v) NP-40 or Triton X-100

Filter sterilize and store up to 6 months at 4°C

This buffer has a 10× concentration of EDTA to chelate the excess magnesium used in kinase reactions.

PBS/BSA

Dissolve 10 mg bovine serum albumin (BSA) in 100 ml PBS (APPENDIX 2). Filter sterilize using a low-protein-binding membrane (e.g., 0.2-μm Millipore GV filters) and store up to several months at 4°C.

Permeabilization buffer

120 mM KCl
25 mM NaHCO₃
5 mM HEPES
10 mM MgCl₂
1 mM KH₂PO₄
1 mM EGTA
300 mM CaCl₂
Filter sterilize and store up to several months at 4°C

This buffer has a free ionized calcium concentration of ~100 nM.

SDS-PAGE sample buffer, 2×

4 ml 0.125 M Tris·Cl, pH 6.8 (APPENDIX 2)
4 ml 10% (w/v) SDS
1 ml glycerol
0.4 ml 2-mercaptoethanol
0.6 ml H₂O
20 mg bromphenol blue
Filter sterilize and store up to 6 months at -20°C

The pH of the Tris buffer is measured at room temperature.

Streptolysin O solutions

600 U/ml stock solution: Make up a stock solution of 600 U/ml streptolysin O in PBS (APPENDIX 2) and snap-freeze in liquid nitrogen. Store at -70°C in small aliquots up to several months.

60 U/ml working solution: Immediately before the experiment, dilute the 600 U/ml stock solution to 60 U/ml with PBS/BSA (see recipe). Keep on ice until ready to use.

Two-dimensional-PAGE lysis buffer

20 mM Tris·Cl, pH 8.0 (APPENDIX 2)
0.3% (w/v) SDS
1% (v/v) 2-mercaptoethanol
Filter sterilize and store up to 6 months at -20°C

Two-dimensional-PAGE sample buffer

6 g urea
4 ml NP-40
0.5 ml 40% ampholytes of the required pH range (UNIT 10.3)
0.154 g DTT
1.12 ml H₂O
Filter sterilize and store in small aliquots up to 1 month at -70°C

IMPORTANT NOTE: *Use the best-purity urea available so that the concentrations of the breakdown products of urea—carbamic acid and ammonia—are minimized. This is important because proteins can be carbamylated in solution by these breakdown products, thereby altering the native protein's net charge and hence its isoelectric point.*

COMMENTARY

Background Information

The permeabilization of cells has become a popular method for the study of the regulation of signal-transduction mechanisms. In practice, similar methodologies can be used to study the different types of receptor-regulated intracellular communication mechanisms such as those regulated by heterotrimeric G-protein-coupled receptors, receptor tyrosine kinases, and cytokine receptors (Hawkins et al., 1983; Stephens and Downes, 1990; Alexander et al., 1992; Stutchfield and Cockcroft, 1993; Slowiejko et al., 1994; Stephens et al., 1994; Cunningham et al., 1995; Martys et al., 1995; Taylor et al., 1995). Although permeabilization protocols are very simple in theory, they are very much more problematic in practice. This is because different cells have different permeabilization properties; hence each time one applies permeabilization protocols to a new cell type, one must reexamine the experimental protocol in detail before reproducible data may be obtained. Similarly, different permeabilization-inducing agents are available, but they are not easily interchangeable, nor do they show predictable properties in the maintenance of signal-transduction processes in different cell types. The current agent of choice is streptolysin O, a bacterial toxin from the organism *Streptococcus pyogenes*. Streptolysin O has been used to study G-protein-coupled receptors and receptor tyrosine kinases; for these systems it appears to work quite reproducibly (Hawkins et al., 1983; Stephens and Downes, 1990; Alexander et al., 1992; Stutchfield and Cockcroft, 1993; Slowiejko et al., 1994; Stephens et al., 1994; Cunningham et al., 1995; Martys et al., 1995; Taylor et al., 1995).

A series of experiments utilizing cell permeabilization will not produce quick results. It will, however, produce data not normally obtainable using other experimental approaches.

A number of preliminary experiments must be performed to determine the optimal conditions for the permeabilization of intact cells, as well as for the time of addition for various reagents. Aspects to be considered include the following.

1. The kinetics of phosphorylation of the protein under study in intact cells must be determined.

2. The time for cold ATP/[γ - 32 P]ATP equilibration with intracellular processes—e.g., phosphatidic acid formation and phosphatidylinositol-4-phosphate or phosphatidylinositol-

4,5-bisphosphate synthesis—must be determined. The timing of the addition of [γ - 32 P]ATP to the permeabilization medium must be optimized—e.g., should the [γ - 32 P]-ATP be added at the same time as the permeabilization agent, or some time later?

3. If possible, the integrity and time course of the receptor activation of a known signal-transduction mechanism should be determined—e.g., one might determine whether MAP kinase is activated under the conditions of permeabilization indicated in the experiments performed under point 2, above, as well as the optimal time for activation and how long the response is detectable.

4. One should experiment with the timing of the addition of receptor agonists—e.g., can a receptor agonist be added at the same time as the permeabilization agent, at the same time as the [γ - 32 P]ATP, or some time after these reagents?

5. It should be determined whether the protein under study is phosphorylated under the same conditions as the reporter activity observed under point 3, above, in the permeabilized cells.

6. The timing of when inhibitors/activators or other reagents need to be added should be determined, as well as their concentration for optimal function in the permeabilized cells.

Once these issues have been resolved, experiments can easily be optimized and the phosphorylation event under study examined in detail.

Critical Parameters and Troubleshooting

A number of problems can be experienced when using permeabilization protocols. High-quality streptolysin O must be used, and each preparation of streptolysin O should be tested according to the supplier's instructions before use.

The timing for addition of all reagents to the cells must be strictly reproduced within experiments and between experiments. If large variability is noted between experiments and the various timings have been strictly observed, then the problem is almost always due to the streptolysin O preparation used. The solution should then be checked per the supplier's instructions.

Another problem that may be encountered is hydrolysis of [γ - 32 P]ATP by endogenous ATPases. This should always be assayed in any

experiment by determining the production of [³²P] inorganic phosphate during the time course of the experiment. If the ATP concentration is depleted by >10% during the course of the experiment, one can include general ATPase inhibitors in the permeabilization buffer. One such inhibitor is ouabain; however the potential exists for the ATPase inhibitor to inhibit whatever process is being studied; hence more experiments are required to determine the result empirically for each inhibitor to be used.

Anticipated Results

Once the optimal conditions for permeabilization, ATP addition, agonist addition, and inhibitor addition have been determined it is relatively straightforward to study a novel phosphorylation event. Initially, one can detect the phosphorylation of the protein under study as a result of receptor activation. If pharmacological tools are available—e.g., inhibitors/activators of specific protein kinases—it is possible to make a provisional identification of the kinase responsible for the phosphorylation event being examined. It is also possible to determine the proximity of the phosphorylation event to receptor activation.

Time Considerations

The entire permeabilization procedure can be completed in ~2 hr. After this time, the samples generated can be prepared for analysis by immunoprecipitation or directly analyzed by SDS-PAGE. Immunoprecipitation times are dependent on the antibodies being used, but high-affinity interactions should only require 1 to 2 hr of incubation at 4°C. Harvesting the immunoprecipitates with protein A-Sepharose will take 1 hr at 4°C, and the washing procedure then takes 30 min before the samples can be prepared for SDS-PAGE.

One-dimensional SDS-PAGE gels can generally be run in ~3 hr for a regular-sized gel or 1 hr for a minigel. The gels can then be stained to the required level in 1 to 2 hr before placing on a gel dryer for 1 to 2 hr. Once the gel has been stained and dried, it can be analyzed by either standard autoradiography or using a Phosphorimager. The exposure times required are dependent on the radioactivity contained in the protein bands. For regular autoradiography using an intensifying screen, one can see a band containing a few hundred cpm with an overnight exposure at -70°C. A Phosphor screen will give similar data with ~4 hr exposure.

For two-dimensional-PAGE analysis, the samples can be placed in the lyophilizer over-

night prior to electrophoresis. The two-dimensional-PAGE procedure will take one day to complete before the gel can be dried and analyzed by autoradiography or with a Phosphorimager.

Phosphopeptide Mapping and Identification of Phosphorylation Sites

UNIT 18.9

Many proteins in the cell are modified by phosphorylation. Protein phosphorylation can affect catalytic activity, localization of a protein in the cell, protein stability, and the ability of a protein to dimerize or form a stable complex with other molecules. There are several techniques available to find out whether or not a protein is modified by phosphorylation. To understand exactly why a particular protein becomes phosphorylated, it may be necessary to identify precisely which amino acid residues are phosphorylated. These residues can then be changed by site-directed mutagenesis, and the mutant protein can be examined for changes in activity, intracellular localization, and association with other proteins in the cell.

Studies geared towards understanding the phosphorylation of a particular protein usually start with labeling of the protein in intact cells followed by phosphoamino acid analysis (UNITS 18.2 & 18.3). Proteolytic digestion of a ^{32}P -labeled protein, followed by separation of the digestion products in two dimensions on a TLC plate, will give rise to a phosphopeptide map (see Basic Protocol 1). Phosphopeptides present on the TLC plate are visualized by autoradiography. These maps give information about the number of phosphate-containing peptides in the digest, and this is related to the number of phosphorylation sites present in the protein. Phosphopeptide maps can also be used to find out whether the sites of phosphorylation on a protein change upon treatment of cells with certain agents. Treatment of cells could lead to a reduction in the labeling of certain peptides and an increase in the labeling of other peptides present on the peptide map. This suggests that treatment results in a loss of phosphorylation at certain sites and an increase in phosphorylation at other sites. The identification of the sites of phosphorylation requires further analysis of the phosphopeptides present on these maps (see Support Protocol 1 and Basic Protocols 2 and 3). If 10 pmol of phosphorylated material can be generated, phosphopeptides can be purified by HPLC and identified directly by mass spectrometry or peptide microsequencing (see Support Protocol 2).

TRYPTIC PHOSPHOPEPTIDE MAPPING OF PROTEINS ISOLATED FROM SDS-POLYACRYLAMIDE GELS

**BASIC
PROTOCOL 1**

^{32}P -labeled proteins are resolved by SDS-PAGE and visualized following autoradiography. Protein bands are cut out of the dried gel and the protein of interest is isolated by extraction from the gel and TCA precipitation in the presence of carrier protein. The precipitated protein is oxidized in performic acid and digested with trypsin. The bicarbonate buffer is evaporated by several rounds of lyophilization, the tryptic peptide mix is spotted on a TLC plate and peptides are resolved by electrophoresis and chromatography in two dimensions and visualized by autoradiography.

Materials

- Samples containing ^{32}P -labeled proteins of interest (UNIT 18.2)
- Fluorescent ink or paint (can be obtained from most arts and crafts supply stores)
- 50 mM ammonium bicarbonate, pH 7.3 to 7.6 (when freshly prepared the buffer has a pH of ~7.5), and pH 8.0 (the pH drifts overnight to ~8.0, ideal for digestion with trypsin or chymotrypsin as in step 18)
- 2-mercaptoethanol
- 20% (w/v) SDS
- 50 mM ammonium bicarbonate, pH 7.3 to 7.6, containing 0.1% (w/v) SDS and 1.0% (v/v) 2-mercaptoethanol

**Analysis of
Protein
Phosphorylation**

2 mg/ml carrier protein (RNase A, BSA, or immunoglobulins) in deionized water
(store in aliquots at -20°C or -70°C)
100% (w/v) trichloroacetic acid (TCA)
96% ethanol, ice-cold
30% (w/v) hydrogen peroxide
98% (w/v) formic acid
1 mg/ml TPKK-treated trypsin (e.g., Worthington) in deionized water or 0.1 mM
HCl (store in aliquots at -70°C or under liquid nitrogen)
Electrophoresis buffers (see recipe): pH 1.9, 3.5, 4.72, 6.5, and 8.9
Green marker dye (see recipe)
Chromatography buffer (see recipe)

Single-edge razor blades or surgical blades
Scintillation counter appropriate for Cerenkov counting
1.7-ml screw-cap microcentrifuge tubes (Sarstedt)
Disposable tissue grinder pestles (Kontes)
Platform rocker
Tabletop centrifuge with swinging-bucket rotor
Glass-backed TLC plates (20×20 cm, 100 μm cellulose; EM Science)
Low volume adjustable pipet with long disposable tips made of flexible plastic,
e.g., gel-loading tips
Air line fitted with filter to trap aerosols and particulate matter
HTLE 7000 electrophoresis apparatus (CBS Scientific)
Polyethylene sheeting (35×25 cm; CBS Scientific)
Electrophoresis wicks (20×28 cm sheet of Whatman 3MM paper folded
lengthwise to give double thickness sheets of 20×14 cm)
Chromatography tank (CBS Scientific)
Fan for drying TLC plates
65 $^{\circ}\text{C}$ drying oven

Additional reagents and equipment for SDS-PAGE (UNIT 10.2) and autoradiography
(APPENDIX 3A)

Isolate ^{32}P -labeled protein by SDS-PAGE and recover from the gel

1. Resolve the samples containing the ^{32}P -labeled protein of interest by SDS-polyacrylamide gel electrophoresis (SDS-PAGE; UNIT 10.2).
2. Following electrophoresis, dry the gel, mark it around the edges with fluorescent ink, and expose to X-ray film (autoradiography; APPENDIX 3A).
3. Localize the protein of interest in the gel by aligning fluorescent markers around the gel precisely with their images on the film. Staple the film and gel together and place this sandwich film-side-down on a light box. Mark the position of ^{32}P -labeled protein bands on the back of the gel using a soft pencil or ballpoint pen (do not use a felt-tip marker).
4. Separate the gel from the film and cut out the protein bands from the individual lanes of the gel using a single-edge razor blade. Strip the paper backing from the gel slices and remove residual bits of paper by scraping gently with a razor blade. Try not to shave pieces from the gel because this will reduce recovery of the protein of interest. Place each gel slice in a 1.7-ml screw cap tube and determine the amount of radioactivity by Cerenkov counting in a scintillation counter.
5. Rehydrate each dry gel slice in 500 μl of 50 mM ammonium bicarbonate, pH 7.3 to 7.6, for 5 min at room temperature. Mash the gel slice using a Kontes tissue grinder pestle until no bits are seen when the tube is held up to the light. Add 500 μl of 50

mM ammonium bicarbonate, pH 7.3 to 7.6, 10 μ l of 2-mercaptoethanol, and 10 μ l of 20% SDS. Boil 2 to 3 min.

6. Extract the protein from the gel by incubation on a rocker for at least 4 hr at room temperature or for at least 90 min at 37°C.

For convenience, extractions can be done overnight.

7. Collect the gel slurry at the bottom of the tube by centrifuging 5 min at 500 \times g, room temperature, in a tabletop centrifuge with a swinging-bucket rotor. Transfer the supernatant to a new 1.5-ml microcentrifuge tube.

IMPORTANT NOTE: The brand of tube is important. From this point on use a brand of tubes that does not produce unwanted side reactions or retain too many cpm at the final transfer step (see Critical Parameters). The authors use microcentrifuge tubes from Myriad Industries.

8. Before starting the second elution, measure the volume of the first eluate and calculate the volume to be used for the second elution so that the volume of the combined eluates will measure \sim 1300 μ l. For the second elution, resuspend the gel pellet in the calculated appropriate volume of 50 mM ammonium bicarbonate containing 0.1% SDS and 1.0% 2-mercaptoethanol. Vortex, then boil 2 to 3 min and extract again by incubation on a rocker for at least 90 min.
9. Separate the gel from the eluate again by centrifugation as in step 7 and transfer the supernatant to the tube containing the first eluate.
10. To clear the combined eluate of gel slurry that has been inadvertently transferred, microcentrifuge 5 to 10 min at full speed, then transfer the supernatant to a new microcentrifuge tube. Before discarding the gel bits, monitor by Cerenkov counting to ensure that 60% to 90% of the 32 P-labeled protein has been extracted.

It is important to remove all gel fragments, and it may be worthwhile to repeat the last centrifugation step one more time.

11. Cool the eluates by placing them on ice. Add 20 μ g carrier protein (10 μ l of a 2 mg/ml stock), mix well, add 250 μ l ice-cold 100% TCA, mix well, and incubate for 1 hr on ice.
12. Collect the protein precipitate by microcentrifuging 5 to 10 min at full speed, 4°C. Decant the supernatant, then microcentrifuge again for 3 min at 4°C and aspirate the last traces of TCA.
13. Wash the TCA precipitate by adding 500 μ l ice-cold 96% ethanol, invert the tube a few times, and microcentrifuge 5 min at full speed, 4°C. Decant the bulk of the supernatant, microcentrifuge again for 3 min at 4°C, and aspirate the residual liquid. Air dry the protein pellet (do not lyophilize).
14. Monitor the precipitate by Cerenkov counting to make sure that the majority of the 32 P-labeled protein has been recovered.

There should be as many or slightly more cpm in the sample at this point as compared to the eluate (see step 10), since the liquid of the eluate will have quenched the counting somewhat.

Incubate with performic acid to achieve oxidation of the 32 P-labeled protein

15. Generate performic acid by incubating 9 parts formic acid with 1 part 30% hydrogen peroxide for 60 min at room temperature. Cool the performic acid by placing it on ice.

16. Resuspend the TCA-precipitated protein pellet in 50 μ l of the ice-cold performic acid and incubate 60 min on ice.
17. Add 400 μ l deionized water, mix, and freeze on dry ice. Evaporate the performic acid under vacuum in a SpeedVac evaporator.

It is extremely important to dilute and then freeze the sample before evaporating it, otherwise the elevated temperature of the SpeedVac evaporator may cause acid hydrolysis of the sample.

A sample (5% to 10% of the digest, at least 200 cpm) can be taken at this point for phosphoamino acid analysis. Lyophilize and proceed as described in UNIT 18.3.

Perform proteolytic digestion with trypsin

18. Resuspend the protein pellet in 50 μ l of 50 mM ammonium bicarbonate, pH 8.0, and add 10 μ g trypsin (10 μ l of a 1 mg/ml stock). Digest for 3 to 4 hr or overnight at 37°C.
19. Add a second 10 μ g aliquot of trypsin and digest again for 3 to 4 hr or overnight at 37°C.
20. Add 400 μ l deionized water, and lyophilize in a SpeedVac evaporator. Resuspend the pellet in 400 μ l deionized water and lyophilize again. Repeat these steps until at least four lyophilizations have been achieved.

At this stage there should be no visible pellet.

21. Resuspend the tryptic digest in 400 μ l electrophoresis buffer or deionized water.

The authors use pH 1.9 buffer or pH 4.72 buffer for samples that will be analyzed by electrophoresis at pH 1.9 and pH 4.72, respectively, and deionized water for samples that will be analyzed by electrophoresis at pH 8.9.

22. Clear the peptide mix of all particulate matter by microcentrifuging 5 to 10 min at full speed, transfer the supernatant to a new microcentrifuge tube, and lyophilize. Measure the amount of 32 P-radioactivity in the final sample by Cerenkov counting.

It is very important that there be no particulate matter in this final supernatant, and it may be worthwhile to repeat this centrifugation step one more time.

23. Resuspend the digest in at least 5 μ l of pH 1.9 electrophoresis buffer, pH 4.72 electrophoresis buffer, or deionized water, and collect the sample at the bottom of the tube by microcentrifuging 2 to 5 min at full speed.

Perform first-dimension electrophoresis on a TLC plate

24. Mark the sample and dye origins on the cellulose side of a glass-backed TLC plate with a small cross, using an extra-soft, blunt pencil, making sure not to perturb the cellulose layer (or alternatively mark on the reverse side with a permanent marker).

This is most easily done by placing the plate on top of a "life-size" marking template on a light box (Fig. 18.9.1).

25. Spot each sample onto the corresponding origin using an adjustable low-volume pipet fitted with a long flexible tip (round, gel-loading tips work well). Apply 0.2 to 0.5 μ l drops, and dry between applications using an air line fitted with a filter to trap aerosols and particulate matter, and a 1 ml syringe or a Pasteur pipet to focus the air flow.

Avoid touching the plate with the air nozzle or the pipet tip, since gouges on the cellulose may affect electrophoresis or chromatography. Ideally, at least 1000 cpm should be loaded onto the TLC plate. A brown ring around the circumference of the spot is normal.

26. Spot 0.5 μl of green marker on the dye origin at the top of the plate (Figs. 18.9.1 and 18.9.2).

This marker dye is green, but separates into its blue (xylene cyanol FF) and yellow (e-dinitrophenyllysine) components during electrophoresis (Fig. 18.9.2D).

27. Prepare the HTLE 7000 apparatus as described below, referring to Figure 18.9.3.
- Fill the buffer tanks so that the level of the electrophoresis buffer is ~ 5 cm deep. Place a sheet of polyethylene on the Teflon cover that protects and insulates the base and tuck the ends down between the base and the buffer tanks to hold the sheet in place.
 - Wet the electrophoresis wicks in electrophoresis buffer and slide them into the slots of the buffer tank with the folded edge up. Fold the ends of the wicks over the polyethylene sheet on the base. Place the second polyethylene sheet over the base, the electrophoresis wicks, and part of the buffer tank.

Figure 18.9.1 Sample and dye origins and blotter dimensions for separation of peptides at different pH values. **(A)** Location of the sample and dye origins for electrophoresis at pH 1.9 and pH 4.72 and **(B)** at pH 8.9. To mark a TLC plate, the plate is placed on top of a life-size template. This is then placed on top of a light box and the origins are marked on the cellulose side using a very blunt extra soft pencil. Dimensions of the blotter and the location of two holes that fit over the sample and dye origins are shown **(C)** for at pH 1.9 and 4.72 and **(D)** for pH 8.9.

- c. Place the second Teflon sheet and the neoprene pad on top, close the apparatus, and secure the lid with the two pins. Inflate the airbag by turning up the air pressure to 10 psi to squeeze out excess buffer from the electrophoresis wicks. Keep the air pressure on until ready to start the first run.
- d. After the samples have been loaded on the TLC plates (steps 25 and 26) and one is ready to start the electrophoresis, shut off the air pressure and open the apparatus. Remove the neoprene pad and the top Teflon and polyethylene sheets, and fold back the electrophoresis wicks. Wipe both polyethylene sheets dry with tissue paper.

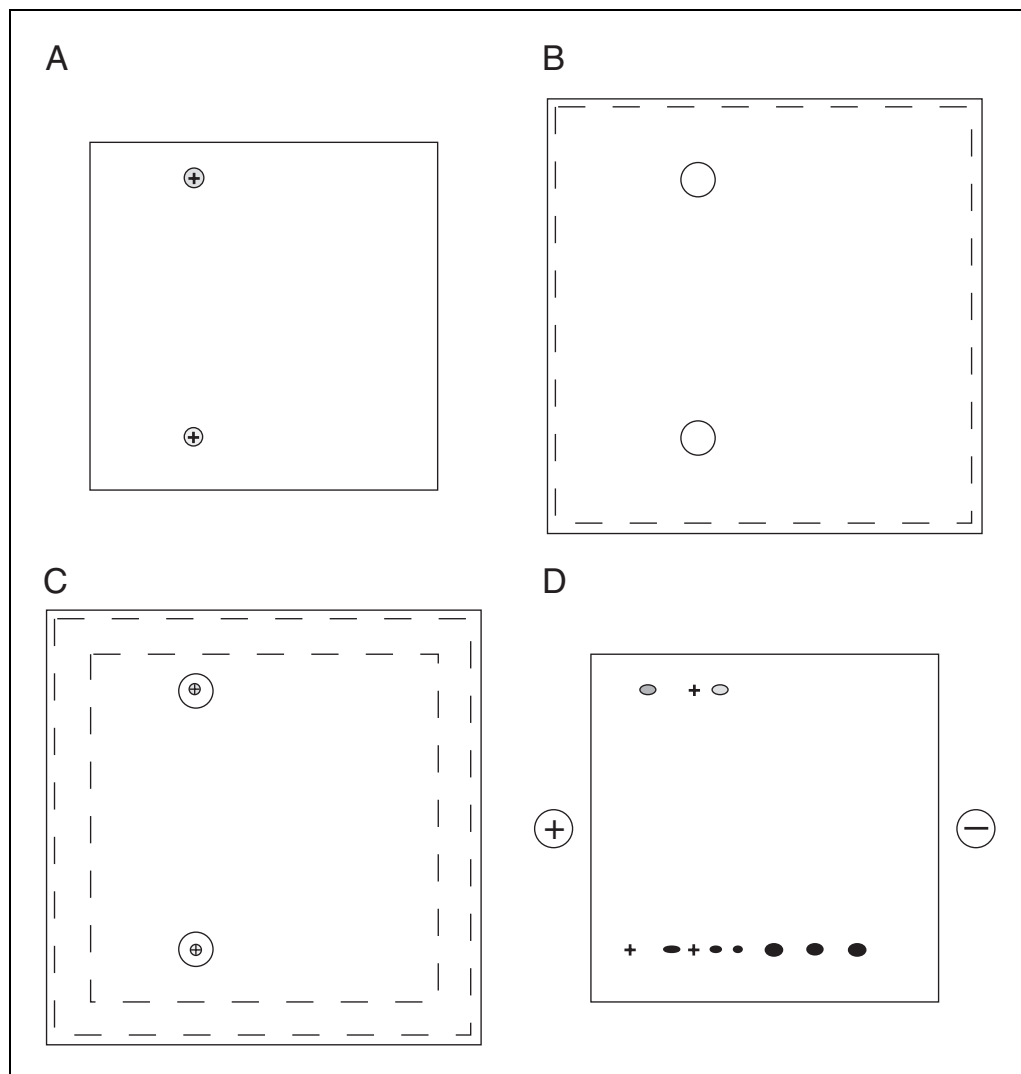

Figure 18.9.2 Separation of peptides by electrophoresis. **(A)** The sample and dye are spotted on their respective origin at the bottom and the top of the TLC plate as described in the text. **(B)** The blotter is soaked briefly in the electrophoresis buffer, and excess liquid is removed by blotting briefly on a piece of 3MM filter paper. **(C)** The TLC plate is wetted by placing the wetted blotter on top, with the sample and marker origins in the centers of the two holes. The blotter is pressed onto the TLC plate around the sample and marker origins to ensure uniform flow of electrophoresis buffer from the blotter towards the sample and marker origins. This will result in concentration of the sample and marker dye on their respective origins, and will improve resolution. The rest of the blotter is pressed with a flat hand onto the TLC plate, the blotter is removed and the plate is examined ; it should be dull-gray with no shiny puddles of buffer. Excess buffer should be allowed to evaporate or be blotted very carefully with tissue paper. The plate is placed on the apparatus and the electrophoresis run for 20 to 30 min at 1 kV. This results in separation of the peptides in the first dimension **(D, peptides shown in black)**. The position of the anode and cathode are indicated in panel D.

- e. Wet the TLC plate containing a sample as described in Figure 18.9.2 and place the plate on the polyethylene sheet covering the base. Fold the wicks over the plate so they cover ~1 cm of the plate at each end and carefully reassemble the apparatus as described above. Avoid lateral movement of the polyethylene sheet when it is in contact with the TLC plate. Secure the lid with the pins, inflate the airbag to 10 psi, turn on the cooling water flow, and start the electrophoresis.

At this point the authors concentrate the sample by wetting the TLC plates with electrophoresis buffer using a blotter with holes around the origin (Figs. 18.9.1 and 18.9.2). The blotter is made from two layers of Whatman 3MM paper, stitched together around the edges. The 1.50-cm holes that surround the origins (Fig. 18.9.1) are cut with a sharp cork borer. These blotters can be reused many times; it is best to keep a separate blotter for each buffer.

The buffer has to move with similar speed from the entire circumference towards the origin. The sample will inevitably streak if the buffer takes a long time to wet the spot, or moves unevenly through the spot.

- f. Perform electrophoresis for 20 to 30 min at 1.0 kV.

Electrophoresis results in separation of the peptides in one dimension (Fig. 18.9.2).

28. After completing the run, disassemble the apparatus and air dry the plate with the help of a fan for at least 30 min after electrophoresis is completed.

Do not dry in an oven as this will bake the peptides onto the cellulose, thereby interfering with the separation in the chromatography dimension.

Perform second-dimension separation by chromatography

29. Apply a drop (~0.5 μ l) of green marker dye in the left or right hand margin of the plate at the same level as the sample origin, avoiding the area that has been compressed by contact with the electrophoresis wick (Fig. 18.9.4). Place the dried plates in an almost upright position in the chromatography tanks with the appropriate chromatography buffer (see Critical Parameters), and replace the lid. Do not disturb or open a tank while chromatography is in progress. Allow the buffer to run to within 1 to 2 cm of the top of the plate.

Figure 18.9.3 Preparation of the HTLE 7000 electrophoresis system.

Figure 18.9.4 Separation of peptides in the second dimension by chromatography. After electrophoresis, air-dry the plate. A fan may be used to facilitate this. Add a small amount of green marker dye in the left hand (A) or right hand margin at the same level as the sample origin. Place the plate(s) almost upright in a chromatography tank, replace the lid and run the chromatography until the buffer front reaches to within 1 to 2 cm from the top of the TLC plate (B and C). This results in separation of the peptides in the second dimension (D, peptides shown in black). Open the tank, take out all plates, let the plates air dry, apply fluorescent ink at the margins of the plate and expose to X-ray film.

See Figure 18.9.4 for illustrations of these procedures. For information on selecting an appropriate chromatography buffer, see Critical Parameters.

30. Remove all TLC plates from the chromatography tank at the time the tank is opened. Allow the plates to dry for 1 hr in a fume hood or for 15 min in a 65°C oven.

Do not use the oven if peptides are to be extracted from these plates for further analysis.

31. Mark the dried plates with fluorescent ink around the edge; these reference marks can be used later to align the autoradiogram with the TLC plate. Expose the plates to X-ray film in the presence of an intensifier screen for autoradiography (APPENDIX 3A), or to a phosphorimager screen. If needed recover peptides for further analysis (see Support Protocol)

X-ray film may be presensitized for increased sensitivity (see APPENDIX 3A).

PROTEOLYTIC DIGESTION OF IMMOBILIZED PROTEINS

ALTERNATE PROTOCOL

Isolation of proteins from polyacrylamide gels is a lengthy and laborious procedure (see Basic Protocol 1). In addition, recoveries can be poor. Saving time can be important if one is working with the limited amounts of ^{32}P radioactivity present in proteins labeled in intact cells. As an alternative, proteins can be transferred to nitrocellulose or PVDF membranes, followed by digestion of the immobilized protein. The peptides are oxidized after digestion and elution from the membrane. Obviously, this approach is not a good choice for proteins that transfer with poor efficiency.

Additional Materials (also see Basic Protocol 1)

Methanol

0.5% (w/v) PVP-360 in 100 mM acetic acid (see recipe)

50 mM ammonium bicarbonate, pH 8.0

PVDF membrane (Immobilon P, Millipore) or nitrocellulose membrane (*UNIT 10.8*)

Saran Wrap or Mylar

Additional reagents and equipment for wet or semidry protein transfer (*UNIT 10.8*)

1. Resolve the ^{32}P -labeled samples by SDS-polyacrylamide gel electrophoresis (*UNIT 10.2*) and transfer the proteins to a PVDF or nitrocellulose membrane using a standard wet or semidry protein-transfer protocol (*UNIT 10.8*).
2. Air dry the membrane and wrap it in Saran Wrap or Mylar to prevent the membrane from sticking to the film, mark with fluorescent ink (see Basic Protocol 1, step 2), and expose the blot to X-ray film (autoradiography; *APPENDIX 3A*).
3. Align the film with the membrane using the fluorescent markers and their images on the film to identify the exact position of the protein of interest on the membrane (see Basic Protocol 1, step 3).
4. Cut out the strips of membrane containing the protein of interest with a single-edge razor blade, then cut this strip into several smaller pieces. Place all pieces of membrane containing a particular phosphate-labeled protein in a single microcentrifuge tube. Quantify the amount of radioactivity present on these strips of membrane by Cerenkov counting.
5. Rewet the membrane by adding 500 μl methanol, wash the membrane strips several times with deionized water, and incubate for 30 min at 37°C with 0.5% PVP-360 in 100 mM acetic acid.
6. Wash the membrane at least five times, each time with 1 ml deionized water, then two times, each time with 1 ml of 50 mM ammonium bicarbonate, pH 8.0.
7. Add enough 50 mM ammonium bicarbonate to cover the pieces of membrane (usually 200 to 400 μl), then add 10 μg TPCK-trypsin (10 μl of a 1 mg/ml stock). Incubate for at least 2 hr at 37°C.
8. Add another 10 μl aliquot of 1 mg/ml TPCK-trypsin and incubate again for 2 hr at 37°C.
9. Vortex briefly, then microcentrifuge briefly at full speed to collect all liquid at the bottom of the tube and transfer the supernatant to a fresh microcentrifuge tube. Rinse the membrane pieces with 500 μl of deionized water, microcentrifuge briefly, and add the rinse to the supernatant.

Analysis of Protein Phosphorylation

18.9.9

**SUPPORT
PROTOCOL 1**

10. Lyophilize in a SpeedVac evaporator and quantitate the elution of ^{32}P -labeled peptides by Cerenkov counting.

80% to 90% of the radioactivity should be in the eluate.

11. Oxidize the peptides by incubation in performic acid (see Basic Protocol, steps 15 to 17).
12. Add 500 μl of deionized water, lyophilize, and proceed with electrophoresis on TLC plate (see Basic Protocol, steps 21 to 31).

ISOLATION OF PHOSHOPEPTIDES FROM THE CELLULOSE PLATE

Individual phosphopeptides can be isolated from the TLC plate for further analysis. The location of the phosphopeptides on the TLC plate is determined by aligning the autoradiogram with the TLC plate. The cellulose containing the phosphopeptide of interest is scraped off the plate and sucked into a pipet tip fitted with a 25 μm filter. Peptides are eluted from the cellulose and lyophilized in a SpeedVac evaporator.

Materials

TLC plate with resolved phosphopeptides and corresponding autoradiogram (see Basic Protocol 1 or Alternate Protocol)
Electrophoresis buffer, pH 1.9 (see recipe)

Single-edge razor blades
1000- μl (blue) pipet tips
Small sintered polyethylene disk to fit inside blue tips (Kontes)
Glass rod or similar instrument to push filters into tips

Prepare the elution tips

1. Using a sharp razor blade, carefully remove the collar portion of the wide end of the blue tip. Trim ~ 3 mm off the small end of the tip as well.
2. Using a glass rod, push a sintered polyethylene disk in through the wide end of the blue tip until it fits snugly in the tip.

Use of a glass rod with the same diameter as the disk helps keep the disk straight, i.e., perpendicular to the length of the tip. Do not push the disk down too far or it will cause the tip to bulge out and crack. The sintered disk will serve as a barrier across the pipet tip to catch the cellulose as it is scraped from the plate. It therefore must fit securely in the tip, able to withstand the pull of the vacuum line.

This is the most difficult part of this protocol—but be consoled by the fact that once made, a good tip will last forever!

3. Test the placement of the disk in the tip by attaching a piece of tubing to the wide end of the tip, with the other end of the tubing connected to a vacuum line. Now apply a strong vacuum and use one finger to block off the small end of the elution tip. Examine to make sure that the sintered disk stays in place.

If the sintered disk stays in place, the elution tip is ready to use.

Mark the location of peptides to be eluted

4. Hold the TLC plate, cellulose side up, over a light box. Place the autoradiogram directly onto the cellulose layer of the plate, precisely aligning the reference marks on the plate with their images on the film.
5. Using a dark laboratory marker, trace the outline of the spot(s) of interest on the (glass) underside of the TLC plate.

Be conservative—when vacuuming two adjacent spots there should always be cellulose left on the plate between the two.

6. Remove the film, put the plate down on the lightbox, and use a soft lead pencil to trace the marker outline, this time on the cellulose side so it will be possible to see the outline without the benefit of the lightbox.

Vacuum the cellulose and elute the peptide(s)

7. Connect the elution tip to a vacuum via a piece of tubing and turn the vacuum on.
8. Use the small end of the elution tip to scrape the cellulose off a spot of interest; the cellulose will be sucked up against the filter barrier in the tip as it is scraped from the plate. When the spot is completely removed from the plate, ease the tubing off the wide end of the elution tip, keeping the small end upright.

The same spot can be vacuumed from multiple plates into one elution tip. However, after repeated use, the small end of the elution tip becomes “dull,” and it becomes increasingly difficult to scrape the cellulose from the plate. When this happens, use a razor blade to trim a thin sliver of plastic from the small end of the tip to recreate the sharp edge.

9. Place the elution tip into a 1.5-ml microcentrifuge tube with the wide end down and the side of the sintered disk containing the vacuumed cellulose up.

The elution tip now becomes a little column.

10. Immediately pipet 100 μ l of electrophoresis buffer, pH 1.9 (elution buffer) onto the cellulose; let this soak in while other spots are vacuumed from the plate.

The elution buffer used here should be pH 1.9. If pH 1.9 buffer fails to elute all the phosphopeptide, try deionized water.

11. When all spots have been vacuumed and the last one has been left to soak in buffer for ~5 min, place the microcentrifuge tubes, tips and all, into a microcentrifuge. Run the microcentrifuge at full speed for ~3 sec, then shut it off. Pipet another 100 μ l elution buffer onto the cellulose in each tube and let it sit and soak for another 5 min before centrifuging it through the column. Repeat the elutions five times to give 600 μ l of eluate in each tube.

This is usually enough to elute >90% of the radioactivity from the cellulose.

12. Remove the elution tip from each of the microcentrifuge tubes, being careful to leave all the eluate in the tube (some may cling to the sides of the tip as drops, which should be removed and added back to the contents of the tube). Save the elution tip. If eluting more than one spot, keep track of which tip was used for which peptide.
13. Clarify the eluate(s) by microcentrifuging 5 min at full speed (a small cellulose pellet will be visible after centrifugation; its size will depend on how snugly the sintered disk fits into the elution tip). Transfer the supernatant to a fresh microcentrifuge tube.

It is very important to remove all traces of cellulose at this point, as contamination of the phosphopeptide with cellulose can ruin further analyses.

14. Count both the eluate and the “empty” elution tips by Cerenkov counting.

~90% of the radioactivity should be in the eluates, with little remaining in the cellulose left in the tips.

Given the pain and frustration involved in their manufacture, a good elution tip should be saved and reused. To clean these tips, apply a vacuum to the small end of the tip and suck the cellulose out (into a vacuum flask) while aspirating ~10 ml elution buffer or deionized water through the tip to rinse it. Dry and then count the tips on a scintillation counter before reusing them.

15. Lyophilize the eluates in a SpeedVac, then count them by Cerenkov counting.

The counts here should be slightly higher than those of the liquid eluate. The number of cpm in this final sample of eluted peptide will often determine how it can be analyzed further.

DETERMINATION OF THE POSITION OF THE PHOSPHORYLATED AMINO ACID IN THE PEPTIDE BY MANUAL EDMAN DEGRADATION

If insufficient material is available for direct sequencing, a manual Edman degradation of the peptide can be performed to determine at which position the phosphorylated amino acid is present in the peptide. During each cycle of Edman degradation, the most amino-terminal amino acid residue is released from the peptide, and a sample from the reaction mixture is taken after each cycle. Phosphoserine or phosphothreonine is released as a derivative of serine or threonine and free phosphate; in contrast, phosphotyrosine is released as the anilinothiazolinone derivative of phosphotyrosine. Free phosphate and the PTH derivative of phosphotyrosine can be separated from the peptide by electrophoresis on a TLC plate. This approach indicates at which cycle the radioactivity and thus the phosphorylated amino acid is released from the peptide.

Materials

- Eluted phosphopeptide (see Support Protocol 1)
- 5% (v/v) phenylisothiocyanate (PITC) in pyridine
- 10:1 (v/v) heptane/ethyl acetate—mix 10 parts heptane with 1 part ethyl acetate
- 2:1 (v/v) heptane/ethyl acetate—mix 2 parts heptane with 1 part ethyl acetate
- 100% (w/v) trifluoroacetic acid (TFA)
- Electrophoresis buffer, pH 1.9 (see recipe)
- 200 to 500 cpm ^{32}P (prepared by diluting ^{32}P orthophosphate with deionized water)
or 2 mg/ml PTH-phosphotyrosine (see recipe)
- Microcentrifuge tubes (Myriad Industries)
- 45°C water bath
- Scintillation counter appropriate for Cerenkov counting
- Glass-backed TLC plates (20 × 20 cm, 100 μm cellulose; EM Science)
- 65°C drying oven or fan
- Additional reagents and equipment for electrophoresis of peptides on a TLC plate (see Basic Protocol 1 and Figure 18.9.3) and autoradiography (APPENDIX 3A)

Determine experimental parameters

1. Decide the number of cycles to be run based on the list of candidate peptides.

The number of cycles is designated as X. The starting volume for each cycle will be 20 μl.
2. Dissolve the eluted peptide in 20 μl deionized water in what will be called the reaction tube (a microcentrifuge tube).
3. Remove a sample equal to 20/(X + 1) μl to a new tube; this is the starting material sample. Store this at 4°C.

This sample will be lyophilized with the other cycle fractions at a later point.

Perform the Edman reactions

4. Add enough deionized water to the reaction tube to restore the volume to 20 μl. Count the sample at this point:
 - a. to insure that the expected number of cpm have in fact been removed from the initial sample (as the starting material sample);

- b. to check the cpm at the start of each given cycle.
5. Add 20 μl of 5% phenylisothiocyanate in pyridine to each reaction tube, vortex well, spin briefly in a microcentrifuge to collect the sample at the bottom, and incubate at 45°C for 30 min.
 6. Add 200 μl of 10:1 heptane/ethyl acetate to each reaction tube and vortex for 15 sec. Microcentrifuge 1 min at full speed to separate the two phases.
The pyridine will partition into the (upper) organic phase.
 7. Carefully remove the upper organic phase using a plastic transfer pipet. Reextract the (bottom) aqueous phase a second time with 10:1 heptane/ethyl acetate as in step 6.
 8. Extract the aqueous phase two more times as in step 6, this time using 2:1 heptane/ethyl acetate.
 9. Freeze the aqueous phase on dry ice and lyophilize in a SpeedVac evaporator.
 10. Dissolve the dried sample in 50 μl of 100% trifluoroacetic acid (TFA) and incubate this at 45°C for 10 min.
 11. Lyophilize the sample in a SpeedVac evaporator.
 12. Count the sample by Cerenkov counting.
There should be the same number of cpm as at the beginning of the cycle (i.e., at step 4 in this case).
 13. Add 20 μl deionized water to the reaction tube, vortex, and microcentrifuge briefly. Remove a portion for analysis of the first-cycle products that is equal to $20/X$. Store this at 4°C with the starting material sample.
 14. Add deionized water to restore the sample volume to 20 μl to start the second cycle. Repeat steps 5 to 12.
 15. After the second cycle, add 20 μl deionized water, resuspend the remaining sample, and remove $20/(X-1)$ μl to a new tube for analysis of the second-cycle products. Repeat steps 4 to 12.
 16. Continue repeating steps 4 to 12 until the desired number of cycles have been run.
For each new cycle, the amount of the sample to be removed is $20/X-Y$ where Y equals the cycle number minus 1.

Analyze the Edman products

17. Lyophilize all samples to dryness in a SpeedVac evaporator. Count all final samples by Cerenkov counting,
18. If lyophilized, dissolve the samples in 5 μl of pH 1.9 electrophoresis buffer or deionized water. Microcentrifuge 2 min at maximum speed to bring down any insoluble material.
Alternatively, if the sample volumes removed after each cycle are small enough, skip steps 17 and 18 and load the samples directly onto the TLC plate.
19. Spot all samples from the analysis of a given phosphopeptide at least 1 cm apart on a line of origins running vertically through the center of the TLC plate (Fig. 18.9.5). As a marker, depending on the phosphoamino acid content of the peptide under investigation, spot 50 to 200 cpm of [^{32}P]phosphate or 1 to 2 μg PTH-phosphotyrosine (0.5 to 1.0 μl of 2 mg/ml PTH-phosphotyrosine) at an origin on that same vertical

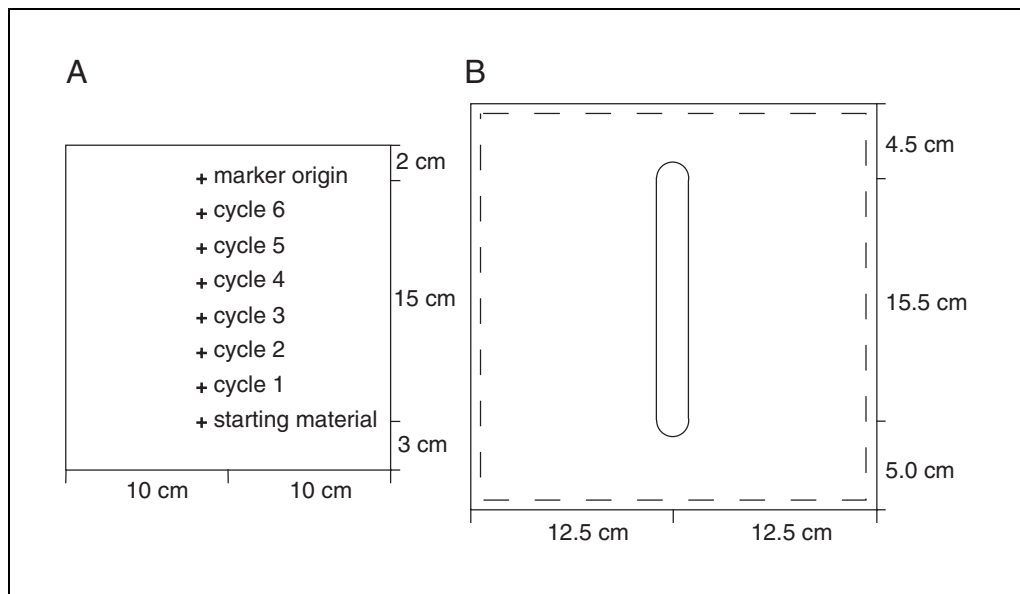

Figure 18.9.5 Sample and dye origins and blotter dimensions for analysis of manual Edman degradation products at pH 1.9. **(A)** Location of the sample and standard origins. To mark a TLC plate, the plate is placed on top of a life-size template on top of a light box and the origins are marked on the cellulose side using a very blunt extra-soft pencil. **(B)** Dimensions of the blotter and the location of the slot that fits over multiple sample and marker origins. The blotter is soaked in electrophoresis buffer, blotted with a sheet of Whatman paper to remove most of the buffer, and placed on top of the TLC plate so that the origins are in the middle of the slot.

line. Load $\frac{1}{3}$ to $\frac{1}{2}$ μl of sample at a time, air drying the sample between applications (see Basic Protocol 1, step 25).

20. Wet the plate as described in Figure 18.9.5.
21. Prepare the HTLE 7000 apparatus and electrophorese the samples for 25 min at 1.0 kV in pH 1.9 electrophoresis buffer (see Basic Protocol 1 and Figure 18.9.3).
22. After drying the plate (either in a 65°C oven or with a fan) mark it appropriately with radioactive or fluorescent markers and expose it to presensitized film with an intensifying screen at -70°C (autoradiography; APPENDIX 3A).

**BASIC
PROTOCOL 3**

**DIAGNOSTIC SECONDARY DIGESTS TO TEST FOR THE PRESENCE OF
SPECIFIC AMINO ACIDS IN THE PHOSHOPEPTIDE**

Further information about a phosphopeptide of interest can be obtained by digestion with sequence-specific proteases or cleavage by site-specific chemicals. After incubation with a protease or chemical, the peptide is analyzed by separation in two dimensions on a TLC plate. A change in mobility upon treatment with a particular reagent indicates that the peptide was susceptible to cleavage, and consequently that the amino acid or amino acid sequence that confers susceptibility to cleavage by this reagent must be present in the peptide.

Materials

- Eluted phosphopeptide (see Support Protocol 1)
- Enzyme to be used for digestion and appropriate buffer (see Table 18.9.1)
- 2-mercaptoethanol

Table 18.9.1 Specificities and Digestion Conditions for Enzymes and Other Cleavage Reagents

Enzyme or reagent	Specificity ^a	Digestion conditions	Comments
TPCK-trypsin	K—X; R—X	pH 8.0-8.3	Does not cut K/R-P; cuts inefficiently at K/R-X-P.Ser/P.Thr and K/R-D/E; cuts wells at K/R-P.Ser/P.Thr; cuts X-K/R-K/R-K/R incompletely
α-Chymotrypsin	F—X; W—X; Y—X	pH 8.3	Does not cleave F/W/Y-P or P.Tyr-X
Thermolysin	X—L; X—I; X—V	pH 8.0, 1 mM CaCl ₂ , 55°C	Will recognize most apolar residues to some extent; CaCl ₂ may affect the electrophoretic mobility
Proline-specific endopeptidase	P—X	pH 7.6	—
Cyanogen bromide (CNBr)	M—X	50 mg/ml CNBr in 70% formic acid, 90 min, 23°C	CNBr is toxic; will only cleave unoxidized methionine
V8 protease	E—X	pH 7.6	V8 will not cleave at every E in whole proteins; does give a consistent pattern
Endoproteinase Asp-N	X—CSO ₃ H; X—D	pH 7.6	Will cleave X-E at high enzyme concentrations
Formic acid	D—P	70% formic acid, 37°C, 24-48 hr	—

^aThe dash indicates the cleavage site. See APPENDIX 1C for definitions of the one-letter abbreviations for amino acids.

Electrophoresis buffer of appropriate pH (see recipe)

Water bath at appropriate temperature for enzyme digestion

Glass-backed TLC plates (20 × 20 cm, 100 μm cellulose; EM Science)

Additional reagents and equipment for chromatography and electrophoresis of phosphopeptides (see Basic Protocol, steps 24 to 31)

1. Dissolve the eluted phosphopeptide in 50 μl of the appropriate buffer in a microcentrifuge tube and microcentrifuge briefly to collect all solution at the bottom of the tube. Check the pH of the peptide solution by spotting 1 μl on a piece of pH paper to be sure that this final pH will allow enzyme activity. If the buffer's pH has been altered dramatically by addition of the peptide, adjust it before adding enzyme.
2. Remove a portion of the sample (usually 50%) to be run both as an undigested control and as a mix with a portion of the digested sample.
3. Add 1 to 2 μg enzyme to the portion of the sample to be digested, vortex, and concentrate the sample in the bottom of the tube by microcentrifuging briefly.
4. Incubate all tube(s) in a water bath at the appropriate temperature for at least 1 hr.
5. Add another aliquot of enzyme and continue the incubation step for an additional hour.
6. Add 1 μl of 2-mercaptoethanol to each sample and boil 5 min to inactivate the enzyme

Do this to all samples to ensure uniformity of sample preparation.

It is necessary to completely inactivate the enzyme prior to loading the sample on the plate when analyzing a mix of digested and undigested peptide, since the undigested sample may be rapidly digested when the two samples are mixed.

7. Lyophilize the samples in a SpeedVac evaporator.
8. Resuspend the samples by vortexing vigorously in 6 μ l of electrophoresis buffer of the appropriate pH. Microcentrifuge at full speed to bring down insoluble material.
9. Load half of the undigested sample on a single TLC plate. Load half of the digested sample on each of two TLC plates; on one of these load the other half of the corresponding undigested sample as a mix.
10. Perform electrophoresis and chromatography on the plate as described above in Basic Protocol 1, steps 24 to 31. Based on the position where the particular phosphopeptide being analyzed ran in the original map, choose a pH and running time that will allow good separation of the peptide from its potential cleavage products but will ensure retention of the smaller cleavage products on the plate.

**SUPPORT
PROTOCOL 2**

**PREPARATION OF PHOSHOPEPTIDES FOR MICROSEQUENCE
DETERMINATION OR MASS SPECTROMETRY**

The following is a general protocol and list of considerations for generating enough material for analysis by mass spectrometry or microsequencing starting with either intact cells or an in vitro system.

1. Optimize ^{32}P labeling of the protein of interest.

If the site of interest is seen only in stimulated cells, a time course of phosphorylation following stimulation may be helpful, as would determination of the optimal concentration of agonist.

If an in vitro system is being employed, determine the optimum conditions (time, and ratio of kinase and substrate concentrations) for the kinase reaction. Include 1 mM cold ATP in the reactions to maximize the stoichiometry. UNIT 18.7, which deals with in vitro phosphorylation reactions, provides a detailed discussion of these parameters and how to manipulate them.

2. Calculate the number of cells or amount of substrate needed to isolate 10 pmol phosphorylated material.

Even under optimal conditions, it is often not possible to achieve more than 25% stoichiometry of phosphorylation in vitro. In intact cells, the stoichiometry may be even less. It cannot hurt to overestimate the amount of starting material required, as the losses taken during the isolation procedures will always exceed expectation.

3. When calculating how to scale up the reactions, consider the following points.

- a. The radioactivity of these samples is only used for visualization purposes—i.e., to determine which gel band to isolate, which phosphopeptide to isolate from the TLC plate, and which HPLC fraction(s) to use for final analysis. Thus, the majority of the material can be unlabeled, as only \sim 1000 cpm per map spot are necessary for analysis at the time when the preparative HPLC is run. When isolating overexpressed protein from cells, labeling only 2 or 3 dishes of the 20 needed to generate enough material may be sufficient. When using an in vitro system, perform only one reaction using γ [^{32}P]-ATP (include only the very minimum amount of cold ATP necessary for kinase activity) to generate the labeled material. To generate enough material for further analysis, perform an additional kinase reaction with unlabeled ATP only. For visualization, mix the labeled and unlabeled samples before resolving them by SDS-PAGE.

- b. The efficiency of protein elution decreases as the amount of gel increases, so try to keep the number of lanes on the preparative gel(s) to a minimum. About four lanes/slices of acrylamide gel can be successfully extracted per tube.
- c. If ~20 μg substrate protein is present in each elution sample, it will not be necessary to add carrier protein at the TCA precipitation step (see Basic Protocol 1 step 11). This will result in a cleaner sample, as the tryptic fragments of the carrier protein will be eliminated from the mix of fragments run on the TLC plate.
- d. The 20 μg trypsin used to digest map samples in Basic Protocol 1 is in vast excess. While it is important that the digestion go as far to completion as possible, it is probably not necessary to scale up the amount of trypsin used. Instead, consider pooling several like samples at the performic acid digestion step (at the end of the 60 min incubation in order to give the protein the maximum time to dissolve). Adding 1 to 5 μg (total) trypsin to even 50 μg of protein for digestion is not unreasonable. Minimizing the amount of trypsin used will in turn minimize the amount of “extra” protein loaded on each TLC plate and ensure that the sample does not streak due to overloading.
- e. Determine the number of TLC plates to be run based on the amount of total protein to be analyzed—total protein includes the amount of trypsin and the amount (if any) of carrier protein used as well as the amount of the protein of interest. Even though the capacity of the TLC plates is ~100 μg , to ensure good separation, no more than 60 μg of protein should be run on each plate.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

Chromatography buffers

Phosphochromatography buffer:

750 ml *n*-butanol
500 ml pyridine
150 ml glacial acetic acid
600 ml deionized water
Store at room temperature

Isobutyric acid buffer:

1250 ml isobutyric acid
38 ml *n*-butanol
96 ml pyridine
58 ml acetic acid
558 ml deionized water

Regular chromatography buffer:

785 ml *n*-butanol
607 ml pyridine
122 ml glacial acetic acid
486 ml deionized water

Store all of the above buffers up to 6 months at room temperature.

Electrophoresis buffers

For each of these buffers, mix well and check the pH. Record the pH and the date on the bottle; if the pH is more than a tenth of a unit off, remake the solution. Do not adjust the pH. Store all buffers at room temperature.

pH 1.9 buffer:

50 ml formic acid (88% w/v)
156 ml glacial acetic acid
1794 ml deionized water

pH 3.5 buffer

100 ml glacial acetic acid
10 ml pyridine
1890 ml deionized water

pH 4.72 buffer

100 ml *n*-butanol
50 ml pyridine
50 ml glacial acetic acid
1800 ml deionized water

pH 6.5 buffer

8 ml glacial acetic acid
200 ml pyridine
1792 ml deionized water

pH 8.9 buffer

20 g ammonium carbonate
2000 ml deionized water

Green marker dye

Prepare a solution containing 5 mg/ml ϵ -dinitrophenyllysine (yellow) and 1 mg/ml xylene cyanol FF (blue) in pH 4.72 electrophoresis buffer (see recipe) diluted 1:1 with deionized water. Store up to 1 year at room temperature.

PTH-phosphotyrosine, 2 mg/ml

Combine 20 μ l of 100 mg/ml phosphotyrosine with 20 μ l of 5% (v/v) phenylisothiocyanate in pyridine. Incubate 30 min at 45°C. Extract twice with 200 μ l of 10:1 (v/v) heptane/ethyl acetate, then twice with 200 μ l of 2:1 (v/v) heptane/ethyl acetate (see Basic Protocol 2, steps 6 to 8, for extraction technique). Freeze the aqueous phase and lyophilize in a SpeedVac evaporator. Dissolve the sample in 0.1 N HCl, incubate 20 min at 80°C, and lyophilize again in a SpeedVac evaporator. Dissolve in 1 ml pH 1.9 buffer (see recipe for electrophoresis buffers).

PVP-360 in 100 mM acetic acid

0.5 g PVP-360 (Sigma)
575 μ l glacial acetic acid
99.4 ml deionized water
Store up to 1 year at room temperature

COMMENTARY

Background Information

Phosphopeptide mapping is a very sensitive technique that can help the investigator answer a variety of questions about a protein of interest. For some, phosphopeptide mapping is a tool to find out whether a particular protein is phosphorylated on one or more sites. This question can be answered by simply running a phosphopeptide map of the protein labeled in living cells. Other investigators want to know whether the increase in phosphorylation seen when cells are treated with a particular agent is restricted to one or more specific sites or whether it is evenly distributed over all phosphorylation sites present in the protein. Finally, detailed analysis of phosphopeptides isolated from a TLC plate can be used to identify the residues that are phosphorylated in a protein of interest.

Several different strategies may be followed to identify the phosphorylation site represented by a particular spot on a phosphopeptide map. This is most definitively accomplished by eluting phosphopeptides from cellulose plates for either direct sequencing or for analysis by mass spectrometry (see Support Protocol; Fischer et al., 1991; Wang et al., 1993; Mitchelhill et al., 1997). While these two techniques require expensive instruments and expertise not found in most laboratories, such analysis can often be arranged by collaboration. However, sometimes it is not possible to take advantage of these techniques, since they require 1 to 10 pmole of material for analysis. For a 50-kDa protein one would need 0.1 to 1.0 μg starting material, assuming 50% recovery and 100% stoichiometry of phosphorylation at the site of interest. Use of an *in vitro* phosphorylation system that mimics the situation in intact cells will simplify matters greatly. Further considerations and strategies for preparation of samples for these two techniques are discussed at the end of this chapter in Support Protocol 2.

Another approach to phosphorylation-site identification is to make an educated guess as to the identity of the site. Clues to a site's identity include phosphoamino acid analysis of the individual phosphopeptide (UNIT 18.3); the result of manual Edman degradation of a phosphopeptide providing the cycle at which the phosphate is released and thus the position of the phosphorylated residue in the peptide (see Basic Protocol 2); and secondary enzymatic digests of the phosphopeptide that can be used in a diagnostic sense to determine the presence of other specific amino acids in the peptide (see

Basic Protocol 3). All three of these techniques are easily accomplished in a laboratory that is already set up for phosphopeptide mapping. The first step in all three is the isolation of the phosphopeptide from the cellulose plate (see Support Protocol 1). The validity of one's guess can be tested by phosphopeptide mapping of a mutant protein lacking a phosphate acceptor at the site in question. Alternatively the guess can be substantiated by synthesizing the tryptic phosphopeptide and testing it for comigration with the phosphopeptide isolated from the peptide map.

Critical Parameters and Troubleshooting

Generating phosphopeptide maps

Keep in mind that the sort of analyses presented throughout this unit will give information regarding only the acid-stable forms of phosphoamino acids (i.e., phosphoserine, phosphothreonine, and phosphotyrosine) and will essentially ignore other forms such as phosphohistidine and phosphoaspartate, should they be present.

Carrier Protein. The authors prefer to use RNase as carrier protein during TCA precipitation, particularly when analyzing proteins labeled in intact cells, because it degrades ^{32}P -labeled RNA species that may have copurified with the protein of interest. The nucleotides generated by the degradation of RNA do not precipitate in TCA.

Cleaving the protein. In order to generate a phosphopeptide map, the ^{32}P -labeled protein needs to be cleaved into smaller fragments that can be separated by electrophoresis and chromatography on TLC plates. To do this requires an enzyme or chemical agent that cleaves reproducibly and with a certain frequency. If not enough cleavage sites are present, the fragments generated will be too large and will not be separated easily by electrophoresis and chromatography on TLC plates. In addition, large fragments may contain multiple phosphorylation sites. This leads to maps that are less informative and more difficult to analyze. The authors routinely use trypsin and chymotrypsin. Other reagents are available (Table 18.9.1), but most of them cut much less frequently and some of them do not work very efficiently on full-length proteins.

Removing ammonium bicarbonate. Following digestion, repeated cycles of lyophilization

are carried out to evaporate all ammonium bicarbonate. The presence of salts in the sample will interfere with the electrophoretic separation of the peptides. After lyophilization, the protein digest appears as an invisible film at the bottom of the tube. The presence of any crystalline material indicates the presence of salts, most likely ammonium bicarbonate that can be removed by additional rounds of lyophilization.

Controlling oxidation. Both cysteine and methionine can give rise to several oxidized derivatives. The oxidation state of these amino acids affects the mobility of peptides during chromatography, resulting in separation of oxidation state isomers. This complicates the interpretation of the phosphopeptide map. To prevent this, the protein or peptides are oxidized by incubation in performic acid at 4°C. Incubation at higher temperatures may give rise to unwanted side reactions and should be avoided.

Elution and TCA precipitation or transfer to a membrane? In Basic Protocol 1, the ³²P-labeled protein is isolated from a small slice of a dried polyacrylamide gel by rehydrating and grinding up the gel followed by elution in a buffer containing SDS and 2-mercaptoethanol. The protein is subsequently TCA precipitated, oxidized, and digested with trypsin. This is a time-consuming and laborious procedure. Yields are variable and usually not better than 50%. The alternative is to transfer the protein to a PVDF membrane; any unoccupied protein-binding sites on the strips of membrane containing the protein of interest are blocked by incubation with PVP-360 in acetic acid before incubation with trypsin. Most peptides dislodge from the membrane during the digestion. This protocol is much faster and less laborious, and does not require the use of additional carrier proteins that may lead to overloading of the TLC plate and to streaky maps. Obviously this method is a poor choice for proteins that transfer poorly from the polyacrylamide gel to a membrane. In addition, it is possible that certain peptides that are generated during protease digestion retain a high affinity for the membrane and therefore fail to elute. If those peptides contain a phosphorylation site, this site will not be represented on the peptide map. This can lead to misinterpretations of the results. It is therefore advisable to first compare maps generated with Basic Protocol 1 and the Alternate Protocol. If these maps are identical, and if the protein transfers well from the gel to the membrane, the Alternate Protocol should be the protocol of choice.

Amount of sample. The authors like to load at least 1000 cpm on a plate for a peptide map. If the final sample has many more than 1000 cpm and a “pretty-looking” map is desired, it may be better to load only a fraction of the sample. Remember that overloading can lead to streaky maps. If a preparative map from which a particular peptide will be isolated is being run, it may be best to run the entire sample on two (or more) separate plates. Theoretically, it should be possible to separate 100 µg of material on a single TLC plate; this is often not the case in practice. Check the rate at which the first drop spotted sinks into the cellulose; as more sample is spotted, this rate will decrease. If, while spotting, one gets to a point where the sample drop just sits on the origin and does not spread into the cellulose, stop loading.

Peptide diffusion. Peptides diffuse during the electrophoresis and chromatography, and this leads to a reduction in resolution and sensitivity. To counteract this, the authors try to keep the area on the TLC plate onto which the sample is spotted as small as possible by spotting only a small amount at a time (i.e., less than 1 µl) and drying the sample origin between spottings. In addition, the sample is concentrated by wetting the TLC plates with electrophoresis buffer using a blotter with holes cut out around the origin (Figs. 18.9.1 and 18.9.3). Pressing the edges of the hole onto the plate results in buffer moving from the blotter towards the center of the hole. This concentrates the sample on the origin. For this process to work well, the origin has to be precisely in the center of the hole. In addition, the buffer has to move with similar speed from the entire circumference towards the origin. The sample will inevitably streak if the buffer takes a long time to wet the spot, or moves unevenly through the spot.

Electrophoresis system. In the authors' laboratories the HTLE 7000 electrophoresis system (Fig. 18.9.2) is used. This system features water cooling and an inflatable airbag that presses the TLC plate against the cooling plate. Water cooling prevents overheating during electrophoresis. The inflatable airbag presses excess buffer from the TLC plate; this limits diffusion of the peptides and improves resolution.

Buffers. Three different buffers are typically used for electrophoresis: pH 1.9, pH 4.72, and pH 8.9. Less often used are pH 3.5 and pH 6.5 electrophoresis buffer. To find out which buffer gives the best separation of peptides generated from a particular protein, all three buffers should be tested. If possible, the authors prefer

to work with pH 1.9 buffer. Most peptides dissolve well at this pH. In addition, use of this buffer results less often in streaky maps. The authors usually spot the digest on the origins as marked in Figures 18.9.1 and 18.9.3. For optimal separation of the phosphopeptides generated from a particular protein, the position of the origin and the electrophoresis time may need to be changed. We prefer to change the time of electrophoresis rather than changing the voltage.

Chromatographic process. Chromatography usually takes 12 to 15 hr, but the exact time may vary depending on the age of the chromatography buffer, the batch of plates, the buffer system, the quality of reagents used in the buffer, and the temperature in the room. Three different chromatography buffers are commonly used: isobutyric acid buffer, regular chromatography buffer, or phosphochromatography buffer (see Reagents and Solutions). Pyridine, which is present in all three chromatography buffers, oxidizes and turns yellow over time. Do not use oxidized pyridine to make up chromatography buffers.

To find out which buffer gives the best separation of the peptides generated from a particular protein, all three chromatography buffers should be compared. Most investigators prefer not to use isobutyric acid buffer because it is particularly foul smelling. During the chromatography run, the air space in the tank saturates with buffer and this makes it possible for the volatile chromatography buffer to run all the way to the top of the TLC plate. When the chromatography tank is opened, most of the buffer-saturated air will escape from the tank. This makes it counterproductive to extend the run after the tank has been opened. Therefore do not open the tank when chromatography is in progress, and take all plates out when the chromatography tank is opened.

Separation of the yellow and blue dye functions as a control for successful electrophoresis and allows one to follow the progress during chromatography. The dyes can also be used as standards relative to which the mobility of phosphopeptides of interest can be described, and can be used as markers for the comparison of one plate to another. The yellow compound is neutral at pH 4.72 and pH 8.9 and defines the position to which neutral peptides migrate; at pH 1.9 ϵ -dinitrophenyllysine is positively charged.

Phosphopeptide identification

After running several phosphopeptide maps, it may become apparent that particular phosphopeptides present on the map change in intensity upon treatment of the cells with specific reagents. Such observations often lead to the next question—what is the identity of peptide “A” that becomes phosphorylated following treatment of the cells with factor “B”? If approximately 1 to 10 pmole of phosphorylated peptide can be generated, the peptide is isolated from the TLC plate, purified by HPLC, and identified by mass spectrometry or microsequencing.

In many cases, it is not possible to obtain a phosphorylated peptide in such quantities. The investigator is then forced to learn as much about the phosphopeptide as possible before making an educated guess. We find it useful to make a list of all possible candidate peptides including some of their properties. The next step is to eliminate as many candidates as possible using mobility predictions and the results of relatively simple experiments that can be performed on the minute amounts of labeled peptides isolated from TLC plates.

Making a list of candidate peptides and eliminating the first candidates

Make a list of all possible phosphopeptides that could be generated from the protein of interest given the enzyme used in the primary digest; be sure to include partial cleavage products on this list. This list of peptides should include the nature and position of amino acids that can be phosphorylated and the peptides' susceptibility to further cleavage by proteases or chemicals (for an example, see van der Geer and Hunter, 1990)

After making such a list, first calculate and then plot the predicted mobilities of all candidate phosphopeptides. See Table 18.9.2 for values that can be used to do this.

To calculate electrophoretic mobility. The mobility of a peptide in the electrophoresis dimension is dependent on its charge (e) to mass (M) ratio, as $M_r = keM^{-2/3}$. When calculating relative mobilities (M_r) the simplified equation $M_r = eM^{-1}$ can be used with good success. The net charge on a peptide is calculated by summing the charges of the N and C termini and those of the side chains of its amino acids at a given pH, and dividing by either the actual mass of the peptide or simply by the number of amino acids in it. Approximate charge values at the specific pHs commonly

Table 18.9.2 Approximate Charge Values at Specific pHs Commonly Used for Electrophoresis^a

	pH 1.9	pH 3.5	pH 4.7	pH 6.5	pH 8.9
Amino-terminal NH ₂	+1	+1	+1	+1	+0.5
Carboxy-terminal COOH	N	-0.5	-1	-1	-1
Arginine	+1	+1	+1	+1	+1
Aspartate	N	N	-0.7	-1	-1
Cysteine (oxidized)	-1	-1	-1	-1	-1
Histidine	+1	+1	+1	+0.5	N
Glutamate	N	N	-0.5	-1	-1
Lysine	+1	+1	+1	+1	+1
Phosphoserine	-1	-1	-1	-1.3	-2
Phosphothreonine	-1	-1	-1	-1.3	-2
Phosphotyrosine	-1	-1	-1	-1.3	-2

^aN indicates neutral.

used for electrophoresis are given in Table 18.9.2.

To calculate chromatographic mobility. A peptide's mobility in the chromatographic dimension is dependent on its hydrophobicity, and thus on its amino acid sequence. The order of the amino acids will also change the peptide's mobility; thus, two peptides of identical sequence which are phosphorylated at one or the other of two possible sites may migrate different distances in the second map dimension, although they migrate identically in the first dimension since their charge:mass ratio is the same. While it is not possible to exactly predict chromatographic mobilities, relative mobilities can be plotted with some success by calculating an average mobility for the peptide based on migratory values of its constituent amino acids. This is not ideal, since the calculated R_f values of individual amino acids are significantly influenced by the presence of their charged amino and carboxy termini, which of course are noncontributory in the context of a peptide. This accounts in part for the compression of the calculated maps compared with the observed peptide migrations. Values for chromatographic mobilities of amino acids have been published in (Boyle et al., 1991); these were determined for each individual amino acid relative to the ϵ -DNP-lysine (yellow) marker using cellulose plates available twenty years ago. The quality of the cellulose used in such plates has changed markedly over the years; contact Ned Lamb for values that have been empirically determined more recently (<http://www.genestream.org>).

Bear in mind that these calculations can also be accomplished using a computer program. Ned Lamb (CNRS, Paris) has constructed a Web site for analysis of phosphopeptide maps, which may be found at <http://www.genestream.org>. Phospepsort 4, the program that he has developed based on an earlier version which originated at the Salk Institute, gives the biophysical characteristics as well as the electrophoretic and chromatographic mobilities of each proteolytic fragment. Alternatively, predicted peptide mobilities can be visualized using the graphical interface to Phospepsort 4: Mobility. In addition, Ned Lamb is working on a program that fits the calculated mobility values to the actual values for peptides of known composition. The Resolve program then reads the position of a spot on the actual map and calculates which peptide(s) derived from the protein being mapped could have the mobility of that spot.

It is imperative to note that to date there is no program that accurately predicts the mobility of all peptides of a protein. This may be explained by the fact that mobilities are calculated using values established for single amino acids rather than for peptides. Plotting predicted phosphopeptide mobilities on a graph using linear axes results in a greatly compressed map as compared to that observed in one's autoradiograms, especially in the chromatographic dimension. Therefore, do not despair if the predicted map of all phosphopeptides in the protein of interest looks nothing like the actual map that was generated experimentally. The value of such predictions comes from the fact that the *relative* positions of phosphopep-

tides are predicted with great accuracy by such programs/calculations. Thus, if the predicted mobility of a hypothetical phosphopeptide places it on the anode side of a cluster of phosphopeptide candidates, while the phosphopeptide of interest on the actual map is present on the cathode side of the cluster, the hypothetical phosphopeptide may be eliminated from further consideration. This example illustrates how careful use of predicted peptide mobility maps may lead to elimination of candidate peptides.

Isolating peptides from TLC plates

Phosphopeptides isolated by elution from cellulose, as described above, can be used without further purification for certain types of analysis. What many people overlook, however, is that this sample is by no means necessarily pure. It includes, in addition to the radioactive phosphopeptide in question, any unlabeled tryptic fragments that may have comigrated with it on the cellulose plate—these peptides are generated from trypsin itself and from the carrier protein used in the TCA precipitation during sample preparation. For this reason, the sample is usually further purified by HPLC to clean it up before analysis by mass spectrometry or microsequencing; the column fractions are counted in a scintillation counter to determine which ones to use for further analysis. However, for manual Edman degradation (see Basic Protocol 2), secondary cleavage (see Basic Protocol 3), and phosphoamino acid analysis (*UNIT 18.3*) no further purification is necessary, as the interpretation of the results relies solely on the visualization of the resultant ³²P-containing reaction products. The presence of unlabeled contaminants does not interfere with the interpretation of the results.

Phosphoamino acid analysis

Perhaps the most obvious step to take with an unidentified phosphopeptide in hand is to determine the phosphoamino acid content of the peptide of interest. This will eliminate many candidate peptides from consideration; this step is obviously not necessary if a long exposure of the phosphoamino acid analysis of the labeled protein in question indicates that only one species of phosphorylated amino acid is present. For phosphoamino acid analysis only 50 cpm of purified phosphopeptide is needed (though in peptide mapping and related protocols one can never have enough cpm). The details of such analysis have been discussed in detail in *UNIT 18.3*. Briefly, the phosphopeptide

eluted from the TLC plate is hydrolyzed by incubation for 60 min at 110°C in 30 μ l of 6 N HCl. The appearance of yellow to brown color in the sample during hydrolysis indicates that some cellulose remained despite efforts to clarify the phosphopeptide eluate. This sometimes causes the sample to streak. After the sample is lyophilized, it is resolved with stainable standards in two dimensions by electrophoresis as described (*UNIT 18.3*). The phosphoamino acid composition is determined by matching the resultant spot(s) on the autoradiogram with the ninhydrin-stained standards on the cellulose plate.

Manual Edman degradation

At pH 8 to 9, phenylisothiocyanate reacts with the free amino group(s) of a peptide to form a corresponding phenylthiocarbonyl peptide. Treatment of these PTC-peptides with acid (TFA) results in the cleavage of the derivatized amino-terminal amino acid and its release as an anilinothiazolinone molecule. This latter species is not stable, and will cyclize to yield the phenylthiohydantoin (PTH) derivative of the amino acid in aqueous acid. If a phosphoserine or phosphothreonine residue is present, a β -elimination during the cyclization releases free phosphate. Phosphotyrosine, however, is simply released as the anilinothiazolinone derivative. This may be converted to the phenylhydantoin form for analysis by incubating it in 0.1 N HCl at 80°C for 20 min. PTH-phosphotyrosine to use as a marker is easily synthesized by reacting phosphotyrosine with phenylisothiocyanate and then heating it in acid (see Basic Protocol 2, step 5); it can be visualized as a dark spot using a hand-held UV light.

While the protocol is relatively simple, each cycle takes ~2 hr to complete and requires at least 100 cpm for an unambiguous result. It is important to run a portion of the starting material out on the TLC plate to show how much, if any, free phosphate is there, since some hydrolysis of the peptide may have occurred during its isolation. Because at each cycle the reaction may not go to completion, one should plan to do at least one more cycle than is predicted to be necessary to release the phosphate (i.e., if all the candidate peptides are phosphorylated at or before the third residue from the N terminus, at least 4 cycles should be run). Thus, how many cpm are in the eluted map spot may determine how many cycles are run. In any case, we generally do not attempt to perform more than 5 or 6 cycles. If no phosphate is released during the course of these

cycles, this conclusion in itself will usually greatly reduce the number of candidate sites.

In addition to the position of the phosphorylated residue, clues to a peptide's sequence may also be gleaned from Edman degradation. The way in which the residual peptide shifts its electrophoretic position on the plate after each cycle will indicate whether an acidic or basic amino acid has just been removed. If the tryptic peptide's carboxy-terminal residue is a lysine, the lysine's ϵ -amino group will be derivatized in the first cycle, and so a positive charge will be lost in that instance as well.

If an automated peptide sequencer is available, 20 or more Edman cycles may be analyzed by coupling the phosphopeptide via carboxyl groups to a Sequelon membrane (Millipore) and letting the machine do the work. At the end, the fractions are counted to see where the radioactivity is released. This method obviously requires far fewer cpm in a phosphopeptide sample than does the manual Edman protocol, since one only analyzes the released material for radioactivity rather than a portion of the whole sample at the end of each cycle. A method for adapting an automated sequencer for such a purpose is discussed in Mitchelhill et al. (1997).

An adaptation of the protocol presented above is found in Fischer et al. (1997). This protocol uses a volatile isothiocyanate (trifluoroethyl isothiocyanate) and volatile buffers; as a consequence the extraction steps can be eliminated and this results in shorter cycle times (~45 min).

Secondary digests

In the past, secondary digests of tryptic phosphopeptides represented a large part of the further analysis of these peptides. The utility of these digests, however, is totally dependent on the sequence of the protein in question. A list of enzymes commonly used in such digests is found in Table 18.9.1, along with their cleavage site(s) and optimal pH and temperature. As is true for trypsin, these enzymes sometimes cleave inefficiently when encountering a cleavage site in a certain sequence context—some of these problematic sites are listed as well. In our experience, the enzymes/reagents that cleave only one amino acid (i.e., proline-specific endopeptidase, V8, or cyanogen bromide) tend to be more useful and give less ambiguous results.

Do not expect that the results of one enzyme digest will eliminate more than a few candidate sites. As it is most likely that the enzyme in question will not cleave the phosphopeptide, it

is imperative that a positive control be included in the digest—i.e., a peptide whose sequence is known and which the enzyme will cleave. If such a peptide is not available, a portion of the primary digest might be used as a positive control—with luck this will contain at least one peptide whose migration will be changed by this secondary digestion.

Running out the mix of undigested and digested peptides is very important, since failure to comigrate with the original peptide will unequivocally demonstrate a change in the phosphopeptide's mobility. A sample treated exactly as the digested sample, but without the cleavage reagent, should be analyzed in parallel. This is to ensure that changes in mobility seen in the digested peptide are truly due to the presence of the cleavage reagent.

When deciding where to spot the samples and what conditions to use to run the plates, keep in mind that if the peptide did not migrate very far in the original map, it may be possible to load two sample on a single plate. Also keep in mind, however, that free phosphate may be released during the enzymatic digestion (due to elevated temperatures and resulting hydrolysis). Free ^{32}P -phosphate originating from the sample loaded to the right may complicate the interpretation of the sample loaded on the left (anode) side of the plate.

It should be noted that additional information about the other amino acids in a phosphopeptide may be gleaned just by running a tryptic digest in the electrophoretic dimension at another pH—identification of the different peptides by their mobility in the chromatography dimension will allow one to compare the mobility of peptides when run at different pHs and decide if a particular spot has changed its migration in the first dimension. Such a change in migration would be affected only if the phosphopeptide contained an amino acid whose charge was changed at the second pH used.

Comigration of a synthesized phosphopeptide with a phosphopeptide isolated from a peptide map

After eliminating all but a few of the candidate peptides, comigration of a synthetic phosphopeptide with the ^{32}P -labeled peptide generated by digesting a protein from labeled cells may provide convincing evidence as to the latter's identity. Obviously, care must be taken that the synthetic peptide be quite pure (generating only one spot on the cellulose plate) and that, while enough is loaded to be easily visualized, the plate not be overloaded (which

would cause streaking and therefore render the comigration ambiguous). If the peptide is synthesized as a phosphopeptide, ~5 to 25 μg of pure peptide is needed for each comigration, as it will need to be ninhydrin stained for visualization. This is by far the easier approach—starting with an unphosphorylated peptide entails not only finding a kinase that will phosphorylate it, but also purifying the phosphopeptide first before running the comigration. In either case, synthesis of peptides, and in particular those with special residues such as phosphorylated amino acids, is not inexpensive, and so this type of experiment is usually attempted after one has accumulated several other clues regarding a site's identity.

The alternative is to mutate the remaining candidate phosphorylation sites. An epitope-tagged version of the mutant protein can then be expressed in cells and mapped to check whether the spot in question disappears from the map. This approach of course assumes that the sequence of the protein in question is known and that one has a clone in hand for mutagenesis.

While satisfying to many, this mutagenesis approach is not definitive, as it can be argued that the mutated form of the protein may not fold correctly and therefore may not be phosphorylated correctly, resulting in a misleading loss of map spots. Another potential problem is that, if the phosphorylation of the site in question is an ordered event, dependent on another site's state of phosphorylation, mutation of this other site could lead to the erroneous conclusion that the disappearance of a particular spot is the direct result of the mutation introduced, rather than an event of secondary consequence. Mutagenesis then should be taken as a supporting argument for the presumed identity of a phosphorylation site, rather than as definitive proof. Taken in conjunction with other evidence, it can nevertheless be quite convincing.

Scaling up phosphopeptide mapping to isolate peptides for mass spectrometry and microsequencing

The most definitive methods for determining the site(s) of phosphorylation in a protein are the determination of the amino acid sequence or mass of the phosphopeptides. While the sensitivity of the instruments used in both these techniques has improved over the past 5 years, both methods require on the order of 1 to 10 pmole of material for analysis. When analyzing the phosphorylation of a receptor protein-tyrosine kinase of which ~10,000

molecules are present on the cell surface, one would need to grow 60 10-cm dishes of cells to isolate the 6×10^{11} molecules (1 pmol) required for a successful analysis. In this calculation, we have assumed 100% recovery and 100% stoichiometry of phosphorylation at the sites of interest. However, since it is very possible that not every molecule is phosphorylated at the sites in question, and that one is likely to take at least a 50% loss of material over the entire protocol, it would be best to start then with at least 240 dishes of cells. The use of overexpressed protein in cells would obviously facilitate the accumulation of sufficient amounts of protein for analysis.

Isolation of enough material for analysis becomes less difficult if an *in vitro* system can be used to generate the phosphopeptides in question. Protein kinases are notoriously promiscuous *in vitro*, so it may be possible to generate the sites of interest using a kinase that is actually not the one responsible for the phosphorylation *in vivo*. The protein of interest produced in bacteria makes a good substrate, as it is most likely not phosphorylated to start with. It is first necessary to show that the phosphopeptides generated by incubation of recombinant protein with a purified kinase *in vitro* comigrate exactly with those purified from labeled cells. If there is any doubt about this, it is reassuring to run the maps for a longer time than usual in the electrophoresis dimension, or at a different pH to further demonstrate comigration. Given the specificity of the two-dimensional separation on these maps, it is unlikely that two phosphopeptides that truly comigrate will not be identical.

Anticipated Results

Upon developing the first autoradiogram of an initial peptide map, depending on the number of spots seen, the researcher will most likely be left wondering what it all means. There are several things to keep in mind when studying the pattern of spots on a peptide map. First, migration in the electrophoresis dimension is a function of the charge to mass ratio of a peptide. Migration in the chromatography dimension is related to the hydrophobicity of a peptide. The more hydrophobic a peptide, the further it migrates in the chromatographic dimension. In general, most phosphopeptides of the protein studied will be represented by one spot in the map. It is possible then to determine the relative stoichiometry of phosphorylation at different sites by comparing the intensity of each spot on the autoradiogram. This, however, relies on the

Figure 18.9.6 An example of a tryptic phosphopeptide map based on that of human Nck-alpha. For the first (horizontal) dimension, electrophoresis was run at pH 1.9 for 25 min at 1.0 kV; the anode is at the left. Ascending chromatography was run for 15 hr in phosphochromo buffer. The sites represented by spots 1 to 7, with the exception of spot 2, have been identified. Spot 1 is an 11-amino-acid, phosphotyrosine-containing peptide. While spot 2 also contains phosphotyrosine, and runs in a position likely to be the doubly phosphorylated version of this peptide, it turns out to be unrelated to spot 1. Spot 3 represents a 5-amino-acid, phosphoserine-containing peptide; this same peptide with an amino-terminal arginine runs as spot 4; thus it can be seen that in this case the tryptic cleavage is largely incomplete. Spot 5 represents a 20-amino-acid phosphoserine-containing peptide which, with an amino-terminal lysine, runs as spot 6. Spot 7 represents a peptide that is unrelated to 5 and 6. Spot 8 represents free phosphate, released during sample preparation.

assumption that all tryptic peptides are recovered during the the entire protocol with similar efficiencies.

There are several cases, however, in which this one phosphopeptide:one spot rule does not hold. One such case is when the enzyme used to digest the protein of interest has not worked to completion, yielding both partial and complete digestion products seen in the map.

Multiple digestion products are also generated at sites where a run of basic residues is present. Trypsin works very efficiently as an endopeptidase, hydrolysing peptide bonds following basic residues. In contrast, trypsin works poorly as an exopeptidase. Trypsin will

cleave randomly within the run of basic residues and is unable to take off additional basic residues that may have been left. This results in a series of digestion products differing by the number of basic residues at their amino- or carboxy-terminus. Addition of such a basic residue to a phosphopeptide changes its migration in both the electrophoresis and the chromatography dimension (it is more positively charged and runs further towards the cathode, it is also more hydrophilic and as a consequence runs less far relative to the buffer front in phosphochromo buffer).

Similarly, a given peptide will migrate differently if phosphorylated at two positions

rather than one. Addition of another negative charge will again make the peptide more hydrophilic and thus it will migrate less far in the chromatography dimension. This time, however, it will migrate further towards the anode in the electrophoresis dimension, giving a diagonal pattern descending in the opposite direction to that seen with the addition of a lysine or an arginine.

It is important to remember that the electrophoretic mobility of a peptide is dependent on its mass. For larger peptides, the slope of the diagonal seen with the addition of either positive or negative charges will be steeper, since the addition of another charge when divided by the mass will make less of a difference to the distance the peptide travels.

While trypsin has been traditionally used in peptide mapping, it may not be the enzyme of choice for proteins phosphorylated by PKA, PKC, or other protein kinases whose recognition sequence involves multiple arginines or lysines, as trypsin often fails to cleave after all such residues when they are present in runs. In addition, trypsin cleaves inefficiently at arginines or lysines two residues amino-terminal of a phosphoserine or phosphothreonine (i.e., R/K-X-P.Ser).

Sometimes an individual peptide may appear to have an electrophoretic partner that migrates directly above or below it in the chromatographic dimension. This sort of pattern may be observed as the result of two different scenarios: (1) it may be the result of incomplete oxidation of the peptide if it contains a methionine residue (in which case the lower spot is the oxidized form), or (2) it may be the result of methylation of the peptide running in the lower position. Such a methylation may occur during the performic acid oxidation and is dependent on the 1.5-ml microcentrifuge tubes being used. Historically we have found that certain tubes are more apt than others to produce such unwanted side reactions; for this reason it is advisable to stock certain lots of tubes that do not produce such artifacts in the final maps. Similarly, brands and batches of tubes appear to differ in the extent to which peptides “stick” to them during the final steps of the protocol.

An exemplary tryptic phosphopeptide map based on that of a real protein (Nck) is shown in Figure 18.9.6. This map illustrates the points mentioned above. Perhaps most importantly, it also illustrates the fact that just because two spots appear to be on a diagonal it is not a foregone conclusion that they are related. Although peptides 1 and 2 appear to represent the

singly and doubly phosphorylated forms of a single tryptic peptide, in this case it turned out that they represent two completely different peptides. Peptides 3 and 4 and 5 and 6, respectively, represent two sets of peptides that are related and differ only by the addition of a basic residue. Spot 8 represents free phosphate, liberated by hydrolysis of phosphoester bonds that has occurred during sample preparation. It is useful to both compare the amount of free phosphate generated in different samples and to use the phosphate spot as another standard marker when comparing peptide mobilities on different plates.

Time Considerations

To generate a two-dimensional phosphopeptide map, at least 9 days will elapse from the time the ^{32}P label is added to the cells until the autoradiogram of the map is in hand. The typical researcher, intrigued by one or more particular spots that appear or disappear from such maps depending on how the cells or samples were treated, may rush to attempt to identify the phosphorylation site represented by such spot(s). Please be advised that this will take at least 4 months of hard work and effort, assuming that everything goes well. There are several different strategies to follow, which are outlined throughout the unit (especially see Background Information). Choice of a particular course will depend on the reagents and the equipment available for analysis.

Use of Protein Phosphatase Inhibitors

UNIT 18.10

Reversible protein phosphorylation is recognized as a major mechanism regulating the physiology of plant and animal cells. Virtually every biochemical process within eukaryotic cells is controlled by the covalent modification of key regulatory proteins. This in turn dictates the cellular response to a variety of physiological and environmental stimuli; errors in signals transduced by phosphoproteins contribute to many human diseases. Thus, defining protein phosphorylation events, and specifically, the phosphoproteins involved, is crucial for obtaining a better understanding of the physiological events that distinguish normal and diseased states.

In studying protein phosphorylation, two common experimental problems arise that mandate the use of protein phosphatase inhibitors. The first problem arises when the goal of the experiment is to decipher physiological events regulated by reversible protein phosphorylation but the hormonal stimuli or signaling pathways involved are not known. This situation is further complicated by the fact that many protein phosphorylations are rapid and transient, thereby eluding investigation. One solution is to employ cell-permeable compounds that inhibit cellular protein phosphatases in order to amplify the basal activity of protein kinases. Inhibition of protein phosphatases also prevents the turnover of protein-bound phosphate, thereby enhancing the detection of phosphoproteins by standard techniques such as SDS-PAGE (UNIT 10.2A) and autoradiography (APPENDIX 3A) or phosphorimaging.

In other situations, the aim may be to analyze the impact of hormones and other physiological stimuli on the function of a specific phosphoprotein. Such detailed biochemical analysis is only made possible after the protein of interest has been separated from other cellular components that potentially interfere with these studies. In this circumstance, the cells or tissues exposed to hormones must be homogenized in the presence of protein phosphatase inhibitors to preserve the cellular phosphorylation events promoted by the hormones. The goal is to utilize the most effective inhibitors to abolish the activity of protein phosphatases that may dephosphorylate the proteins of interest during the lengthy protein isolation procedures. This unit describes the general or basic protocols for inhibiting the cellular PP1/PP2A activity with okadaic acid (see Basic Protocol 1) as well as in vitro with microcystin-LR (see Basic Protocol 2). Basic Protocols 3 and 4 describe approaches recommended for inhibiting cellular and in vitro activity, respectively, of PP2B/calcineurin. Finally, Basic Protocol 5 outlines a widely utilized strategy for inhibiting protein tyrosine phosphatases. The reader should be aware that these Basic Protocols are deliberately designed to cover the widest range of experimental situations and therefore represent prototypic procedures that can be readily used with many phosphatase inhibitors that are not specifically mentioned in this unit.

A variety of very effective inhibitors, particularly those targeting protein serine/threonine phosphatases, are currently commercially available. Some of these compounds are cell-permeable and yet others are better utilized in vitro to suppress phosphatase activity in lysates and/or cell fractions. This unit describes methods for defining physiologically relevant protein phosphorylation events. Thus, in some cases, cells in culture are treated with cell-permeable phosphatase inhibitors to detect and establish the in vivo phosphorylation events. In other cases, the cells are stimulated with known physiological stimuli that modify cellular protein phosphorylation. In either situation, subsequent analyses require that the cells be homogenized in buffers containing phosphatase inhibitors that preserve the protein modifications through the steps of protein purification and analysis. This in turn facilitates the identification of the particular amino acids modified and sets

the stage for more defined molecular approaches, such as site-directed mutagenesis, that will allow the investigator to establish the functional role of individual protein phosphorylation events.

PROTEIN SERINE/THREONINE PHOSPHATASES

Serines and threonines constitute the major sites of protein phosphorylation in all eukaryotic cells. Varying estimates suggest that even in cells transformed using oncogenic viral protein tyrosine kinases, >97% of the protein-bound phosphate appears on serines and threonines. Thus, it is not surprising that numerous microorganisms produce toxins and natural products that elicit their deleterious effects by inhibiting cellular protein serine/threonine phosphatases (McCluskey et al., 2002). Many of these compounds show some degree of selectivity for subgroups of protein serine/threonine phosphatases and may provide insight into the cellular phosphatases that catalyze protein dephosphorylation events. The specificity of some of these compounds has been determined in vitro as differences in their concentration-response curves for the inhibition of purified protein phosphatases. When used in vivo, the chemical properties of the compounds, many of which are hydrophobic, do not allow accurate estimates of cellular concentration or predict their subcellular distribution. Thus, the in vitro specificity of the phosphatase inhibitors may be lost and other more direct molecular approaches may be required to define the protein phosphatases that regulate specific cellular events. The principal use of phosphatase inhibitors, as described in this unit, is to complement the in vitro use of purified phosphatases (UNIT 18.5) to define the regulatory importance of reversible protein phosphorylation, rather than to identify the physiologically relevant protein phosphatases.

Early biochemical studies classified eukaryotic protein serine/threonine phosphatases into two major groups, termed type-1 (PP1) and type-2 protein phosphatases (Shenolikar and Nairn, 1991). The type-2 phosphatases are further separated into three distinct groups, PP2A, PP2B, and PP2C, showing very different profiles of inhibition by the available compounds (Table 18.10.1). Molecular cloning of mammalian phosphatase catalytic subunits further expanded this family of enzymes, which to date includes up to five additional phosphatase catalytic subunits numbered PP3 to PP7. Of these five, all but PP7 share a highly conserved catalytic site, and therefore are similarly inhibited by various compounds. Yet others, such as PP2C or PP7, show complete insensitivity to the known phosphatase inhibitors and there are no currently available tools to inhibit these phosphatases.

Table 18.10.1 Commercially Available PP1/PP2A Inhibitors^a

Compound	Phosphatases	Recommended use	Supplier(s)
Okadaic acid	PP2A > PP1	In vivo	Alexis Biochemicals, Sigma
Calyculin A	PP1 ≥ PP2A	In vivo	Alexis Biochemicals, Sigma
Tautomycin	PP1 > PP2A	In vivo	Biomol Research Laboratories
Cantharidin A	PP2A > PP1	In vivo	—
Microcystin-LR	PP1 = PP2A	In vitro	Alexis Biochemicals, Sigma
Nodularin	PP1 = PP2A	In vitro	—
Fostreicin	PP2A>>PP1	In vitro	A.B. Scientific, Sigma, Alexis Biochemicals

^aAll compounds listed in this table also inhibit PP3, PP4, PP5, and PP6. Their shared sensitivity to these compounds results in their inclusion in the category of PP2A-like enzymes. In contrast, these compounds show no significant inhibitory activity towards PP2B, PP2C, and PP7. As the compounds possess little structural homology, several different inhibitors may be used to validate the physiological effects of inhibiting their shared targets, serine/threonine phosphatases.

Table 18.10.2 Commercially Available PP2B (Calcineurin)^a Inhibitors

Compound	Phosphatases	Recommended use	Suppliers
Cyclosporin A ^b	PP2B	In vivo	Alexis Biochemicals, Sigma
FK506	PP2B	In vivo	Alexis Biochemicals
Cypermethrin ^c	PP2B	In vivo	Alexis Biochemicals
Deltamethrin	PP2B	In vitro	Alexis Biochemicals

^aPP2B (calcineurin) is a Ca²⁺/calmodulin-activated protein serine/threonine phosphatase and, like many Ca²⁺/calmodulin-activated enzymes, is inhibited by the calcium chelator, EGTA. Inhibition of PP2B activity using EGTA is not a very viable approach in cells and the compounds listed in this table more effectively suppress cellular PP2B activity.

^bA number of inactive and partially active compounds related to cyclosporin are available. Rapamycin, which shares common target proteins with FK506, namely FK506-binding proteins or FKBP, does not inhibit PP2B activity and is used as control for FK506.

^cCompounds related to cypermethrin, such as resmethrin, show weak or no activity as PP2B inhibitors and can function controls for the pyrethroid inhibitors.

The compounds listed in Table 18.10.1 inhibit several classes of protein serine/threonine phosphatases. Enzymes such as PP3, PP4, PP5, and PP6 share structural homology to PP2A and therefore show similar sensitivity to these compounds. In contrast, PP2B is inhibited by a distinct group of compounds (Table 18.10.2) that show no activity against either PP1 or the PP2A-like phosphatases.

PP1/PP2A Classes of Protein Serine/Threonine Phosphatases

PP1 and PP2A together account for >90% of protein serine/threonine phosphatase activity in most eukaryotic cells. With the exception of mammalian skeletal muscle, where PP1 predominates, most cells and tissues possess equivalent amounts of PP1 and PP2A. This has made okadaic acid and calyculin A, both potent cell-permeable PP1/PP2A inhibitors, the most widely utilized compounds for studying cellular protein phosphorylation.

INHIBITION OF CELLULAR PP1/PP2A ACTIVITY WITH OKADAIC ACID

Okadaic acid (OA), a polyether produced by marine dinoflagellates, is concentrated by shellfish and is a common cause of diarrhetic shellfish poisoning in humans. OA is commercially available as a free acid or as a potassium, sodium, or ammonium salt. Prevailing evidence favors the sodium salt of OA as the most readily permeable across cell membranes.

Biochemical studies demonstrate that OA inhibits the purified PP2A catalytic subunit with an IC₅₀ value of 0.2 to 1.0 nM (Cohen et al., 1989). This concentration of OA, however, has little effect on PP2A activity in cell lysates, which typically exhibit 30- to 150-fold higher IC₅₀ values than the purified enzyme. Extensive dilution of cell extracts enhances the efficacy of OA as a PP2A inhibitor. This may suggest that OA binds, albeit with low affinity, to other cellular components in cell extracts. This may be more of an issue in intact cells where significantly higher OA concentrations (10 to 100 nM) are required for effective PP2A inhibition.

PP1, unlike PP2A, has a higher IC₅₀ value for OA (10 to 100 nM; Cohen et al., 1989), whether assayed with purified enzyme or cell lysates, and the sensitivity of PP1 activity to OA is not modified by dilution of cell lysates. In some cellular studies, OA concentrations between 10 and 50 nM resulted in significant enhancement of protein phosphorylation, presumably reflecting the inhibition of PP2A and other PP2A-like enzymes. In contrast, OA concentrations >10 μM are needed to effectively inhibit cellular PP1 activity.

Protein
Phosphorylation**

18.10.3

This difference in affinity can provide an opportunity to discriminate between the physiological functions of the two major classes of cellular protein serine/threonine phosphatases, namely PP1 and PP2A.

Numerous studies suggest that the predominant site of OA accumulation is the lipid bilayer of the plasma membrane (Suganuma et al., 1989; Nam et al., 1990; Namboodiripad and Jennings, 1996). OA transfers slowly from this site to other compartments and this may account for the slow onset of phosphatase inhibition by OA in most cells (up to 90 min) as well as the requirement of 10- to 100-fold higher concentrations of OA to inhibit PP2A activity in intact cells compared to cell lysates. Thus, it is surprising to find that OA can also be washed out of cells, albeit thorough washing can take hours. This reversible behavior may allow investigators to analyze the reversal of phosphorylation events triggered by OA.

Duration of OA treatment to elicit maximal changes in cellular protein phosphorylation is largely empirically determined and must be defined for each individual cell type. In general, cells display a maximal response to micromolar concentrations of OA within 10 to 30 min. Lower OA concentrations require significantly longer exposure times (up to 2 hr). Due to their remarkable ability to activate multiple cellular signaling pathways, OA and other cell-permeable phosphatase inhibitors display some cytotoxicity. This is partially alleviated by lowering OA concentrations and reducing exposure times. Thus, OA treatments for several hours or days are not recommended. If longer times are necessary, calyculin A (CA), which inhibits PP1 and PP2A with near equal potency, may be a better substitute. While the literature on calyculin A is less extensive, this compound can be used at much lower concentrations (0.1 to 1.0 μM) than OA to yield similar physiological effects.

OA induces errors in DNA repair that are not mediated by phosphatase inhibition, (Nakagama et al., 1997) which suggests the presence of additional targets for OA. This behavior mandates that appropriate controls be used in cellular studies. In this regard, the treatment of cells with vehicle (DMSO) is commonly used as a control for OA, CA, and other phosphatase inhibitors that are dissolved in this solvent. There are, however, a number of commercially available inactive OA analogs that may serve as better controls. The best of these is 1-norokadaone, whose structure closely matches that of OA and maintains some of the non-phosphatase-mediated effects elicited by OA. Structure-function studies that established a critical role for the acidic side-chain of OA in phosphatase inhibition also generated a number of inactive OA analogs in which the critical carboxylate group is esterified (Nashiwaki et al., 1991). Such compounds, like methyl okadaate, show low or no activity in vitro as PP1/PP2A inhibitors. However, these compounds may not be effective negative controls, as they are slowly de-esterified in cells, yielding the active OA.

Finally, OA, CA, and several other phosphatase inhibitors show significant activity as tumor promoters in mouse skin and gut (Fujuki et al., 1988; Suganuma et al., 1990). Thus, it is important that the investigator takes extreme care in handling and disposing of solutions containing these compounds.

Materials

Cultured mammalian cells grown to <50% confluence (*APPENDIX 3F*)

0.1 or 1.0 mM okadaic acid sodium salt (Alexis Biochemicals or Sigma), in DMSO (store at -20°C in a light-proof container under N_2)

0.1 or 1.0 mM 1-norokadaone (Calbiochem or Sigma) in DMSO (store at -20°C in a light-proof container under N_2)

NOTE: Okadaic acid (OA), either as sodium, potassium, or ammonium salt, shows increased solubility in aqueous solutions compared to the free acid. The solutions of the OA salts are also more stable during storage. However, for reasons that are not entirely clear, aqueous solutions of OA lose their activity as phosphatase inhibitors over time. By comparison, the stock solutions of OA in DMSO (or ethanol or methanol) can be stored in a dark glass container under nitrogen at -20°C for many months without significant loss of activity.

1. Prepare cultured mammalian cells to $\sim 50\%$ confluence (*APPENDIX 3F*).

Okadaic acid activates a variety of cell signaling pathways and physiological events in mammalian cells (Schonthal, 1998). Thus, responses of different mammalian cells to OA vary widely. In general, changes in protein phosphorylation in quiescent or confluent cells induced by OA are less profound. Moreover, quiescent cells often initiate apoptosis following OA exposure (Kiguchi et al., 1994; Morimoto et al., 1997). In contrast, programmed cell death appears less of a problem when analyzing actively growing cultured cells.

2. Add okadaic acid (final concentration $10\ \mu\text{M}$) to the culture medium or exchange with fresh medium containing $10\ \mu\text{M}$ okadaic acid. Expose control cells to medium containing vehicle (DMSO) or the inactive analog, 1-norokadaone. Incubate cells for 30 min prior to harvesting (*APPENDIX 3F*) for analysis of physiological functions (Schonthal, 1998) and/or phosphoproteins (Chapter 18).

The maximum (final) concentration of DMSO in the assay should not exceed 1.0% (v/v).

Inactive analogs, such as 1-norokadaone, should also be analyzed at a final concentration of $10\ \mu\text{M}$.

INHIBITION OF PP1/PP2A ACTIVITY IN VITRO WITH MICROCYSTIN-LR

Microcystin-LR, a cyclic heptapeptide produced by the blooms of cyanobacteria in freshwater lakes, is a member of a family of cyclic peptide products that inhibit PP1 and PP2A at nanomolar or subnanomolar concentrations. Many members of this family, including the cyclic pentapeptides, nodularins, show similar phosphatase target specificity. Liver cells possess a unique uptake mechanism for these compounds. Hence, microcystins are potently hepatotoxic but in general, microcystins do not enter most tissues and cells.

The broad specificity of microcystin-LR for PP1, PP2A, and other PP2A-like phosphatases as well as its remarkable potency and stability in buffered solution (compared to OA or CA) makes this compound an ideal reagent for preservation of cellular protein phosphorylations in lysates and during lengthy chromatographic purification of phosphoproteins. Microcystin-LR is also significantly less expensive than CA or OA and thus well suited for inclusion in large volumes of buffers used for dialysis and protein chromatography. Moreover, in contrast to OA and CA, no special precautions are needed in the storage of microcystin-LR, although prolonged storage of stock solutions should be at -20°C . It is, however, necessary to take some steps to avoid ingestion of this compound as toxicological studies show that very small quantities of microcystins can lead to serious liver failure and extensive tissue damage.

X-ray crystallography defined the binding site for microcystin-LR in the catalytic center of PP1 α . Other studies suggest that microcystin-LR forms a stable adduct with a highly conserved cysteine adjacent to the PP1 catalytic site. This process is spontaneous and slow and plays no role in phosphatase inhibition. However, the possibility remains that prolonged exposure (days to weeks) of phosphatases to microcystins generates the enzyme-toxin adduct and limits subsequent studies. For example, following short-term

exposure to microcystins, the observed phosphatase inhibition is readily reversed by dilution or dialysis. Significant adduct formation may prevent enzyme reactivation and reversal of covalent modifications.

Materials

Tissue or cells

0.1 or 1.0 mM microcystin-LR (Alexis Biochemicals or Sigma) in DMSO (store at -20°C)

1. Homogenize tissue or cells in buffers containing 1 μM microcystin-LR and process samples for functional or phosphoprotein analyses (Chapter 18).

BASIC PROTOCOL 3

INHIBITION OF CELLULAR PP2B/CALCINEURIN ACTIVITY WITH CYCLOSPORIN A

PP2B, also known as calcineurin, is a Ca^{2+} /calmodulin-activated protein serine/threonine phosphatase. PP2B was thus the first phosphatase determined to be directly controlled by a second messenger. PP2B is the therapeutic target for the two major immunosuppressants, cyclosporin A and FK506. These drugs, however, do not directly interact with the PP2B catalytic subunit but function through intermediate protein receptors collectively known as immunophilins to inhibit enzyme activity. Distinct immunophilins bind cyclosporin A and FK506. However, both drug/receptor complexes are effective PP2B inhibitors. The unique activity of these compounds on T-lymphocytes is due to their ready access to T-cells, the low abundance of their target, PP2B, in T-lymphocytes, and the key role of PP2B in activating cytokine genes that promote T-cell proliferation. PP2B and the immunophilins are, however, widely expressed in mammalian tissues and PP2B also plays an important role in regulating the physiology of mammalian heart, brain, and other tissues. While the reduced access within various tissues may limit the utility of these compounds in animals, both cyclosporin A and FK506 are excellent inhibitors of PP2B functions in experimental systems such as tissue slices and cultured cells.

Cyclosporin A has an apparent IC_{50} value for PP2B inhibition ranging from 10 to 100 nM. The use of cyclosporin A is limited by its poor solubility in aqueous solutions and its slow entry into mammalian cells. In contrast, FK506 is a ten-fold more potent PP2B inhibitor and enters cells rapidly. However, commercial availability of FK506 is still restricted, therefore, this protocol focuses on cyclosporin A, which is widely available from many different commercial sources. There are also numerous inactive analogs of cyclosporin available for use as controls. Many of these inactive analogs bind effectively to the target cyclophilin but fail to inhibit PP2B activity. In contrast, another immunosuppressant, rapamycin, binds to the same immunophilin as FK506 but does not inhibit PP2B and can be used as a control for FK506. Rapamycin is a potent inhibitor of the signaling pathway controlled by the protein kinase, TOR (target of rapamycin), and therefore, has its own effects on cellular protein phosphorylation.

Materials

0.1 mM cyclosporin A (Alexis Biochemical or Sigma) in DMSO

Cultured cells

1. Add 0.1 mM cyclosporin A (final concentration 0.1 to 1 μM) to culture medium or exchange with fresh medium containing cyclosporin A. Incubate cells for 60 min prior to harvesting for analysis.

The slow entry of cyclosporin A into cells often requires incubating cells and tissue slices for periods >1 hr, as very few physiological events respond to this drug in periods under 30 min.

IN VITRO INHIBITION OF PP2B/CALCINEURIN ACTIVITY WITH CYPERMETHRIN

BASIC
PROTOCOL 4

Cypermethrin and other type II pyrethroids are synthetic insecticides that show activity as PP2B inhibitors and are available from many commercial sources. In addition, a number of pyrethroid analogs, resmethrin, allethrin, and permethrin, show reduced or no activity as PP2B inhibitors and can be used as controls. This is particularly important for cellular studies using cypermethrin, as many of the type-II pyrethroids have a wide range of physiological effects including oxidative stress, cytotoxicity, and tumorigenesis. Only a few of these are likely to be mediated by PP2B inhibition. Given the availability of cyclosporin A, a better characterized and more potent PP2B inhibitor, the value of using pyrethroids in mammalian cells is questionable.

Materials

- 1.0 mM cypermethrin (Alexis Biochemicals) in DMSO and store in dark glass containers pretreated with 1% polyethylene glycol (PEG)
- Sample cell extracts or subcellular fractions

NOTE: Cypermethrin and other type II pyrethroids are sold in both solid and liquid form. The liquid form represents cypermethrin dissolved in organic solvents, such as DMSO, acetone, or ethanol. Hydrophobicity of these compounds means that long-term storage in plastic or polyethylene containers should be avoided because these compounds adhere to such surfaces and may be slowly extracted from solution. Many pyrethroids are also light-sensitive. If stored in dark glass containers pretreated with 1% (w/v) PEG to prevent surface adherence, stock solutions of cypermethrin are stable for many months. For cellular studies using cypermethrin, the compound should be added directly to the culture medium as its PP2B inhibitory activity is reduced when made up in fresh medium. While the underlying basis for a time-dependent loss of cypermethrin activity is not clear, this provides a strong argument for using cypermethrin and the pyrethroid inhibitors solely for in vitro studies of PP2B function.

1. Add 1.0 mM cypermethrin (10 to 20 μ M final concentration) to cell extracts or subcellular fractions and analyze phosphoproteins within a period not exceeding 60 min.

Cypermethrin addition in vitro should result in rapid PP2B inhibition that is evident within minutes. Prolonged incubations with this compound are not recommended.

INHIBITION OF PROTEIN TYROSINE PHOSPHATASES WITH SODIUM ORTHOVANADATE

BASIC
PROTOCOL 5

Protein tyrosine phosphatases (PTPases) represent a larger family of enzymes derived from a common ancestral gene and share no structural homology with the protein serine/threonine phosphatases (Sefton and Shenolikar, 1995). Thus, PTPases are not sensitive to any of the compounds described above. PTPases share a common catalytic mechanism that involves the formation of an enzyme phospho-intermediate with the modification of a conserved cysteine within the catalytic cleft. While cysteine-modifying reagents, such as phenyl arsene oxide, and metals such as zinc chloride, potently inhibit PTPases, these reagents are non-specific and likely target many proteins other than PTPases and therefore, will not be further discussed here.

Currently, the most useful reagent for inhibiting PTPases in vivo and in vitro is vanadate, a phosphate analog. One might predict that vanadate would also be non-specific and inhibit many phosphotransferases and phosphohydrolases, including protein serine/threonine phosphatases. However, the remarkable chemistry of the vanadium metal

Analysis of
Protein
Phosphorylation

18.10.7

ion (Gordon, 1991) can be exploited to produce a preferential and effective PTPase inhibitor.

Materials

Sodium orthovanadate (Sigma)

0.1 M NaOH

Sample cells

Boiling water bath or heating block

Additional reagents and equipment for metabolic labeling (Sefton, 1997) or immunoblotting with an anti-phosphotyrosine antibody (DiGiovanna et al., 1996)

1. Dissolve sodium orthovanadate (200 mM final concentration) in sterile, distilled water (often a yellowish solution) and adjust pH of the solution to 10.0 with 0.1 M NaOH. Place solution in a boiling water bath until the solution clarifies or becomes translucent. Readjust pH to 10.0 and store the stock solution in a flint glass container at room temperature or dispense into aliquots in plastic containers and store at -20°C .

Sodium orthovanadate, whether solid or in solution at neutral pH, slowly oxidizes and acquires a yellow color. The presence of thiols, often used to maintain protein structure and function following the homogenization of tissues or cells, promotes a rapid (<30 min) conversion to the oxycation, vanadyl. Finally, vanadate, particularly in solutions below 0.1 mM at neutral pH, also undergoes polymerization, which is also associated with increased yellow color. All of these factors result in reduced vanadate activity as a PTPase inhibitor. While vanadate slowly reverts to a colorless active monovalent form, especially on dilution, this process is greatly accelerated by increasing pH and temperature, as described above.

2. Incubate cells with 0.1 mM orthovanadate for periods not to exceed 2 to 3 hr before analyzing tyrosine-phosphorylated proteins by metabolic labeling (Sefton, 1997) or immunoblotting with an anti-phosphotyrosine antibody (DiGiovanna et al., 1996).

Maximal inhibition of cellular PTPase activity often requires up to 1.0 mM vanadate. This concentration of vanadate is also chosen to preserve protein tyrosine phosphorylation following cell disruption. However, much lower concentrations of vanadate are recommended for the treatment of intact cells to limit or avoid cytotoxicity. Even 0.1 mM vanadate is detrimental to cell function if the duration of treatment extends for several hours or days. This, however, makes the complete inhibition of PTPases achieved in cell lysates and other fractions by 1.0 mM vanadate easier to interpret than the results of cellular studies where changes in cell function cannot always be attributed to PTPase inhibition. Finally, some protein serine/threonine phosphatases display low but measurable PTPase activity in vitro and are not inhibited by 1.0 mM vanadate. These enzymes may account for slow dephosphorylation of tyrosine-phosphorylated proteins during lengthy isolation procedures.

COMMENTARY

Background Information

In contrast to the large number (300 to 500) of genes encoding mammalian protein kinases, many fewer genes encode the catalytic subunits of protein serine/threonine phosphatases (Cohen, 1997). Thus, the functional diversity of protein serine/threonine phosphatases arises through other mechanisms that include a rapidly expanding number of regulatory subunits that may dictate the substrate specificity and subcellular localization of the phosphatase catalytic subunits (Cohen, 2002). This means that the approaches outlined in this unit for

inhibiting protein serine/threonine phosphatases, while highly effective, may not distinguish between the functions of various intracellular pools of these enzymes. In addition, many phosphatase inhibitors are highly hydrophobic and may display significant differences in accessing intracellular pools of phosphatases. Hence, these protocols are most appropriately used for detecting and defining the physiological role of the phosphorylated protein substrate as opposed to making conclusions regarding the types or pools of phosphatases involved.

While more genes encode protein tyrosine phosphatases than serine/threonine phosphatases, these too fall far short of the numbers representing the complimentary protein tyrosine kinases. Mammalian PTPases can be separated into two broad groups, transmembrane “receptor” PTPases and soluble PTPases (Fischer et al., 1991). Many transmembrane PTPases contain two catalytic domains and emerging studies suggest that only one of these domains plays an active role in enzyme catalysis. The “inactive” catalytic domain is thought to regulate the function of receptor PTPases. It is unclear whether the second catalytic site functions as a decoy for PTPase inhibitors or if other mechanisms account for the apparent reduced sensitivity of transmembrane PTPases to vanadate. Considerable anecdotal evidence points to the preferential inhibition of soluble PTPases in cells treated with vanadate.

While the protocols discussed in this unit focus on a few pharmacological reagents, more potent and selective phosphatase inhibitors are likely to become available to investigators in the near future. The driving force behind the development of new phosphatase inhibitors is the desire by pharmaceutical companies to provide new therapies for human diseases associated with defects in signal transduction. The proof-of-principle for phosphatase inhibitors as potential medicines has already been established by the two PP2B/calcineurin inhibitors, cyclosporin A and FK506, which are the most effective immunosuppressants currently available. However, both compounds function by an indirect mechanism (i.e., via cellular receptors or immunophilins) to inhibit PP2B activity and both cause side-effects or toxicity in humans. Thus, there is a continued need for novel PP2B/calcineurin inhibitors as safe and improved immunosuppressants. With the availability of three-dimensional structures for PP2B/calcineurin and other phosphatases with bound inhibitors, improvements in structure-activity profiles for phosphatase inhibitors are inevitable.

The current paucity of reagents to inhibit protein tyrosine phosphatases (PTPases) should change very rapidly in the coming years as many pharmaceutical companies are currently embarked on the search for PTPase inhibitors (Shenolikar and Brautigan, 2000). With growing evidence that a specific PTPase, PTP1B, antagonizes insulin signaling in many mammalian tissues, several compounds have been identified that selectively target this phosphatase (Goldstein, 2001). Whether these com-

pounds eventually emerge as therapies for diabetes is uncertain, but they will undoubtedly yield excellent tools for the investigation of signaling pathways regulated by PTP1B and other PTPases.

Despite having a common catalytic mechanism, some phosphatases have been defined as “dual-specificity” in that they dephosphorylate adjacent phosphotyrosines and phosphothreonines in their target substrates, many of which control gene expression and cell proliferation. Perhaps due to differences in the architecture of their catalytic centers, dual-specificity phosphatases also display a decreased sensitivity to vanadate. Recent studies show that some members of the PTPase family do not act on phosphoproteins but rather they dephosphorylate phospholipids (Maehama et al., 2001). One example of this is PTEN, a tumor-suppressor gene that is mutated in many human cancers. PTEN functions as a lipid phosphatase that antagonizes insulin signaling. Development of selective PTEN inhibitors may also yield new therapies for diabetes. The ability of vanadate to inhibit both PTP1B and PTEN may account for its ability to elicit physiological effects similar to insulin and other growth factors.

The focus of this unit on a few selected protein serine/threonine phosphatase inhibitors should not minimize the value of a multitude of other protein serine/threonine phosphatase inhibitors currently available to researchers. Several hundred natural products appear to elicit their effects on mammalian cell physiology by inhibiting phosphatases. Such compounds include antibiotics such as tautomycin, insecticides such as cantharidins, and other structurally diverse compounds (McCluskey et al., 2002). Among these, one particular compound bears special mention, fostreicin, produced by a strain of *Streptomyces*, may be the most specific currently available inhibitor of the PP2A-like enzymes. Fostreicin demonstrates an IC_{50} value for PP2A of 1 to 3 nM while $>100 \mu\text{M}$ fostreicin is needed to inhibit the structurally related serine/threonine phosphatase, PP1. Use of fostreicin is, however, limited by its propensity to be inactivated by oxidation and thus must be stored in the presence of a large excess of antioxidants. Commercially available fostreicin, therefore, contains numerous additives, making it very difficult to use as a specific reagent in cellular studies. Nevertheless, it is likely that selective PP1 and PP2A inhibitors can and will be developed (see Key References). Compared to most

current serine/threonine phosphatase inhibitors, which display cytotoxicity and tumor promoter activity, clinical trials established fostreicin as a potential anti-neoplastic drug. This also hints at the possibility that more selective PP1 or PP2A inhibitors may be better experimental tools than currently available compounds whose cytotoxicity may be a result of inhibiting many different protein serine/threonine phosphatases. On the other hand, it is the remarkable chemistry of the vanadium metal ion that makes the current compounds such effective tools for analyzing highly labile and difficult-to-detect cellular phosphorylation events.

Finally, a number of broad-acting or non-specific reagents have been used to inhibit protein phosphatases. These include sodium fluoride (50 mM) and sodium pyrophosphate or glycerophosphate (10 mM). These compounds suppress protein dephosphorylations in cell lysates and fractions, although not as effectively as other inhibitors. They can serve as alternatives for inhibiting phosphatases *in vitro* but show no utility in phosphoprotein analysis in intact cells.

Critical Parameters

Treatment of cells with the cell-permeable phosphatase inhibitors described in this unit is often so effective that it saturates and occludes the physiological signaling pathways, making studies that utilize combinations of hormones and phosphatase inhibitors difficult to interpret. Many mammalian proteins are regulated both positively and negatively by phosphorylation, generally occurring at distinct sites. Thus, the treatment of cells with phosphatase inhibitors may facilitate both types of modifications and yield a compound functional readout, which may bear little or no relationship to the physiological mechanisms that orchestrate the orderly control of protein function. Even when utilizing phosphatase inhibitors *in vitro*, artifactual or post-homogenization phosphorylations can result from inappropriate exposure of proteins to kinases normally located in distinct subcellular compartments and therefore are not normally physiological regulators of these proteins. Thus, this unit stresses the detection of cellular protein phosphorylation and events bearing on the functional role of such modifications.

The pharmacological approach to studying cellular protein phosphorylation as described in this unit can be employed by investigators from many backgrounds. However, further op-

timization of the outlined experimental strategy may be necessary for individual cell types, where permeability of the compounds and the array of phosphatases inhibited may dictate unique physiological consequences. Thus, the investigator is encouraged to undertake pilot studies that determine the optimal concentrations of the compound and the duration of cell exposure required to obtain a measurable and meaningful cellular response. Also, as emphasized above, while the cell-permeable phosphatase inhibitors display some target specificity, they cannot unequivocally define the phosphatases that regulate specific phosphoproteins or physiological events. Finally, the investigator should be aware that many of the compounds described above display some capacity to bind proteins other than phosphatases albeit with much lower affinity. Thus, control experiments should utilize compounds, such as the inactive okadaic acid or cyclosporin analogs, that fail to inhibit the target phosphatases. These controls should provide a more compelling argument supporting the biological effects uniquely observed with the active compounds as reflecting the inhibition of the target protein phosphatases.

To define the specific phosphatases, the investigator must turn to more molecular approaches that may involve the overexpression of phosphatases (currently a very challenging task), or the endogenous protein inhibitors that show exquisite selectivity for individual phosphatases (Oliver and Shenolikar, 1998). An alternate to overexpression may be the microinjection of phosphatases and the inhibitor proteins, an approach that has been successful in modulating cellular phosphatase activity (Alberts et al., 1993; Mulkey et al., 1994; Morishita et al., 2001). The difficulty of introducing protein inhibitors into cells, whether by overexpression or microinjection, is that most, if not all, of these proteins are tightly regulated by covalent modification. The functions of various inhibitors may be enhanced or dampened by reversible protein phosphorylation, making it difficult to predict their effects on phosphatases. Yet another approach is the use of antisense oligonucleotides or interference RNAs to “knock-down” expression of specific protein phosphatases. While this approach harbors tremendous specificity, it is difficult to control the effectiveness of these inhibitors which lower phosphatase expression, and elicit appropriate physiological responses that cannot be readily predicted. The use of dominant-negative reagents, including inactive phos-

phatase catalytic subunits or fragments of phosphatases, has shown some promise in suppressing phosphatase functions, but these reagents most likely rely on their competition with endogenous phosphatases for regulators rather than substrates, thereby making it difficult to predict the physiological outcome. However, catalytically inactive phosphatases have proven very useful in deciphering the functions of PTPases. These inactive phosphatases function as substrate traps and form stable complexes with cellular phosphoproteins, allowing identification of the potential physiological substrates of the PTPase. Even in this situation, there are serious concerns that overexpression of inactive PTPases may distort the natural specificity of these enzymes and yield spurious or unreliable data. Protein serine/threonine phosphatases themselves also occasionally form stable complexes with cellular substrates and such complexes can be isolated using affinity chromatography based on phosphatase inhibitors, such as microcystin-LR, immobilized on Sepharose or other dextran surfaces. Such affinity matrices are not commercially available but a number of publications describe the synthesis and use of such resins. The reader may refer to Campos et al. (1996) or Damer et al. (1998). However, this approach has thus far been more successful in identifying phosphatase regulators than substrates.

Troubleshooting

The use of phosphatase inhibitors as described in this unit is associated with several problematic issues regarding compound stability and permeability. First and foremost, many of these compounds are highly hydrophobic. Some are light-sensitive and others difficult to store for long periods. These factors contribute to the problem of defining their precise concentration in culture media and buffers and predicting their effects on target phosphatases. In cellular studies, there are additional problems in that external inhibitor concentration is not an accurate predictor of the intracellular concentration of compounds, which are not evenly distributed throughout the cell. Thus, the literature reports widely varying IC_{50} values for inhibition of purified phosphatases and the sensitivity of known PP1 and/or PP2A-regulated events in cells. Thus, the protocols described in this unit deliberately err on the side of using excess phosphatase inhibitors. While this ensures effective phosphatase inhibition, additional problems may arise in terms of the cytotoxicity elicited by these reagents, which varies

widely among different cell types. Quiescent, confluent and highly differentiated cells appear more susceptible to programmed cell death in response to phosphatase inhibitors such as OA and CA, although the prolonged overactivation of multiple signaling pathways by these inhibitors may also contribute to the cytotoxicity observed in actively growing cells. Thus, investigators are encouraged to determine the lowest concentrations of inhibitors and shortest duration of cell exposure necessary for a consistent and measurable physiological response.

Anticipated Results

Phosphatase inhibitors that inhibit the major mammalian protein serine/threonine or tyrosine phosphatases unmask an array of kinase cascades and thereby enhance the phosphorylation of a wide range of proteins. This in turn permits the investigator to detect and analyze novel phosphorylation events. By selecting specific phosphatase inhibitors and restricting their concentrations, the investigator can also inhibit a subset of cellular phosphatases yielding more defined results by not only limiting the panel of phosphoproteins visualized but also the sites modified on the given phosphoprotein. For an example of a specific phosphatase inhibition experiment, refer to Haysstead et al. (1989). Functional effects associated with the rapid phosphorylation-dephosphorylation of cellular proteins are more readily visualized in the presence of phosphatase inhibitors. These experiments can establish the importance of protein phosphorylation in physiological events where the precise protein target or phosphorylation event has not been identified. However, readouts such as gene expression that result from increased phosphorylation of nuclear proteins often require long exposure of cells to phosphatase inhibitors and thereby risk the potentially confounding effects of cytotoxicity. Here, a compromise must be reached and inhibitor concentrations lowered to levels that maintain cell viability and still promote the transcription activation of target genes.

Time Considerations

A common scenario for the experiments described above is that cells are metabolically labeled using ^{32}P -orthophosphate for periods between 90 and 120 min (Sefton, 1997). Phosphatase inhibitors are then added to the media and the cells incubated for a further 30 min. Following homogenization, the phosphoproteins are analyzed using SDS-PAGE (UNIT 10.2A)

and autoradiography or phosphorimaging, which adds an additional 2 to 3 hr. Thus, the total time required may be minimally estimated at 6 hr.

In the absence of metabolic labeling, SDS-PAGE may be followed by electrophoretic transfer and analysis of changes in protein mobility reflecting increased phosphorylation or the modification of specific proteins. Phosphorylation sites may be identified by western immunoblotting using phosphospecific antibodies. These approaches provide different pieces of information but carry similar total time considerations.

Design and Use of Analog-Sensitive Protein Kinases

Many protein kinases can be engineered to accept analogs of ATP that are not efficiently used by wild-type kinases. These engineered kinases, which are referred to as “analog-sensitive” or “*-as*” alleles, are also often sensitive to protein kinase inhibitor variants that do not block the activity of nonmutant kinases. Selective *in vitro* use of radiolabeled ATP analogs by *-as* kinases can be exploited to identify the direct phosphorylation targets of individual kinases in complex extracts. In organisms in which it is practical to replace wild-type kinase genes with engineered alleles, the *in vivo* activity of an *-as* kinase can be reversibly blocked with an allele-specific inhibitor. Thus, analog-sensitive kinases can be effective tools for discovery of the cellular functions and phosphorylation targets of individual enzymes. A theoretical background for the design and use of these alleles is discussed in the Commentary section at the end of this unit, as are strategies for construction of candidate *-as* alleles of any kinase.

In vivo use of analog-sensitive kinase alleles requires access to kinase inhibitor analogs. This unit describes protocols for synthesis of 1NM-PP1 and 1NA-PP1 (see Basic Protocols 1 and 2), which are among the most effective allele-specific inhibitors of *-as* kinases. These protocols assume knowledge of organic synthesis, and it is advisable to work with a chemist that can provide assistance if one is not familiar with organic chemistry methods. Under no circumstances should one attempt these protocols if not comfortable with safety procedures fundamental to synthetic organic chemistry. Much of the equipment required for these procedures is uncommon in molecular biology groups but readily accessible in chemistry laboratories. The authors have provided information relevant to analysis of NMR spectra for researchers familiar with this technique. A detailed description of product analysis is, however, beyond the scope of this section.

The authors have also supplied a protocol for production of γ -³²P-labeled *N*⁶(benzyl)ATP, an ATP analog that is commonly selectively used by *-as* kinases, from the ADP analog (see Basic Protocol 3 and Support Protocols 1 and 2). This procedure employs enzymatic phosphorylation of *N*⁶(benzyl)ADP by immobilized nucleoside diphosphate kinase (NDPK), and can be used to produce other γ -labeled ATP analogs from ADP analogs (Mourad and Parks, 1966; Kraybill et al., 2002). Commercial availability of *N*⁶(benzyl)ADP, as well as other ADP analogs, is still somewhat limited. A method for synthesis of *N*⁶(benzyl)ADP has been published (Shah et al., 1997; Shah and Shokat, 2002). Labeling of ADP analogs by the procedure provided here requires moderately large quantities (~2.5 mCi) of [γ -³²P]ATP, and it is therefore advisable to ensure that this raises no issues with one's license to use radioactive materials.

A final protocol (see Basic Protocol 4) describes the assays for testing inhibition of analog-sensitive kinases in yeast.

NOTE: Although the protocols described in this unit are directly derived from published material, it is important to note that the use of analog-sensitive kinases, analog-sensitive kinase inhibitors, and ATP analogs is protected by U.S. patents 6,610,483; 6,521,417; 6,390,821 and 6,383,790, as well as patents in other countries, which are owned by Princeton University and exclusively licensed to Cellular Genomics Incorporated (CGI) of Branford, Connecticut. Information regarding accessing rights to make and use the technology can be obtained by contacting CGI.

SYNTHESIS OF 1NM-PP1

This protocol and the one that follows for 1NA-PP1 (see Basic Protocol 2) are based on previously published methods (Bishop et al., 1998; Bishop et al., 1999). The synthetic schemes are diagrammed in Figure 18.11.1. A representative NMR spectrum is presented in Figure 18.11.2.

Materials

1-naphthylacetic acid (Acros Organics)
Hexane
N,N-dimethylformamide (DMF; Aldrich)
Oxalyl chloride (Aldrich)
Tetrahydrofuran (THF; Aldrich)
Sodium hydride (Aldrich)
Malononitrile (Aldrich)
1 N H₂SO₄
Ethyl acetate
MgSO₄, anhydrous
1,4-dioxane (Aldrich)
Sodium bicarbonate (Aldrich)
Dimethyl sulfate (Aldrich)
Diethyl ether (Et₂O)
Silica Gel 60 (pore size 0.040 to 0.063 mm; Merck)
Ethanol (Aldrich)
Triethylamine (Aldrich)
tert-butylhydrazine hydrochloride (Aldrich)
Chloroform (CHCl₃)
1% (v/v) methanol in CHCl₃
Formamide (Aldrich)
Activated charcoal
Celite

Büchi Rotavapor Model R-200 or equivalent rotary evaporator
Ice bath
Separatory funnel
Oil baths, 80°, 100°C, 180°C
10-in. (25.4-cm) length × 2-in. (5.0-cm) i.d. chromatography column
TLC plates (Silica Gel F₂₅₄; EM Science) and tank
Reflux condenser
Filter paper
Buchner funnel

Synthesize 1-naphthylacetylmalononitrile

1. Dissolve 3.72 g 1-naphthylacetic acid (20.0 mmol) in 100 ml hexane.
2. Add 146 mg *N,N*-dimethylformamide (DMF; 2.0 mmol).
3. Add, dropwise, 12.7 g oxalyl chloride (100 mmol).
4. Wait for gas evolution to stop (~30 min), then remove solvent under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator.
5. Redissolve the residue (containing the acid chloride) in 30 ml tetrahydrofuran (THF).
6. Suspend 1.06 g sodium hydride (44.0 mmol) in 10 ml THF.

Figure 18.11.1 Synthetic schemes of 1NM-PP1 and 1NA-PP1. Conditions: (i) 5 eq oxalyl chloride, 0.1 eq DMF, room temperature, 1 hr; (ii) 2 eq NaH, 1 eq malononitrile, THF, 0°C to room temperature, 1 hr; (iii) 8 eq NaHCO₃, 5 eq dimethyl sulfate, dioxane/water (6:1), reflux, 1 hr; (iv) 2 eq triethylamine, 1 eq *tert*-butylhydrazine hydrochloride, EtOH, reflux, 1 hr; (v) 1 eq *tert*-butylhydrazine, DMF, room temperature, 1 hr; (vi) formamide, 180°C, 10 hr.

Figure 18.11.2 NMR data for 1-*tert*-butyl-3-naphthalen-1-ylmethyl-1*H*-pyrazolo[3,4-*d*]pyrimidin-4-ylamine (1NM-PP1). Compound is white powder; ¹H NMR (CDCl₃, 400 MHz) δ 1.82 (s, 9H), 4.73 (s, 2H), 4.87 (br s, 2H), 7.17 (d, J = 7 Hz, 1H), 7.37 (t, J = 8 Hz, 1H), 7.52 (m, 2H), 7.78 (d, J = 8 Hz, 1H), 7.87 (m, 1H), 8.19 (m, 1H), 8.23 (s, 1H); ¹³C NMR (CDCl₃, 100 MHz) δ 29.2, 32.7, 60.0, 101.1, 123.5, 125.6, 125.8, 126.2, 126.6, 128.2, 128.9, 131.9, 133.9, 134.0, 140.5, 154.5, 154.7, 157.6, HRMS (EI) molecular ion calculated for C₂₀H₂₁N₅ 331.17993, found 331.17951.

7. Dissolve 1.45 g malononitrile (22.0 mmol) in 10 ml THF and add dropwise to the NaH/THF suspension (step 6) on an ice bath.
8. Add the THF solution of acid chloride from step 5 dropwise to the malononitrile solution with vigorous stirring. Stir for 1 hr.
9. Add ~15 ml of 1 N H₂SO₄ and 50 ml water.
10. Extract three times, each time with 100 ml ethyl acetate, in a separatory funnel.

The ethyl acetate phase is the top phase.

11. Combine ethyl acetate extracts and dry by addition of ~5 g anhydrous MgSO₄.
12. Evaporate the solvent under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator, to yield 1-naphthylacetylmalononitrile, a yellow solid.

Yield should be ~70%.

Synthesize 1-naphthylmethyl(methoxy)methylidenemalononitrile

13. Dissolve 2.23 g 1-naphthylacetylmalononitrile (from step 12; 10.0 mmol) in a mixture of 18 ml dioxane and 3 ml water.
14. Add 6.8 g sodium bicarbonate.
15. Add 4.9 ml of dimethyl sulfate with vigorous stirring. Heat the reaction mixture at 100°C on an oil bath for 2 hr.
16. Cool the reaction mixture to room temperature.
17. Dilute with 70 ml water and extract three times, each time with 100 ml Et₂O, in a separatory funnel.
18. Combine the Et₂O extracts and dry over anhydrous MgSO₄.
19. Evaporate the Et₂O under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator to give an oil.
20. Prepare a 10-in. (25.4-cm) × 2-in. (5.0-cm) column containing 200 g Silica Gel 60, saturated with 1:1 Et₂O/hexane (the mobile phase).
21. Dissolve the oil from step 19 in a small amount of mobile phase and apply to column. Elute with mobile phase. Sample the eluate as it emerges from the column and analyze by thin-layer chromatography (TLC) using 1:1 Et₂O/hexanes as the mobile phase. Pool fractions containing a species with R_f of ~0.24.
22. Evaporate solvent under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator to produce a white crystalline solid 1-naphthylmethyl(methoxy)methylidenemalononitrile.

Yield should be ~75%.

Synthesize 5-amino-1-tert-butyl-3-(1'-naphthylmethyl)-4-cyano-1H-pyrazole

23. Dissolve 1.74 g of 1-naphthylmethyl(methoxy)methylidenemalononitrile (from step 22; 7.0 mmol) in 50 ml ethanol.
24. Add 1.51 g triethylamine (15.0 mmol) and 0.92 g *tert*-butylhydrazine hydrochloride (7.4 mmol). Reflux at 80°C on an oil bath for 1 hr.
25. Cool the mixture and evaporate the solvent under reduced pressure.
26. Suspend the residue in water and extract three times, each time with 50 ml CHCl₃, in a separatory funnel.

The CHCl₃ phase is the top phase.

27. Combine the CHCl_3 extracts, dry over anhydrous MgSO_4 , and evaporate the solvent under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator, to give a yellow solid.
28. Prepare a 10-in. (25.4-cm) \times 2-in. (5.0-cm) column containing 100 g Silica Gel 60, saturated with CHCl_3 (the mobile phase).
29. Dissolve the yellow solid in a minimal volume of CHCl_3 and apply to the column. Elute with 1% methanol in CHCl_3 . Sample the eluate as it emerges from the column and analyze by thin-layer chromatography (TLC) using 1% methanol in CHCl_3 as the mobile phase. Pool fractions containing a species with R_f of ~ 0.1 .
30. Evaporate solvent to obtain a white solid, 5-amino-1-*tert*-butyl-3-(1'-naphthylmethyl)-4-cyano-1*H*-pyrazole.

Yield should be $\sim 75\%$.

Synthesize 4-amino-1-*tert*-butyl-3-(1'-naphthylmethyl)-1*H*-pyrazolo[3,4-*d*]-pyrimidine (1NM-PP1)

31. Suspend 0.9 g 5-amino-1-*tert*-butyl-3-(1'-naphthylmethyl)-4-cyano-1*H*-pyrazole (from step 30; 3.4 mmol) in 20 ml of formamide.
32. Heat this suspension at 180°C on an oil bath, stirring with a reflux condenser for 10 hr.
33. Cool reaction mixture and dilute with 80 ml water.
34. Collect precipitate by filtration on paper in a Buchner funnel.
35. Dissolve precipitate in 40 ml room temperature ethanol.
36. Add 1 g powdered activated charcoal. Boil at 80°C for 10 min.
37. Pour a celite pad on a Buchner funnel using a slurry of celite in ethanol. Filter the hot mixture through this celite pad. Collect the filtrate.
38. Evaporate the solvent to obtain 1NM-PP1 as a white powder.

Expect yields of $\sim 75\%$.

SYNTHESIS OF 1NA-PP1

1NA-PP1 can be synthesized in the same manner as 1NM-PP1, with two differences. First, the acid chloride (1-naphthoyl chloride) is directly used in the first step of the synthesis, since it is commercially available. Second, a different condition is used in the reaction that forms the pyrazole ring, giving much better yields than the original procedure. A representative NMR spectrum is presented in Figure 18.11.3.

Materials

1-naphthoyl chloride (Aldrich)
 Tetrahydrofuran (THF; Aldrich)
 Sodium hydride (Aldrich)
 Malononitrile (Aldrich)
 1 N H_2SO_4
 Ethyl acetate
 MgSO_4 , anhydrous
 1,4-dioxane (Aldrich)
 Sodium bicarbonate (Aldrich)
 Dimethyl sulfate (Aldrich)

Synthesize 1-naphthoymalononitrile

1. Dissolve 3.80 g (20 mmol) 1-naphthoyl chloride in 30 ml tetrahydrofuran (THF).
2. Dissolve 1.06 g sodium hydride (44.0 mmol) in 10 ml THF.
3. Dissolve 1.45 g malononitrile (22.0 mmol) in 10 ml THF and add dropwise to the NaH/THF suspension on an ice bath.
4. Add the THF solution of 1-naphthoyl chloride from step 1 dropwise to the malononitrile solution with vigorous stirring. Stir for 1 hr.
5. Add ~15 ml of 1 N H₂SO₄ and 50 ml water.
6. Extract three times, each time with 100 ml ethyl acetate in separatory funnel.

The ethyl acetate phase is the top phase.

7. Combine ethyl acetate extracts and dry by addition of anhydrous MgSO₄.
8. Evaporate the solvent to yield 1-naphthoymalononitrile, a yellow solid.

Yield should be approximately 70%.

Synthesize 1-naphthyl(methoxy)methylidenemalononitrile

9. Dissolve 2.20 g 1-naphthoymalononitrile (from step 8; 10.0 mmol) in a mixture of 18 ml dioxane and 3 ml water.
10. Add 6.8 g sodium bicarbonate.
11. Add 4.9 ml of dimethyl sulfate with vigorous stirring. Heat the reaction mixture at 100°C on an oil bath for 2 hr.
12. Cool the reaction mixture to room temperature.
13. Dilute with 70 ml water and extract three times, each time with 100 ml Et₂O.
14. Combine the Et₂O extracts and dry over anhydrous MgSO₄.
15. Evaporate the Et₂O under reduced pressure to give an oil.
16. Prepare a 10-in. (25.4-cm) × 2-in. (5.0-cm) column containing 200 g Silica Gel 60, saturated with 1:1 Et₂O/hexane (the mobile phase).
17. Dissolve the oil from step 15 in a small amount of mobile phase and apply to column. Elute with mobile phase. Sample the eluate as it emerges from the column and analyze by thin-layer chromatography (TLC) using 1:1 Et₂O/hexanes as the mobile phase. Pool fractions containing a species with R_f of ~0.22.
18. Evaporate solvent under reduced pressure in a Büchi Rotavapor or equivalent rotary evaporator, to produce a white crystalline solid, 1-naphthyl(methoxy)methylidenemalononitrile.

Yield should be ~75%.

Synthesize 5-amino-1-tert-butyl-3-(1'-naphthyl)-4-cyano-1H-pyrazole

19. Add 0.38 g sodium ethoxide (5.5 mmol) and 0.68 g *tert*-butylhydrazine hydrochloride (5.5 mmol) to 10 ml DMF. Stir mixture at room temperature for 0.5 hr.
20. Filter the mixture. Save the filtrate, which contains *tert*-butylhydrazine.
21. Dissolve 1.17 g 1-naphthyl(methoxy)methylidenemalononitrile (from step 18; 5.0 mmol) in 20 ml DMF. Add the *tert*-butylhydrazine-containing filtrate from step 20. Stir the reaction mixture at room temperature for 1 hr.
22. Evaporate the solvent under reduced pressure.

23. Suspend the residue in water and extract three times, each time with 50 ml CHCl₃, in a separatory funnel.
24. Combine the CHCl₃ extracts, dry over anhydrous MgSO₄, and evaporate the solvent to give a yellow solid.
25. Prepare an 80-in. (20.3-cm) × 1.5-in. (3.8-cm) column containing 100 g Silica Gel 60, saturated with CHCl₃ (the mobile phase).
26. Dissolve the yellow solid in a minimal volume of CHCl₃ and apply to the column. Elute with 1% methanol in CHCl₃. Sample the eluate as it emerges from the column and analyze by thin-layer chromatography (TLC) using 1% methanol in CHCl₃ as the mobile phase. Pool fractions containing a species with R_f of ~0.1.
27. Evaporate solvent to produce a white solid, 5-amino-1-tert-butyl-3-(1'-naphthyl)-4-cyano-1H-pyrazole.

Yield should be ~75%.

Synthesize 4-amino-1-tert-butyl-3-(1'-naphthyl)-1H-pyrazolo[3,4-d]pyrimidine (1NA-PP1)

28. Suspend 0.99 g 5-amino-1-tert-butyl-3-(1'-naphthyl)-4-cyano-1H-pyrazole (3.4 mmol) in 20 ml of formamide.
29. Heat this suspension at 180°C on an oil bath, stirring with a reflux condenser for 10 hr.
30. Cool the reaction mixture and dilute with 80 ml water.
31. Collect the precipitate by filtration on paper in a Buchner funnel.
32. Dissolve precipitate in 40 ml room temperature ethanol. Add 1 g powdered activated charcoal. Boil at 80°C for 10 min.
33. Pour a celite pad on a Buchner funnel using a slurry of celite in ethanol. Filter the hot mixture through this celite pad. Collect the filtrate.
34. Evaporate the solvent to obtain 1NA-PP1 as a white powder.

Expect yields of ~75%.

PREPARATION OF γ -³²P-LABELED N⁶(BENZYL)ATP

NDPK is a ubiquitous enzyme that catalyzes the exchange of γ phosphate between nucleoside triphosphate species and nucleoside diphosphate species by means of a bi-bi-ping-pong mechanism involving a phospho-enzyme intermediate (Weaver, 1962; Mourad and Parks, 1966). In this protocol, 6× His-tagged NDPK is immobilized in the solid phase by metal affinity chromatography, and the column-bound NDPK is equilibrated with [γ -³²P]ATP in low magnesium to generate the labeled phospho-enzyme. The column is then washed to remove residual ATP, and a ten-fold molar excess of N⁶(benzyl)ADP is added in the presence of larger amounts of magnesium. Eluate from this stage contains a mixture of [γ -³²P]N⁶(benzyl)ATP and N⁶(benzyl)ADP, and can be used directly in kinase reactions. This protocol can also be used to generate γ -³⁵S-labeled nucleoside triphosphates.

Materials

- 1:1 slurry of cobalt affinity resin (IDA-Co²⁺-Sepharose) in HBS/0.02% sodium azide (see Support Protocol 1)
- HEPES buffered saline (HBS): 150 mM NaCl/100 mM HEPES, pH 7.4
- Purified NDPK-6×His (see Support Protocol 2)
- Phosphate-buffered saline (PBS): 150 M NaCl/100 mM sodium phosphate pH 7.4 (see APPENDIX 2 for sodium phosphate buffer)
- [γ -³²P]ATP (~3000 Ci/mmol or ~7000 Ci/mmol)
- 1 mM N⁶(benzyl)ADP (Shah et al., 1997; Shah and Shokat, 2002)
- PBS (see above) containing 5 mM MgCl₂
- 2-mm glass beads (VWR)
- 1-ml disposable pipet tip
- Stand and clamp to accommodate 1-ml disposable pipet tip

NOTE: All steps are performed at room temperature.

Prepare cobalt affinity column

1. Place a 2-mm glass bead inside a 1-ml disposable pipet tip and flick the tip to make sure the bead is firmly lodged near the end. Use scissors to remove the end of the tip where it extends beyond the glass bead. Mount this miniature column in a clamp on a stand.
2. Add 200 μ l of 1:1 slurry of cobalt affinity resin in HBS/0.02% sodium azide (prepared as in Support Protocol 1) to the column prepared in step 1.
3. Add 1 ml HBS and allow the buffer to drain until level with the top of the beads.

If desired, a 1-ml pipet can be used to drive fluid flow through the beads. If this is done, be careful to avoid introducing a negative relative pressure in the column when removing the pipet, as this can disturb the beads.

Add NDPK-6×His and radiolabeled ATP to column

4. Add ~165 μ g purified NDPK-6×His.

If the NDPK is in a buffer other than the recommended HKG buffer (see Support Protocol 2), it must be freed of any chelators or reducing agents, including EGTA, before addition to the column.

5. When this has flowed into the column, follow with 1 ml PBS. If desired, retain the eluate to quantify protein retention.

PBS is used in place of HBS in all steps subsequent to addition of NDPK. IDA-Co²⁺ appears to have a weak affinity for the various nucleoside phosphate species; PBS competitively blocks these interactions. A slight lavender color may be noticed on the initial addition of PBS. This is insoluble cobaltous phosphate. It has not been found to interfere with any subsequent steps, nor has the use of PBS caused any significant loss of enzyme from the column.

NDPK-6×His has an A₂₈₀ extinction coefficient of 1.31 for a 1 mg/ml solution, as calculated using the Gill equation.

6. Dilute 833 pmol [γ -³²P]ATP (2.5 mCi at 3000 Ci/mmol, 5.8 mCi at 7000 Ci/mmol) with PBS to contain no greater than 1 mM reducing agent.

Commercial [γ -³²P]ATP may contain an appreciable quantity of DTT or other reducing agent. This should be diluted so that enzyme is not lost from the column due to reduction of cobalt.

The reactions can be scaled for use of smaller quantities of label.

7. Add the radioisotope to the column and allow it to flow through, driving the flow if necessary.

A moderate darkening of the column due to a low level of metal reduction may be observed, and a small amount of reduced metal may be present in the eluate. This should not normally be cause for concern. Small samples of the load and eluate may be taken to quantify label retention on the column by liquid scintillation counting.

8. Wash the column at least twice, each time with 1 ml PBS.

The eluate should be sampled to quantify label release in these steps, to ensure that residual [γ - ^{32}P]ATP has been cleared from the column.

Add N^6 (benzyl)ADP to column and elute N^6 (benzyl)ATP

9. Add 8 μl of 1 mM N^6 (benzyl)ADP (8 nmol) to 32 μl PBS containing 5 mM MgCl_2 .

This ADP analog and others can be synthesized using published procedures (Shah et al., 1997; Shah and Shokat, 2002).

10. Carefully add this to the column, and then gently force it into the beads until the liquid is again level with the top of the beads.

11. Add 250 μl PBS containing 5 mM MgCl_2 and gently force it through the beads until level, collecting the eluate.

A small sample of the eluate should be taken for liquid scintillation counting to determine yield.

SUPPORT PROTOCOL 1

PREPARATION OF COBALT AFFINITY RESIN (IDA- Co^{2+} -SEPHAROSE)

Materials

Iminodiacetic acid (IDA)–Sepharose slurry (Sigma)
200 mM cobalt chloride
HEPES-buffered saline (HBS): 150 mM NaCl/100 mM HEPES, pH 7.4
HBS (see above) containing 0.02% sodium azide
15-ml conical tubes

1. Place ~3 ml of IDA-Sepharose bead slurry in a 15-ml conical tube.
2. Wash several times with water, each time by filling the 15-ml conical tube and then decanting.
3. Wash once with 200 mM cobalt chloride.
The binding is essentially instantaneous.
4. Wash four times with HBS.
5. Store beads at 4°C in a bead volume equivalent of HBS containing 0.02% sodium azide.

SUPPORT PROTOCOL 2

EXPRESSION AND PURIFICATION OF NDPK

A 6 \times His–tagged NDPK from *S. cerevisiae* is expressed in BL21(DE3) *E. coli* and purified by metal-affinity chromatography.

Materials

pJDB1 expression plasmid: available from the Shokat Laboratory
(justinb@itsa.ucsf.edu) or Weiss Laboratory (elweiss@northwestern.edu)
E. coli strain BL21(DE3) (Novagen)
IPTG
Cobalt affinity resin (IDA- Co^{2+} -Sepharose; see Support Protocol 1)
HIK200 buffer (see recipe), 4°C

HEK10 buffer (see recipe), 4°C

HKG buffer (see recipe), 4°C

Liquid nitrogen

30°C shaking incubator

5-ml chromatography column

MWCO 15,000 dialysis membrane

Additional reagents and equipment for transformation of *E. coli* (UNIT 1.8), growing bacterial cultures (UNIT 1.2), preparation of bacterial lysates (UNIT 1.7), dialysis (APPENDIX 3C), and determination of protein concentration (UNIT 10.1A)

Grow transformed bacteria

1. Transform (UNIT 1.8) the pJDB1 expression plasmid into *E. coli* strain BL21(DE3).

This plasmid is a derivative of pET19b containing the S. cerevisiae gene YNK1 with a C-terminal 6×-His tag. This plasmid confers resistance to kanamycin. Cells carrying this plasmid should be cultured in medium containing 30 μg/ml kanamycin for the transformation procedure (see UNIT 1.2).

2. Grow transformed strain to mid-log phase ($OD_{600} = 0.5$ to 1.0) at 37°C (UNIT 1.2).
3. Add IPTG to the culture for a final concentration of 0.4 mM.
4. Incubate with shaking at 37°C for 3 hr.

Prepare bacterial lysate

The following steps are performed at 4°C, using chilled buffers.

5. Isolate *E. coli* cells by centrifugation (UNIT 1.7).
6. Produce clarified lysate by method of choice (UNIT 1.7), ensuring that the salt concentration is not less than 150 mM in the final extract.
7. Prepare a 5-ml column of IDA-Co²⁺-Sephrose.

A 5-ml column is appropriate for a 1-liter-scale expression.

Purify lysate by cobalt affinity chromatography and dialysis

8. Apply the lysate (from step 7) to the column.
9. Wash with 4 column volumes HIK200 buffer.
10. Elute with 2.5 column volumes HEK10 buffer.
11. Dialyze (APPENDIX 3C) against three changes of HKG buffer, each time for 2 hr, using a MWCO 15,000 dialysis membrane.
12. Determine protein concentration by measuring A_{280} (UNIT 10.1A), divide into aliquots, and freeze using liquid nitrogen. Store at -80°C.

NDPK-6×His has an A_{280} extinction coefficient of 1.31 for a 1 mg/ml solution, as calculated using the Gill equation (also see UNIT 10.1A).

The purified protein has a tendency to precipitate in buffers containing <250 mM salt. Highly concentrated solutions may exhibit some precipitation at even higher salt concentrations. If precipitation is observed during dialysis, the precipitated protein may be resolubilized by slow addition of 2.5 M KCl. If necessary; a final KCl concentration as high as 800 mM is acceptable.

Storage buffer should be free of DTT or other reducing agents, as these will complicate subsequent use of the enzyme.

IN VIVO INHIBITION OF ANALOG-SENSITIVE KINASES IN YEAST

If the activity of a protein kinase of interest is required for growth under some or all conditions, halo assays can be used to evaluate inhibition of *-as* alleles of this kinase. These simple experiments involve placement of a small disc of filter paper saturated with a compound of interest onto a solid-medium plate that has been uniformly spread with yeast cells. If the compound inhibits growth of the cells, a clear zone or “halo” will be evident around the filter disc. The size of this halo is a function of the sensitivity of the cells to the compound. These assays are a convenient way to evaluate sensitivity to a number of different compounds. Alternatively, a traditional liquid culture and inhibitor assay may be performed. Both methods are included here.

Materials

Inhibitors: INM-PP1 (see Basic Protocol 1) and INA-PP1 (see Basic Protocol 2)

DMSO

Yeast cells of interest containing wild-type (control) and analog-sensitive kinase alleles

Appropriate liquid and solid yeast media (*UNIT 13.1*)

5-mm sterile filter discs

Additional reagents and equipment for growing yeast cells (*UNIT 13.2*)

For the halo assay

- 1a. Make 10 mM, 1 mM, and 0.5 mM working solutions of inhibitors (1NM-PP1 and 1NA-PP1) in DMSO.
- 2a. Grow yeast cells of interest (containing *-as* analog-sensitive kinase gene; also include wild-type control) to log phase in liquid medium (*UNIT 13.2*).
- 3a. Dilute cultures to $OD_{600} = 0.2$. Place 2 to 3 ml of a diluted culture onto a solid medium plate (*UNITS 13.1 & 13.2*) such that the entire surface of the plate is covered with excess liquid medium. Allow cells to settle for 2 to 5 min.
- 4a. Tilt the plate so excess liquid pools along one edge. Remove most of this liquid with a pipet. Rock the plate a few times to ensure that remaining liquid is evenly distributed. Allow the plate to dry.
- 5a. Place 5-mm sterile filter discs onto the plate.
Four or five evenly spaced discs can generally be placed on a single plate.
- 6a. Gently pipet 10 μ l of inhibitor solution onto the middle of a filter disc. Include a DMSO-only control. Allow cells to grow and measure diameter of growth inhibition zones.

For the liquid culture assay

- 1b. Make a stock solution of the inhibitor of interest (1NM-PP1 or 1NA-PP1) dissolved in DMSO, containing between 10 mM and 25 mM inhibitor.

The solution can be stored at room temperature in a dark box.

- 2b. Grow yeast cells of interest (containing *-as* analog-sensitive kinase gene; also include wild-type control) to mid-log phase in liquid medium (*UNIT 13.2*).

Remember to grow enough cells to perform inhibitor treatment and a DMSO-only control. If planning to use conditioned medium, grow enough excess culture to provide medium for subsequent incubations with and without inhibitor.

Fresh and conditioned media generally differ in pH and nutrient concentration. The use of conditioned medium avoids effects caused by adaptation to new medium.

- 3b. Add inhibitor stock solution to the liquid medium. When assaying a range of inhibitor concentrations, ensure that the final concentration of DMSO is the same in all incubations. If fresh nonconditioned medium is used, add the inhibitor stock to fresh medium while actively mixing, either by swirling in a flask or stirring with a magnetic bar. Add the same amount of DMSO to a second portion of fresh medium for a no-inhibitor control. Harvest the cells from the culture grown in step 2 by filtration or centrifugation, and resuspend them in the inhibitor-containing and control medium, respectively. If conditioned medium is used, remove cells from an appropriate volume of culture by filtration or centrifugation. Collect the cleared conditioned medium (filtrate or supernatant), add inhibitor to one portion and DMSO for control to a second portion, then resuspend the cells back into the inhibitor- (or DMSO)-containing conditioned medium.

Direct addition of concentrated inhibitor to growing cultures is not recommended.

- 4b. Incubate and perform phenotypic analysis as desired.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see APPENDIX 2; for suppliers, see APPENDIX 4.

HEK10 buffer

20 mM HEPES, pH 7.4
10 mM EDTA
250 mM KCl
Store indefinitely at room temperature

HIK200 buffer

20 mM HEPES, pH 7.4
200 mM imidazole
50 mM KCl
Store indefinitely at 4°C

HKG buffer

20 mM HEPES, pH 7.4
250 mM KCl
20% (v/v) glycerol
Store indefinitely at room temperature

COMMENTARY

Background Information

Understanding the function of any protein kinase requires identification of its direct phosphorylation targets and evaluation of effects caused by its inactivation. This kind of characterization is among the most challenging in contemporary molecular biology. The study of protein kinase function has been greatly advanced through the use of cell-permeable compounds that inhibit the enzymatic activity of these proteins. Protein kinase inhibitors with relatively high specificity have been identified in screens of chemical compound libraries (Gray et al., 1998). Such compounds have already proven useful in treat-

ment of cancers caused by deranged protein kinase signaling (Druker et al., 2001). However, kinase inhibitors generally block the activity of a group of closely related enzymes. This lack of perfect specificity can prove problematic if closely related kinases control different processes in the cell type being studied. Acquisition of specific kinase inhibitors through exhaustive screening of compound libraries is furthermore a laborious process, and is beyond the capabilities of most molecular biology laboratories.

In the absence of perfectly specific protein kinase inhibitors, it is necessary to use alternative means to inactivate a kinase of interest.

Despite their power, each of these approaches has drawbacks. Depletion techniques (such as RNAi) do not address the function of the kinase's enzymatic activity. Furthermore, the kinetics of depletion can be very slow, which may allow homeostatic mechanisms to compensate for loss of enzyme function through activation of alternate pathways. Endogenous kinase genes can be replaced with catalytically inactive alleles in organisms that are easy to manipulate genetically. This is not straightforward with essential kinases, and is also subject to concerns about phenotypes that arise through adaptation. It is possible to generate conditional alleles that are rapidly inactivated under restrictive conditions (most often elevated temperature). These alleles are usually generated through random mutagenesis of the kinase of interest, and the biochemical reason for their effect on activity is generally obscure. More importantly, the phenotype of any conditional allele must be weighed against the effects of the restrictive conditions on wild-type cells. Temperature shifts can cause major perturbation of cell physiology, significantly complicating interpretation of conditional mutant phenotypes.

Given limitations in the above approaches, chemical and genetic approaches have been combined to allow highly specific inhibition of many protein kinases. The ATP-binding site of many protein kinases can be mutated to create kinase variants that are inhibited by cell-permeable compounds that do not appreciably affect the activity of wild-type protein kinases (Bishop et al., 2000; Weiss et al., 2000; Carroll et al., 2001; Sekiya-Kawasaki et al., 2003; Wang et al., 2003; reviewed in Bishop et al., 2001). Allele-specific inhibition of these kinases *in vivo* can be used to determine an individual protein kinase's physiological function without the confounding effects of temperature shift and adaptation. These "analog-sensitive" or "*-as*" mutant enzymes can often use derivatized forms of ATP that are poorly used by wild-type kinases (Shah et al., 1997; Bishop et al., 1998; Polson et al., 2001; Shah and Shokat, 2002). Specific use of ATP analogs by *-as* kinases *in vitro* can be exploited to directly identify kinase phosphorylation targets in complex protein mixtures (Shah and Shokat, 2002; Ubersax et al., 2003). Substrate specificity of *-as* kinase alleles does not appear to differ from corresponding wild-type alleles (Witucki et al., 2002). This is consistent with the physical separation between the mutated region of the

ATP-binding pocket and the substrate-recognition domain.

Design of analog-sensitive protein kinase alleles

The primary sequences and three-dimensional structures of protein kinase ATP-binding sites are conserved (Hanks and Hunter, 1995), and it is therefore straightforward to design candidate analog-sensitive kinase alleles. Analog-sensitive protein kinase alleles are constructed by substitution of glycine or alanine for an amino acid in kinase subdomain V, which is typically bulky and hydrophobic. This "gatekeeper" residue forms part of a hydrophobic pocket that interacts with the adenosine moiety of ATP; many competitive inhibitors of protein kinases bind in this site. Replacing the large side chain at this position with a smaller one alters the shape of the pocket, allowing molecules that do not interact with wild-type kinases to bind. Glycine substitutions at this position are referred to as "*-as1*" alleles and alanine substitutions as "*-as2*" alleles. The rationale behind this approach is supported by analysis of crystal structures of Hck-PP1 complex and the c-Src(*-as1*)-*N*⁶(benzyl)ATP (Schindler et al., 1999; Witucki et al., 2002). The nature of these alleles is illustrated in Figure 18.11.4, which schematizes some of the kinase-inhibitor contacts that are important for association of PP1 with the ATP binding site of Hck, as well as the engineered extra space present in Hck1-*as1* that allows binding of 1NA-PP1.

Figure 18.11.5 shows an alignment of amino acids in subdomains V and VII that are relevant to the construction of analog-sensitive kinases. The gatekeeper amino acid, which is mutated to alanine or glycine to create the *-as1* and *-as2* alleles, is shaded in gray. The amino acid that must be changed to construct *-as* kinase alleles can be most easily identified using a freely available online resource at <http://kinase.ucsf.edu/ksd/>. This Web site includes thorough instructions for use of the database. It is advisable to use the GenBank GI number of the protein kinase of interest to search for the appropriate alignment using the "Search by: family name" option. Alignments are generated as Microsoft Excel format files, for download to a computer, or in HTML format for viewing using a Web browser. In these alignments, ATP-contacting amino acids are highlighted green, and the gatekeeper residue is highlighted red.

Figure 18.11.4 Inhibitor binding. Important contacts between PP1 and the ATP binding site of the Src-family protein kinase Hck (left) and the space created in the *-as1* allele that allows 1NA-PP1 binding (right). The right panel is inferred from the structure of c-Src(*-as1*).

Figure 18.11.5 Subdomain V and VII alignments. Analog-sensitive alleles of these protein kinases, whose wild-type sequences are shown, have been engineered. The gatekeeper residue in each kinase and the site of the second mutation (immediately amino terminal to the DFG motif) in Cla4 and JNK are shaded in gray.

Troubleshooting

Specific activity of *-as* kinases

The ideal analog-sensitive kinase allele is functionally silent (i.e., still recognizes ATP, is not a hypermorph or hypomorph, is localized to the same cellular compartments as the wild-type kinase, etc.) and yet has features not found in any wild-type protein kinases: it preferentially uses unnatural ATP analogs, and is selectively inhibited by low concentrations of compounds that do not affect wild-type kinases. In practice, *-as* kinase alleles may require relatively high concentrations of inhibitor to block activity, and they may exhibit substantially reduced catalytic activity. It is advisable to construct both *-as1* and *-as2* alleles: reduction of enzyme activity is generally more severe in *-as1* alleles than in *-as2* alleles, while *-as2* alleles are sometimes less

sensitive to inhibitor than *-as1* alleles. Sensitivity to inhibitor can be enhanced in some cases by an additional mutation outside the adenosine-binding pocket: kinases mutable to optimal analog sensitivity generally have the sequence (L/I)ADFG in subdomain VII. In Figure 18.11.4, this residue is shown shaded in gray. If in the sequence XDFG the amino acid at position X is anything other than glycine or alanine, introduction of alanine at this position may greatly enhance sensitivity to inhibitor. This amino acid was identified as an important determinant of PP1 binding to Hck (Schindler et al., 1999). Changing the sequence TDFG in the yeast PAK Cla4p ADFG greatly enhances sensitivity of the *-as2* allele (Weiss et al., 2000); such double-mutant kinases are called *-as3* alleles. The *prk1-as3* allele exhibits similarly enhanced sensitivity to inhibitor (Sekiya-Kawasaki et al., 2003).

While *-as* alleles of some protein kinases exhibit minor reduction in enzymatic activity, *-as1* and *-as2* alleles of some kinases have greatly reduced catalytic activity. The structural features that determine tolerance for the *-as* alleles are presently poorly understood. However, alignment of the ATP-binding sites of *-as* kinases that work well with those that do not may suggest compensatory mutations that ameliorate loss of activity in *-as1* and *-as2* alleles. MEKK1-*as1* (I1288G), for example, exhibits low kinase activity using both ATP and *N*⁶-phenethyl-ATP as substrates. MEKK1 contains cysteine at position 1238 on the β 2 strand, which should be in direct contact with the oxygen atom in the ribose ring of ATP; the vast majority of kinases contain Val at corresponding positions. A Cys1238 to Val mutation introduced into MEKK1-*as1* restored the kinase activity of MEKK1-*as1* (using ATP) to wild-type level, and this double-mutant enzyme was also able to use *N*⁶-(phenethyl)-ATP more efficiently than MEKK1-*as1* (Dennis Templeton, pers. comm.). If one constructs a *-as* allele that is severely compromised, it is advisable to change highly divergent residues in the ATP binding site to the consensus amino acid.

Heterologous expression systems for protein kinases (e.g., bacterial or insect cell expression) can produce active wild-type forms of mammalian kinases. However, the authors have found that these heterologous expression systems often do not provide active forms of *-as1* or *-as2* alleles of protein kinases. The reasons for this are particular to each protein kinase, but some common problems have been encountered. Many protein kinases require phosphorylation of an activation site (often in the activation segment). These residues may or may not be phosphorylated in a *trans*-auto-phosphorylation-dependent manner, or may be phosphorylated by an "upstream" kinase. In heterologous expression systems, such upstream kinases are absent and the function of activation-site phosphorylation must be carried out by the kinase itself in a nonoptimal reaction. Since the *-as* alleles of a given kinase may already be slightly less active with ATP as a phosphodonor than wild-type enzyme, this non-natural phosphorylation reaction may proceed extremely inefficiently, resulting in production of an inactive *-as* kinase allele. This can be corrected by incubation of the *-as* kinase with 1 mM ATP for 1 to 3 hr prior to assay, to greatly favor any phosphorylation activity to "autoactivate" the kinase.

Naturally, if the normal upstream kinase is known, it is preferable to activate the *-as* kinase by direct incubation with this enzyme. Interestingly, a number of *-as* kinases that cannot be activated by these means and never shown sufficient activity via heterologous expression systems are fully able to complement the function when expressed in the homologous cell where it normally carries out its function. Therefore, heterologous expression results with *-as* alleles should be interpreted with caution.

Phosphorylation target identification by allele-specific ATP analog use

While ATP analogs like *N*⁶(benzyl)ATP are poorly used by most wild-type kinases, they are apparently accepted moderately well by some (Kraybill et al., 2002). This can result in background labeling that is independent of *-as* kinase addition. It is therefore important to characterize the level of background labeling that occurs when γ -³²P labeled ATP analogs are added to the protein mixture of interest; in some cases it will be necessary to reduce the level of background. The nature and magnitude of endogenous kinase activity in cell extracts and fractions varies significantly depending on the extract source, preparation, and fractionation strategy. Therefore, optimal strategies for background reduction are likely to be case-specific. However, the inclusion of significant concentrations of unlabeled ATP is often helpful. Since *-as* kinases can have higher *K_m*'s for ATP than wild-type kinases, ATP will often more effectively compete for ATP analog binding to wild-type kinases than to the *-as* kinase of interest. Consequently, background labeling will be reduced to a greater extent than *-as* kinase-dependent signal.

ATP is rapidly depleted in many extracts. In most cases, it is preferable to maintain a constant ATP concentration through the use of an ATP regenerating system. Addition of ATP, a molar excess of phosphocreatine, and creatine kinase will serve this purpose: the excess phosphocreatine acts as a substrate for creatine kinase in the conversion of ADP to ATP. If an ATP regenerating system is to be used in *-as* kinase substrate labeling experiments, it is advisable to first determine the ATP concentration that gives the greatest inhibition of background labeling without significantly compromising *-as* kinase-dependent signal. To this end, one should set up a series of extract labeling reactions in which

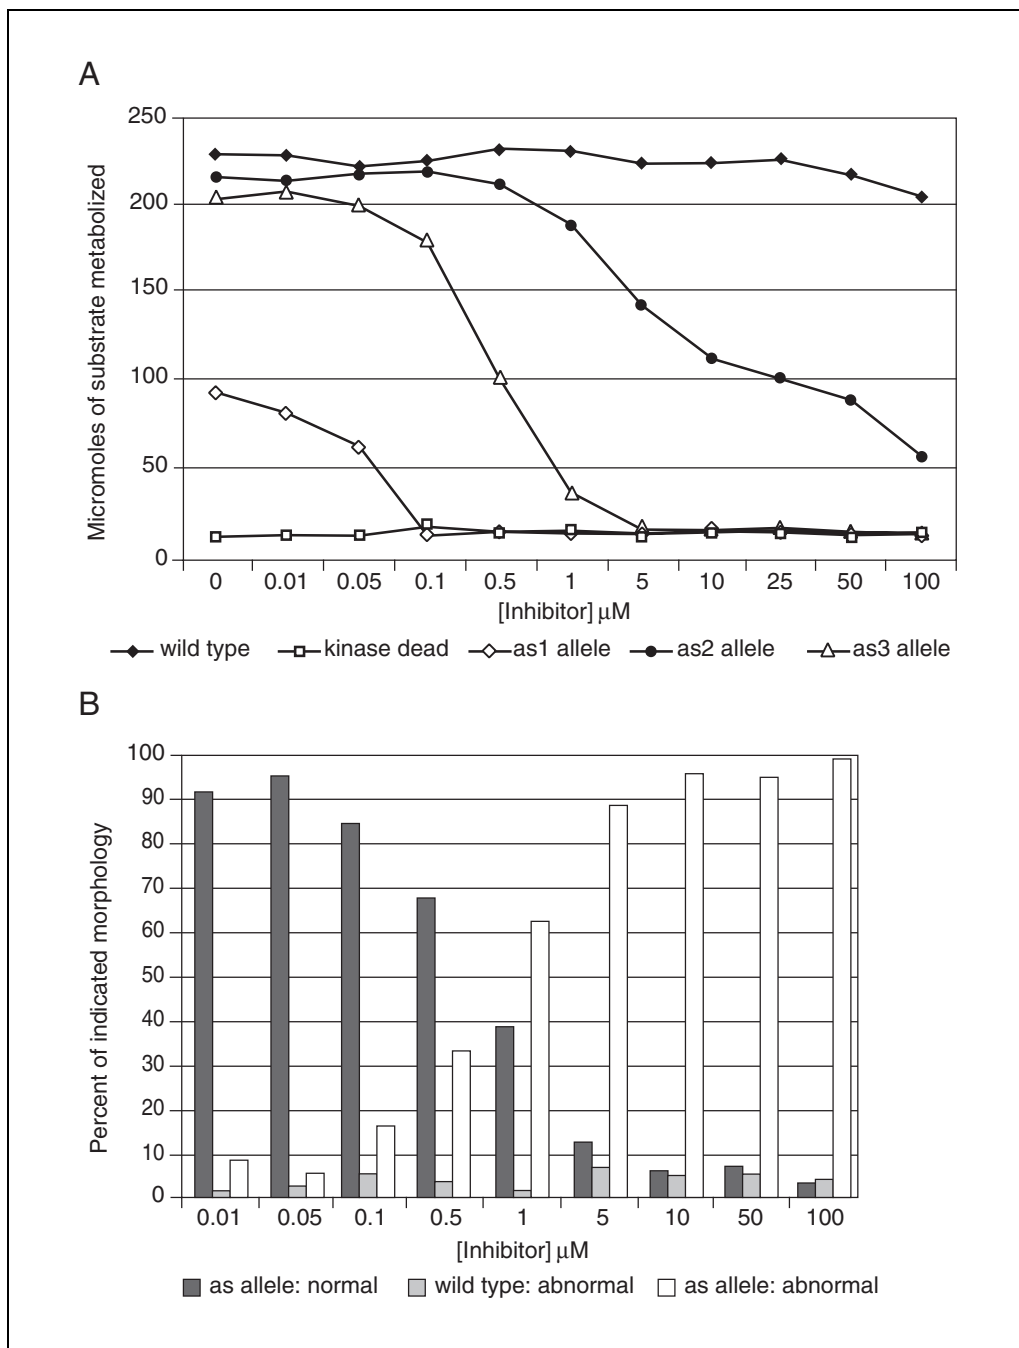

Figure 18.11.6 Hypothetical data from $-as$ kinase inhibition experiments. **(A)** Inhibition curves for a kinase-dependent metabolic process in which the amount of metabolite consumed in a fixed time can be measured. **(B)** Simple morphometric analysis of the inhibition of a kinase required for normal cell morphogenesis. Percent of normal wild-type cells is omitted for clarity.

the ATP concentration is varied from 100 μM to 2 mM.

It may not be possible to detect specifically labeled proteins in complex mixtures directly if the $-as$ kinase of interest has low specific activity, the extract exhibits high background labeling, or the phosphorylation targets of that $-as$ kinase are very rare. If a protein or complex of interest can be affinity purified, how-

ever, specific labeling by $-as$ kinases may be easier to demonstrate. In this approach, labeling reactions are performed using $[\gamma\text{-}^{32}\text{P}]\text{N}^6(\text{benzyl})\text{ATP}$ (or other radiolabeled analog) in a complex protein mixture with and without $-as$ kinase. The protein or complex of interest is then isolated from the two reactions and incorporation of label compared (Ubersax et al., 2003).

Anticipated Results

Analog-sensitive kinase alleles should ultimately be useful for *in vivo* analysis of kinase function in a wide range of model systems. There is, therefore, no general method for their use, but rather a set of principles for good experimental design. Ideally, the endogenous kinase of interest should be replaced by the *-as* allele. Once this is accomplished, two major questions must be answered in any *-as* kinase experiment: (1) how well does the mutant kinase supply function in the absence of inhibitor; and (2) how completely is the *-as* kinase activity of interest blocked by addition of allele-specific inhibitor? These questions can be answered through quantitative evaluation of phenotypic responses to a wide range of inhibitor concentrations.

Figure 18.11.6 shows hypothetical examples of dose-response experiments that evaluate *-as* kinase function and inhibition. Ideally, the *in vivo* function of the *-as* kinase in question should be significantly inhibited at PP1 derivative concentrations $<10 \mu\text{M}$. When a kinase is required for a process or enzyme activity with a measurable steady-state rate, the progress of this process or activity over a fixed time should be measured in the presence of increasing inhibitor concentrations (Fig. 18.11.6A). If the kinase is required for cell morphogenesis, organization of intracellular structures, or cell-cycle progress, the percentage of cells with abnormal (or cell-cycle-arrested) morphology should be scored (Fig. 18.11.6B). Naturally, inhibitor treatment of wild-type cells should be used as a control. When possible, the effects of *-as* kinase inhibition should also be measured relative to the phenotype of a catalytically inactive kinase allele. With extended PP1 analog treatment, the phenotype of a fully inhibited *-as* allele should be identical to a catalytically inactive kinase allele.

Figure 18.11.6A shows hypothetical inhibition curves for wild-type, catalytically inactive, *-as1*, *-as2*, and *-as3* alleles of a kinase required for a cell's consumption of a measurable compound. The measurements involved in such assays should be performed on cells that have been pretreated with inhibitor, allowing time for the treatment to have maximal effect. While the *-as1* allele in this experiment is sensitive to low concentrations of inhibitor, it is also severely compromised relative to wild-type and is therefore of limited utility. The *-as2* allele is less compromised, but is not sufficiently sensitive to inhibitor.

The *-as3* allele is sufficiently sensitive while retaining adequate *in vivo* activity in the absence of inhibitor. The phenotype of this allele "saturates" at $\sim 5 \mu\text{M}$ inhibitor. It may be advisable to use slightly higher concentrations in future assays to ensure inactivation. Figure 18.11.6B shows morphological phenotypes over a range of inhibitor concentrations. A number of researchers have published examples of dose-response analysis with *-as* kinases (Bishop et al., 2000; Weiss et al., 2000; Weiss et al., 2002; Sekiya-Kawasaki et al., 2003).

Thus far, most *in vivo* inhibition studies using *-as* kinases have been performed in the budding yeast *Saccharomyces cerevisiae*. The considerable pace of yeast experiments is in part due to the ease of gene replacement in this organism; *-as* kinase inhibition is also clearly useful in metazoans (Wang et al., 2003). The authors have included guidelines for *-as* kinase inhibition in yeast. The specific assay conditions will, of course, depend on the nature of the process of interest.

Detection of MAP Kinase Signaling

UNIT 18.12

Transmission of extracellular signals to their intracellular targets is mediated by a network of interacting proteins that relay biochemical messages, thereby controlling many cellular processes. Several related intracellular signaling pathways, collectively known as mitogen-activated protein kinase (MAPK) signaling cascades, have been elucidated in the past decade (Seger and Krebs, 1995). Transmission of signals via these cascades is usually initiated by activation of a small G protein (e.g., Ras) and followed by sequential stimulation of several sets of cytosolic protein kinases. Four distinct MAPK cascades, ERK (extracellular signal-related protein kinase), JNK (c-Jun NH₂-terminal kinase), p38 MAPK, and BMK (big MAPK), also known as ERK5, have been elucidated to date (Fig. 18.12.1). Each is named after the subgroup of its MAPK components and is composed of up to five levels: MAP4K (MAPK kinase kinase), MAP3K (MAPK kinase kinase), MAPKK (MAPK kinase), MAPK, and MAPKAPK (MAPK-activated protein kinase) (Fig. 18.12.1). One or more components in each of these levels phosphorylates and activates components in the next level, until a downstream component phosphorylates a target regulatory molecule. These cascades can cooperate in transmitting signals from most extracellular stimuli and can thus determine a cell's fate in response to the ever-changing environment. For a detailed description of the MAPK cascades, see Background Information.

Since the majority of MAPK cascade components are kinases, the methods used to detect MAPK cascade activation involve determination of protein kinase phosphorylations and activities. Anti-phospho-MAPK antibodies are used as a fast and convenient tool to monitor the activation of MAPKs (see Basic Protocol 1). The actual activity of these kinases is often detected by immunoprecipitation followed by phosphorylation of specific substrates. The activity assay is performed while the enzyme is still bound to the beads for immunoprecipitation, and the amount of incorporated phosphate is monitored by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography (see Basic Protocol 1; Fig. 18.12.2). An alternative method involves affinity purification with a specific substrate of the examined kinase, followed by phosphorylation; this assay is described for JNK (see Basic Protocol 3; Fig. 18.12.2). When the identity of the kinase is not known, or there are no reagents available for its determination, an in-gel kinase assay should be used (see Basic Protocol 2; Fig. 18.12.2). Support protocols detail the preparation of EGF-stimulated Rat1 cells (Support Protocol 1) and GST-Jun-glutathione beads (Support Protocol 2), as needed for these assays.

CAUTION: Investigators should wear gloves for all procedures involving radioactivity and should be careful not to contaminate themselves and their clothing. When working with ³²P, investigators should frequently check themselves and the working area for radioactivity using a hand-held monitor. Any radioactive contamination should be cleaned up using appropriate procedures. Radioactive waste should be placed in appropriately designated areas for disposal. Follow the guidelines provided by your local radiation safety adviser (also see APPENDIX 1F).

DETERMINATION OF MAP KINASE (ERK) ACTIVATION USING ANTIBODIES

This protocol describes determination of ERK activity using either anti-phospho-MAPK antibodies or by immunoprecipitating the enzyme with specific antibodies and then performing a phosphorylation reaction in vitro. ERK is used here as an example; with appropriate reagents, this method can be performed with most MAPK isoforms and other components of the MAPK cascade. This protocol results in fast and efficient detection of

Supplement 67

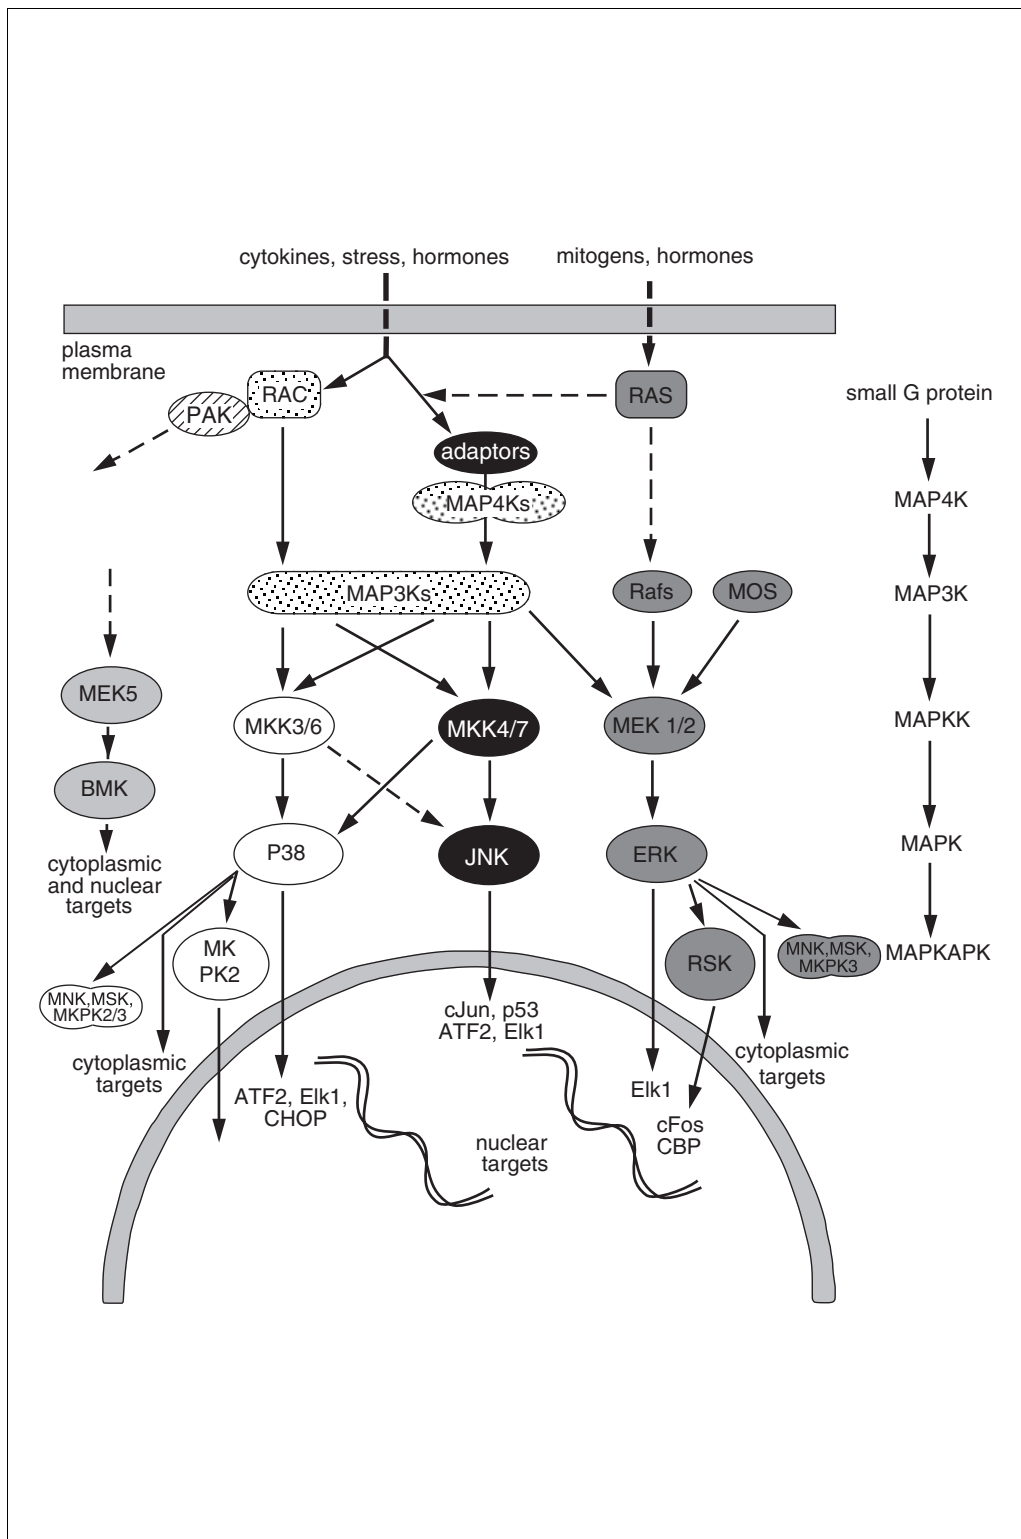

Figure 18.12.1 Schematic representation of mitogen-activated protein kinase (MAPK) cascades. The extracellular signal-related protein kinase (ERK) cascade is represented by light gray shading, the c-Jun NH₂-terminal kinase (JNK) cascade by dark gray shading, the stress-related protein kinase p38 MAPK cascade by white, and the big MAPK (BMK) cascade by stippled shading. Components that are shared by more than one cascade are indicated by combinations of shading. The connections between components from different levels are shown by arrows; the specifics of these interactions have yet to be defined. Abbreviations: MAP4K, MAPK kinase kinase; MAP3K, MAPK kinase kinase; MAPKK, MAPK kinase; MAPKAPK, MAPK-activated protein kinase.

the activity of desired protein kinases and reliable quantification of phosphorylation. Since the solid support (immunoprecipitating beads) may influence the kinase activity, however, the results do not always accurately reflect the specific activity of the examined kinase. As an alternative, it is possible to elute the kinases of interest from the immunoprecipitating beads (or isolate them by other means) and then determine their activity in solution (Seger et al., 1994). These methods can be used with almost all tissue culture cell lines, homogenized animal organs, and even whole lower organisms.

Materials

Six 6-cm tissue culture plates of EGF-stimulated Rat1 cells (Support Protocol 1, steps 1 to 4)
Homogenization buffer (see recipe), ice cold
Kinase buffer (see recipe), ice cold
Coomassie protein assay reagent (Pierce)
Protein standards: 5, 10, 20, 50, 100, and 200 $\mu\text{g/ml}$ BSA in homogenization buffer
Blocking solution: TBS-T (*UNIT 20.3*) containing 2% (w/v) bovine serum albumin (BSA)
Antibodies for immunoblotting:
 Primary antibody: goat monoclonal anti-phospho-MAPK antibody (anti-DP-ERK, Sigma)
 Secondary antibody: alkaline phosphatase (AP)/enhanced chemiluminescence (ECL)-conjugated anti-goat antibody (see *UNIT 10.8*)
 Polyclonal anti-general ERK antibody from different species than original primary antibody (e.g., Sigma; optional, for second immunoblotting)
 Horseradish peroxidase (HRP)/enhanced chemiluminescence (ECL)-conjugated secondary antibody against species of the anti-general ERK antibody (optional, for second immunoblotting)
Tris-buffered saline with Triton X-100 (TBS-T; *UNIT 20.3*)
Protein A-Sepharose beads, swollen and packed (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2*)
Antibody for immunoprecipitation: anti-ERK C-terminal antibody (e.g., Sigma)
0.5 M LiCl solution, ice cold
RadioImmunoPrecipitation Assay (RIPA) buffer (see recipe), ice cold
3 \times reaction mixture (RM \times 3; see recipe)
2 mg/ml myelin basic protein (MBP)
4 \times SDS-PAGE sample buffer (see recipe)
10% to 12% or 15% SDS-polyacrylamide gel (*UNIT 10.2A*)
Prestained protein markers, 16 to 175 kDa (New England Biolabs)
Running buffer: 25 mM Tris-Cl (pH 8.3)/188 mM glycine/0.1% SDS
Staining solution: 40% (v/v) methanol/7% (v/v) acetic acid/25 g/liter Coomassie brilliant blue R-250
Destaining solution: 15% (v/v) isopropanol/7% (v/v) acetic acid in water
1.5-ml microcentrifuge tubes, prechilled to 4°C (four sets of six, each labeled 1 to 6)
Sonicator
Stopwatch
1-ml pipet tips, prechilled to 4°C
Microcentrifuge, 4°C
96-well flat-bottomed microtiter plates
Microtiter plate reader, 595 nm wavelength
End-over-end rotator
Nitrocellulose membrane (see *UNIT 10.8*)
Flat plastic or glass box to accommodate gel
Shields for radioactive work

Tube heater/shaker (e.g., Eppendorf Thermomixer) *or* water bath, 30°C

Flat container for washing gel

Whatman 3MM filter paper, cut larger than the gel

X-ray film (not needed if phosphoimager is used)

Film cassette for either X-ray film or phosphoimager

X-ray film developer or phosphoimager

Additional reagents and equipment for preparation of EGF-stimulated Rat1 cells (Support Protocol 1), SDS-PAGE (UNIT 10.2A), transfer of proteins to nitrocellulose membrane, immunoblotting, and chemiluminescent detection (UNIT 10.8), and autoradiography (APPENDIX 3A)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO₂ incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO₂ to maintain pH 7.4.

Prepare cytosolic extracts

1. Add 350 μ l ice-cold homogenization buffer to each plate of EGF-stimulated Rat1 cells on ice, tilt the plate gently, and scrape the cells into the buffer using a plastic scraper or rubber policeman. Using prechilled pipet tips, transfer the cells and buffer to labeled, prechilled 1.5-ml microcentrifuge tubes.

Special consideration should be given to the composition of homogenization buffer. The authors recommend using β -glycerophosphate, which serves both as a buffer and as a general phosphatase inhibitor; rather than Tris or HEPES. Sodium orthovanadate is used to inhibit tyrosine phosphatases, and the mixture of pepstatin A, aprotinin, leupeptin, and benzamide is used to inhibit proteinases. Ice-cold homogenization buffer blocks most of the phosphatase and proteinase activities in cell extracts.

2. Disrupt the cells by sonication (two 7-sec, 50-W pulses per 0.5-ml sample) on ice.

Sonication allows extraction of proteins from the cytosolic and nuclear fractions of the cells but not from the membrane fraction; therefore, the extract is called a cytosolic extract. Cellular extraction with nonionic detergents, which extract proteins from the membrane, cytosolic, and some nuclear fractions of the cell, makes determination of the protein concentration somewhat difficult but is often used. Extraction with RIPA buffer or by freeze-thawing can be used for some kinases, but these methods are less effective (see Critical Parameters).

Figure 18.12.2 (at right) Detection of mitogen-activated protein kinase (MAPK) activity by the methods described in this unit. **(A)** Detection of extracellular signal-related protein kinase (ERK) activity by immunoprecipitation and myelin basic protein (MBP) phosphorylation. NIH-3T3 cells were grown to subconfluency in 6-cm plates and then starved as described in Support Protocol 1. Cells were then stimulated with 100 μ M sodium orthovanadate and 200 μ M hydrogen peroxide (VOOH) for 15 min, or 50 ng/ml epidermal growth factor (EGF) for 5 min, or left untreated (basal). Cytosolic extracts were prepared by sonication and the resulting proteins (300 μ g) were incubated with either 30 μ l anti-ERK C-terminal antibody (Santa Cruz Biotechnology)-conjugated protein A-Sepharose beads (+) or with unconjugated protein A-Sepharose beads (-). The phosphorylation reaction on MBP was performed as described in Basic Protocol 1. **(B)** Detection of protein kinase activity by the in-gel kinase assay. MCF7 cells overexpressing the ErbB-2 receptor were stimulated with 50 ng/ml EGF for the indicated times. The in-gel kinase assay was performed as described in Basic Protocol 2. ERK1 and ERK2 bands are indicated. The identity of other bands was not determined. **(C)** Detection of c-Jun NH₂-terminal protein kinase (JNK) activity by an affinity assay. α T3-1 cells were treated with 100 nM D-Trp gonadotropin-releasing hormone for the indicated times. The JNK assay was performed as described in Basic Protocol 3. GST-cJun and a degradation product (p30) are indicated. Abbreviation: GST-Jun, glutathione-S-transferase-conjugated cJun.

3. Microcentrifuge the cytosolic extracts 15 min at $14,000 \times g$, 4°C . Transfer supernatants to fresh, prechilled, and prelabeled tubes. Take 5- to 10- μl aliquots of these extracts for protein determination. Store the remainder of each cytosolic extract on ice until needed.

Determine the protein concentration of each sample at this stage so that identical amounts of proteins from the different samples can be compared and the relative amount of protein kinases in each sample determined accurately. Comparing samples based on cell number, rather than protein concentration, can result in differences of up to 20% in the amount of protein. Such differences can cause even larger ones when phosphorylation is assessed immunologically.

Do not leave samples on ice >45 to 90 min, to avoid unnecessary exposure to phosphatases and proteinases (see Critical Parameters).

Determine protein concentration

4. Add 10 μl of each cytosolic extract to 190 μl kinase buffer in labeled 1.5-ml microcentrifuge tubes.

Dilutions of $\geq 1:20$ are usually necessary to ensure that the sample protein concentrations are in the linear range of the protein determination assay. This dilution is not always necessary with some Coomassie protein assay reagents that have extended ranges.

5. Transfer 10 μl of each of the protein standards into two wells each of a 96-well, flat-bottomed microtiter plate.

Protein standards should be prepared in the same buffer as was used for the cell extraction.

6. Transfer 10 μl of each of the diluted cytosolic extracts into two wells of the same microtiter plate. Add 200 μl Coomassie protein assay reagent to all wells.
7. Place the microtiter plate in a microtiter plate reader and measure the absorbance of the samples at 595 nm (A_{595}). Calculate the protein concentrations of the cytosolic extracts by comparing the absorbance of the sample with the standard curve.
8. Based on the calculated protein concentrations, transfer a volume of each cytosolic extract containing 100 to 500 μg protein into a fresh, prechilled 1.5-ml microcentrifuge tube.

Detect activation of ERK

At this stage, activation of ERK can be determined using small amounts of extracted proteins either by immunoblotting with anti-phospho and anti-general-ERK antibodies (steps 9a to 17a) or by immunoprecipitation followed by an in vitro kinase assay (steps 9b to 24b).

To detect ERK activation using anti-phospho antibody

- 9a. Load cytosolic extract on a 10% or 12% SDS-PAGE gel along with a prestained protein marker and electrophorese at 150 V (UNIT 10.2A). Once the dye front has reached the end of the gel, remove the gel from the apparatus and proceed to step 10a.
- 10a. Transfer the separated proteins onto a nitrocellulose membrane for 45 min at 100 V, 4°C (UNIT 10.8). At end of transfer period, rinse membrane with TBS-T and place in flat container.
- 11a. Incubate nitrocellulose membrane in blocking solution for 60 min at room temperature.

Milk is not recommended for blocking because it probably contains phosphorylated casein, which may interfere with the detection of the anti-phospho-ERK antibody.

- 12a. Incubate blot with primary antibody (goat monoclonal anti-DP ERK antibody diluted according to manufacturer's instructions).
- 13a. Wash blot in flat container at least three times, each time for 15 min with TBS-T at 23°C.
- 14a. Incubate blot with secondary antibody (AP/ECL-conjugated anti-goat antibody) for 45 min at room temperature.
- 15a. Wash blot at least three times, each time for 10 min with TBS-T.
- 16a. Detect phosphorylated ERK using chemiluminescent detection (AP/ECL; e.g., *UNIT 10.8*).

After detecting the phosphorylated ERK it is recommended that it be determined whether there is an equal amount of ERK, using anti-general ERK antibody, as described in step 17a.

- 17a. Incubate the blot in blocking solution for 30 min at room temperature. Incubate blot with "new" primary antibody (polyclonal anti-general ERK antibody) from different species than primary antibody used in step 12a. Incubate with HRP/ECL-labeled secondary antibody (if AP/ECL-conjugated secondary antibody was used in step 14a) against species used for the "new" primary antibody and detect using chemiluminescent detection (*UNIT 10.8*).

It should be noted that the different antibodies may interfere with the detection of one another; therefore, the above step must be performed using another, identical blot, or an additional stripping step must be performed on the original blot (UNIT 10.8).

Two or three bands are usually stained by the antibodies. When two bands appear, these are the p42 ERK2 and p44 ERK1. In some cell lines and tissues, a third band at 46 kDa is detected (ERK1b). The intensity of the bands is elevated in the treated samples, reflecting their regulatory phosphorylation upon stimulation, while the amount of ERK as detected by the anti-total ERK antibody is not changed for up to 2 hr of stimulation.

An alternative way to detect ERK activity is by immunoprecipitation followed by in vitro kinase assay (steps 9b to 24b).

To detect ERK activation by immunoprecipitation

- 9b. Place 180 μ l swollen, packed protein A-Sepharose beads in a 1.5-ml microcentrifuge tube. Add 320 μ l PBS and 25 μ l of the antibody to be conjugated, diluted according to the manufacturer's instructions. Rotate the mixture for 1 hr at room temperature on an end-over-end rotator to allow the antibody to bind to the protein A.

This step can be done at 4°C for 16 hr. Ideally, this step should be performed either before or simultaneously with the preparation of cytosolic extracts so that the immunoprecipitation step can proceed without delay.

Anti-C-terminal antibodies are generally used for the determination of kinase activity, because their binding to the kinase does not interfere with its kinase activity. Usually 1 to 5 μ g per reaction is sufficient. Polyclonal antibodies are available from a number of suppliers (e.g., Transduction Laboratories, Sigma, Santa Cruz Biotechnology, Upstate Biotechnology, and Zymed Laboratories).

These volumes are calculated for ten reactions (usually 10 to 20 μ l beads is used per reaction), but because of the density of the beads they will probably only be sufficient for eight reactions. The amounts can be scaled up as long as the proportions are maintained.

For easy handling of the resin, cut the ends of the pipet tips to enlarge their openings.

- 10b. Resuspend beads in 1 ml ice-cold PBS and microcentrifuge 1 min at 14,000 \times g, 4°C. Remove supernatant and add 1 ml ice-cold homogenization buffer. Repeat

centrifugation three more times with homogenization buffer, ending with a final addition of an equal volume of ice-cold homogenization buffer.

Antibody-conjugated beads can be stored in homogenization buffer for ≤ 3 days at 4°C.

- 11b. Add 30 μl antibody-conjugated bead suspension (15 μl beads and 15 μl homogenization buffer) to a 300- μl sample of cytosolic extract containing 50 to 500 μg total protein in prechilled 1.5-ml microcentrifuge tubes. Rotate on end-over-end rotator for 2 hr at 4°C.
